  - Some older pacemakers will require Pulse Width testing (as the only option). Starting Pulse Width should be the current setting.
  - Thresholds are related to Amplitude and Pulse Width settings. When testing using Voltage, the programmed amplitude should be at least twice the measured threshold. When using Pulse Width, the programmed pulse width should be at least three times the measured threshold. The exception is when the auto capture is programmed ON.
- Useful tricks to performing Threshold testing:
  - **i.** Always test at a rate of at least 10 bpm above the patient's intrinsic rate —this helps to prevent fusion and makes loss of threshold seem as a pause related to a change in rate.
  - **ii.** When starting out, *always run paper during the entire test* (press the 25 button under the screen). This will make it easier for you to verify loss.
  - **iii.** Atrial Thresholds:
    1. The safest way to test Atrial Thresholds for any patient is in DDD mode. This will ensure ventricular support if the patient has any form of block—and for patients with intrinsic conduction, assist by adding another visual clue when Atrial capture is lost.
    2. If patient has intact intrinsic conduction, one can test it in two ways:
       - **a.** Atrial Thresholds in DDD mode will result in an Ap/Vs response at the paced atrial rate. Capture is verified by paced P waves and by QRS response. Loss of capture will result in a slight pause in rate (the difference between the intrinsic PR and the AV Delay), a loss of P wave capture, and will be immediately followed by a paced ventricular response (you will transition from a narrow upright QRS to a wide-paced QRS). *Suggested Settings: Mode:*

DDD, Rate: at least 10 bpm above intrinsic rate, AV Delay: max allowed (300 or 400 ms).

b. Atrial Thresholds in AAI mode will result in a ventricular response on the surface EGM at the paced atrial rate. Capture is verified by paced P waves and by QRS response. Loss of capture will result in a pause in rate as well as a loss in P wave capture. *Suggested Settings: Mode: AAI, Rate: at least 10 bpm above intrinsic rate.*

3. For patients with block, performing atrial thresholds in DDD mode is required to provide support for ventricular function. Here, capture is verified by loss of P waves only. Loss of capture will result in ventricular-only pacing. *Suggested Settings: Mode: DDD, Rate: 10 bpm max above intrinsic rate, AV Delay: 150 ms or greater. Increasing the AV Delay separates the P waves from the paced QRS, allowing the P waves to be seen easier. Keep the rate as low as possible when testing in this manner to allow the most space between paced QRSs.*

SPECIAL TESTING AND PARAMETERS FOR BRADYCARDIA THERAPY DEVICES

Pacemaker programming is very complex; however, for simplicity, medical personal should be at least familiar with the most common pacing modes. The North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) published as a joint effort the pacemaker code. This joint project is known as the *NBG pacemaker code*. The NBG was initially published in 1983 and was last revised in 2002.[6] It describes the five-letter code for operation of implantable pacemakers and defibrillators (**Figure 27.10**).

Generic Pacemaker Code (NBG): NASPE/BPEG

Position	I	II	III	IV	V
Function	Pacing chamber	Sensing chamber	Response(s) to sensing	Rate modulation	Multisite pacing
Specific Designations	O=none A=Atrium V=Ventricle D=Dual (A+V)	O=none A=Atrium V=Ventricle D=Dual (A+V)	O=none T=Triggered I=Inhibited D=Dual (T+I)	O=none R=Rate modulation	O=none A=Atrium V=Ventricle D=Dual (A+V)

- The first two positions of this code (Chamber Paced and Sensed) are relatively straightforward.
- The third position could be confusing. The most frequently used programs are the DDD (dual-chamber pacing and sensing both triggered and inhibited mode), VVI (for single-chamber, ventricular pacing in the inhibited mode), VDD (ventricular pacing with atrial tracking), and DDI (dual-chamber pacing and sensing, but inhibited mode only).
- The third position is described as follows:
  - D (Dual): In DDD pacemakers, atrial pacing is in the inhibited mode (the pacing device will emit an atrial pulse if the atrium does not contract). In DDD and VDD pacemakers, once an atrial event has occurred (whether paced or native) the device will ensure that an atrial event follows.
  - I (Inhibited): The device will pulse to the appropriate chamber unless it detects intrinsic electrical activity. In the DDI program, AV synchrony is provided only when the atrial chamber is paced. If on the other hand intrinsic atrial activity is present, then no AV synchrony is provided by the pacemaker.
  - T (Triggered): Triggered mode is only used when the device is being tested. The pacing device will emit a pulse only in response to a sensed event.
- The fourth position, rate modulation, increases the patient's heart rate in response to "patient exercise." A number of mechanisms (vibration, respiration, and pressure) are used to detect "patient exercise." As the exercise wanes, the sensor indicated rate returns to the programmed mode.
- The fifth position describes multisite pacing functionality. Atrial multisite pacing is being investigated as way to prevent atrial fibrillation. Ventricular multisite pacing is a treatment for pacing a patient with dilated cardiomyopathy.

FIGURE 27.10 The North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) published as a joint effort the pacemaker code. This joint project is known as the NBG pacemaker code. The NBG was initially published in 1983 and was last revised in 2002. It describes the five-letter code for operation of implantable pacemakers and defibrillators.

Main Pacing Modes

- The ***AAI or AAIR*** is an atrial demand pacing (atrium paced, atrium sensed, and pacemaker inhibited in response to sensed atrial beat) and is appropriate for patients with sinus node dysfunction who have intact AV nodal function. Patients with symptomatic sinus bradycardia or sinus pauses, but with an intact ability to accelerate their heart rate with exertion, can be programmed in an AAI mode. Those who cannot adequately accelerate their heart rate should have rate-responsive capability available.
- The *VOO* pacemaker is asynchronous ventricular pacemaker; there are no adaptive rate control or antitachyarrhythmia functions.
- The ***VVI or VVIR*** pacemaker is a ventricular "demand" pacemaker with electrogram-waveform telemetry; there are no adaptive rate control or

antitachyarrhythmia functions. Those who cannot adequately accelerate their heart rate should have rate-responsive capability available. The new leadless pacemaker (***Micra***) is VVI pacemakers.

- The ***VDD*** pacemaker is used for AV nodal dysfunction with intact and appropriate sinus node behavior.
- The **DDD *or DDDR*** pacemaker is a multiprogrammable "physiologic" dual-chamber pacemaker; there are no adaptive rate control or antitachyarrhythmia functions. Those who cannot adequately accelerate their heart rate should have rate-responsive capability available.
- The ***DDI*** pacer is used for a patient with a dual-chamber pacemaker that has episodes of paroxysmal atrial fibrillation. DDI prevents high ventricular rates. Some DDD pacemakers are programmed to enter the DDI mode when high atrial rates occur.

One of the most important aspects of checking the pacemaker function is to evaluate for percentage of pacing. BLOCK-HF trial[7] showed that the increased RV pacing can lead to RV-pacing-induced cardiomyopathy. Likewise, in patients with biventricular pacemakers, less than 90% pacing is considered inadequate. Investigations should be done to find the cause of less biventricular pacing (eg, higher LV thresholds than the programmed parameter, high frequency of PVCs, atrial fibrillation with rapid ventricular rates) and to correct it.

Important Programmable Features

Mode switching: This is the algorithm that identifies the presence of atrial tachyarrhythmias and switch the device to a nontracking mode (VVI, DVI, or DDI), allowing the pacing rate to be driven by the programmed lower-rate limit or sensor-indicated rate.

Minimizing ventricular pacing: *Managed ventricular pacing (MVP)*[8] from Medtronic and its likeness *ventricular pace suppression* (VPS) from Biotronik, *SafeR* pacing[9] from Sorin, *ventricular intrinsic preference* (VIP)[10] from St. Jude Medical, and *Rhythmiq* from Boston Scientific all have an atrial-based pacing mode that significantly reduces unnecessary right ventricular pacing by primarily operating in an AAI(R) pacing mode while providing the safety of a dual-chamber backup mode if necessary.

Rate-adaptive pacing: This refers to an increase in the pacing rate in response to a combination of sensors including association of an activity sensor giving a rapid response for short-duration exercise, a metabolic sensor, or minute ventilation sensor, to improve exercise capacity, particularly in patients with

chronotropic incompetence.

SPECIAL TESTING AND PARAMETERS FOR TACHYCARDIA THERAPY DEVICES

Appropriate ICD programming is crucial to deliver critical therapy to true arrhythmia (VT/VF) and to avoid unnecessary shock or inappropriate shocks. Multiple trials have been conducted with this aim in mind, namely, *PainFree I*,[11] *PainFree II*,[12] *PREPARE*,[13] *ShockLess*,[14] and *MADIT-RIT*[15] all of which showed that along with delivery of painless therapies and optimal programming, the use of discrimination algorithms play an important role in specifically reducing inappropriate shocks.

Tiered-therapy ICDs have 2 to 3 zones defined by the longest RR interval in each zone. The primary determinants of the boundaries of therapy zones are programming of specific therapies and SVT discrimination. The lower boundary between sinus and VT zone is programmed at approximately 180 to 188 bpm in primary prevention patients and at 30 to 60 ms greater than the cycle length of the slowest observed VT (150–160 bpm in most trials) in secondary prevention patients. Programming in the VT zone is focused on preventing therapy for SVT and nonsustained VT. We routinely program three zones in primary prevention patients, using the slowest VT zone for monitoring only at 160 to 166 bpm. In secondary prevention patients, the slower VT zone is programmed with three to four sequences of ramp/burst ATP compared with 1-burst ATP followed by shocks in the faster VT zone. The following are the SVT discriminators:

- *Onset:* Sudden onset is usually indicative of ventricular tachycardia.
- *Stability:* Wobbly R-R interval is indicative of atrial fibrillation.
- *Morphology:* Comparing the morphology of the tachycardia to an acquired template in sinus rhythm can help in discriminating supraventricular versus ventricular arrhythmias.
- *A/V counter:* More (V) than (A) is indicative of ventricular tachycardia.

ARRHYTHMIA REPORTING

One of the most important aspects in device interrogation is reporting on any documented arrhythmia on the device such as atrial fibrillation, ventricular tachycardia, supraventricular tachycardia, or pacemaker-mediated tachycardia.

When reporting these arrhythmias, it is essential to report the number of episodes and their length and the percentage of mode switching. Greater than

five and a half hours of atrial fibrillation has been associated with stroke, and these patients should be recommended for anticoagulation. Most devices will have a printed log of events for all arrhythmias and therapies and a report if the delivered therapies (whether ATP or ICD shocks) were appropriate or inappropriate.

In special situations, particularly cases with lead failure causing oversensing resulting in multiple inappropriate ICD firing, placing a magnet over the device will suspend all tachy therapies.

NEW ON THE HORIZON FOR PACING CARDIAC DEVICES

Leadless pacemakers: About 93% smaller than other modern-day pacemakers, the recent FDA-approved Micra pacemaker (Medtronic, Minneapolis, MN) (**Figure 27.11**) is the world's smallest pacemaker, yet it offers a complete set of features. The proprietary hybrid battery chemistry provides improved longevity, reliability, and predictable performance. It is MRI SureScan, which allows the patient to be safely scanned using either a 1.5-T or a 3-T full-body MRI. Currently, the device has a 99.2% implant success rate. About 96% of patients experienced no major complications at 6 months. The device has a 51% lower complication rate than traditional pacing systems, with no dislodgements or systemic infections.[16]

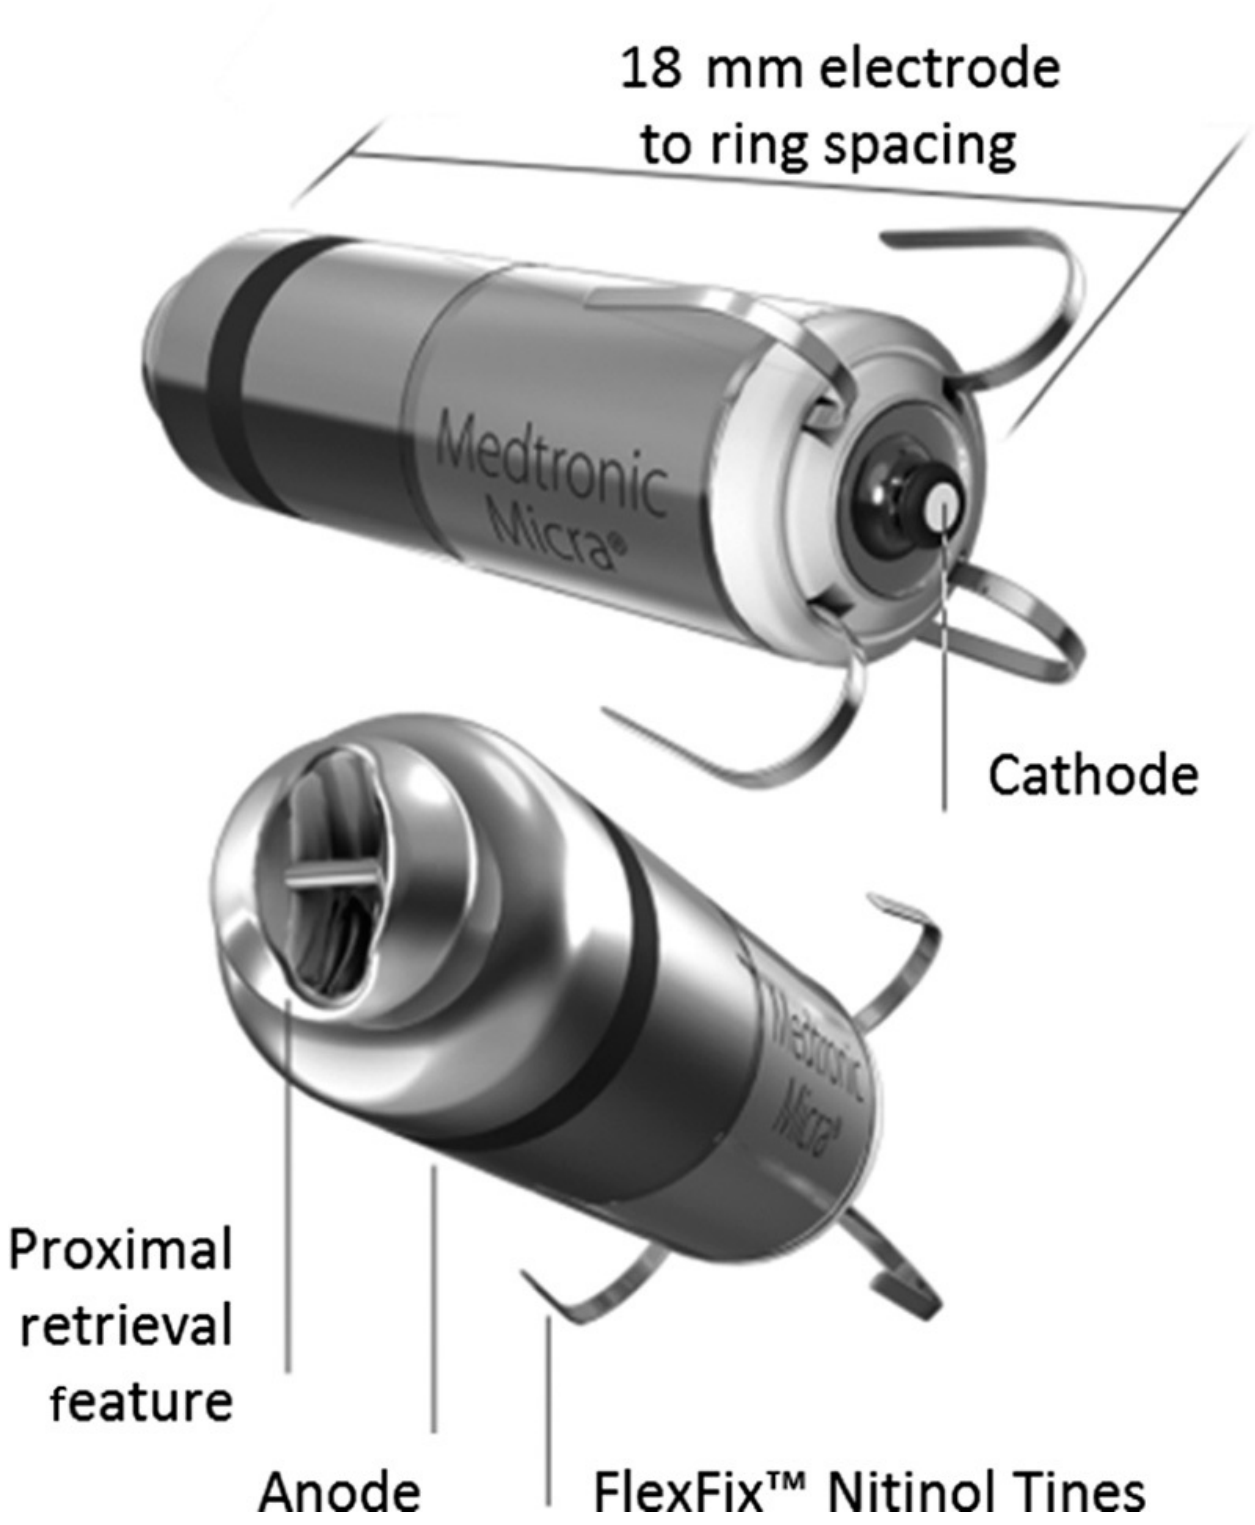

FIGURE 27.11 Leadless pacemaker Micra (Medtronic, Minneapolis, Minnesota).

SonR-Closed-Loop Optimization: The new Sorin SonR tip atrial lead is a

bipolar sugar-coated lead that picks up vibrations that reflect global contractility and not just local cardiac wall movements. The embedded sensor is a micro-accelerometer that detects cardiac muscle vibrations that reflect the first heart sound and are correlated with LV $dP/dt_{max.}$ The SonR tip lead performs automated V-V and A-V optimization at rest and during exercise. The recently published RESPOND-CRT trial[17] showed 30% reduction of all-cause mortality or heart failure hospitalization at 24-month follow-up (**Figure 27.12**).

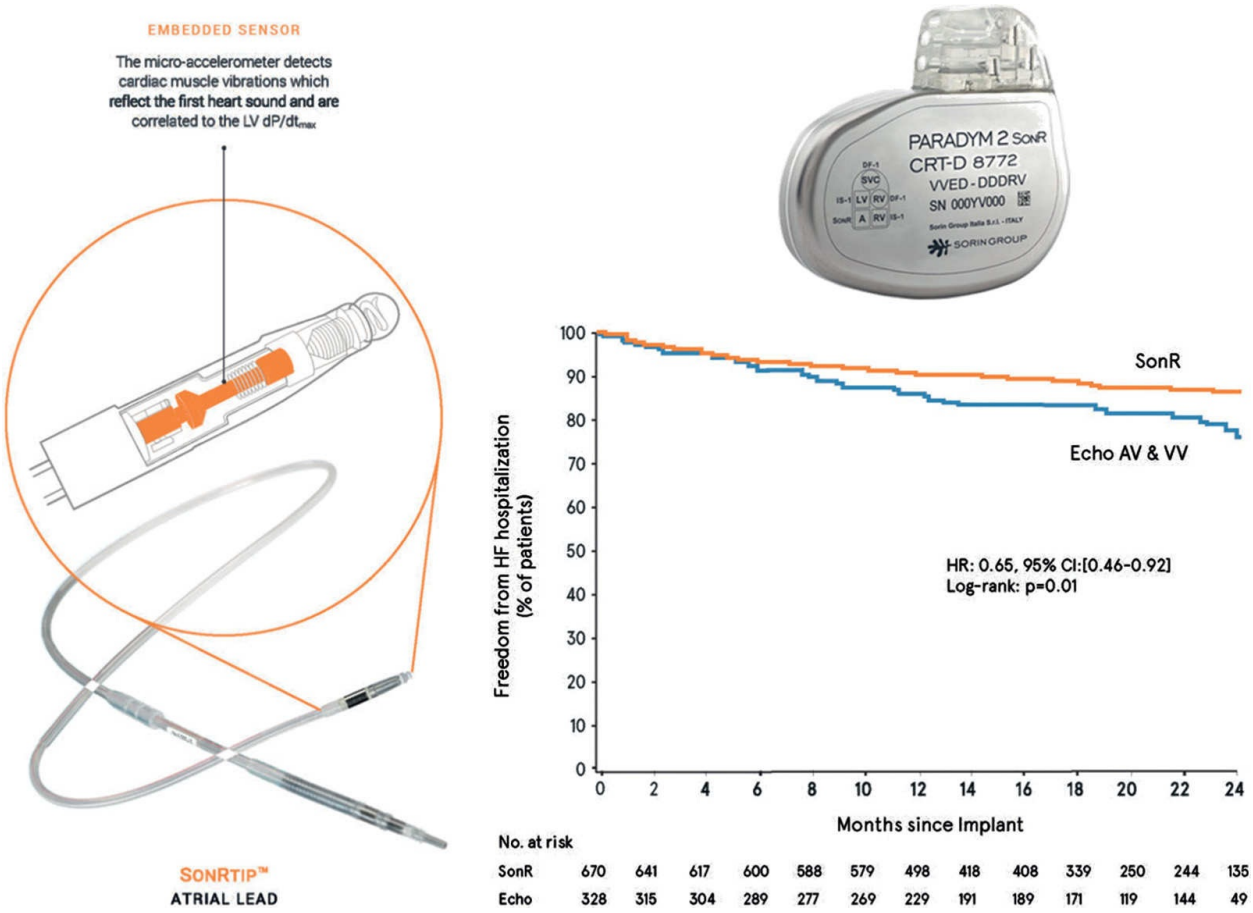

FIGURE 27.12 SonR tip atrial lead from Sorin, and the results of the RESPOND-CRT trial.

WiSE-CRT system: The WiSE-CRT system (EBR Systems, Sunnyvale, CA) uses a multicomponent strategy to provide leadless cardiac resynchronization. A tiny (9.1 mm × 2.7 mm, 0.05 cm^3) receiver electrode composed of polyester-covered titanium is implanted endocardially in the LV. A subcutaneous pulse generator is placed in the left lateral thorax and generates ultrasound pulses, which are converted to electrical pacing stimuli by the endocardial seed (**Figure 27.13**). All patients in the WiSE-CRT study had a traditional pacemaker or defibrillator; the subcutaneous WiSE-CRT pulse generator detected the RV pacing pulse from the standard system, which triggered endocardial LV pacing. In the initial trial, patients with failed coronary sinus lead placement, nonresponse to CRT, or need for an upgrade to CRT were enrolled. Data from small studies demonstrated significant QRS narrowing, absolute EF improvements of 5%, and improvements in composite clinical scores at 6 months.[18] The initial WiSE-CRT study was stopped for safety reasons.

Following delivery system redesign, early data from 14 patients demonstrated no implant-related adverse events.

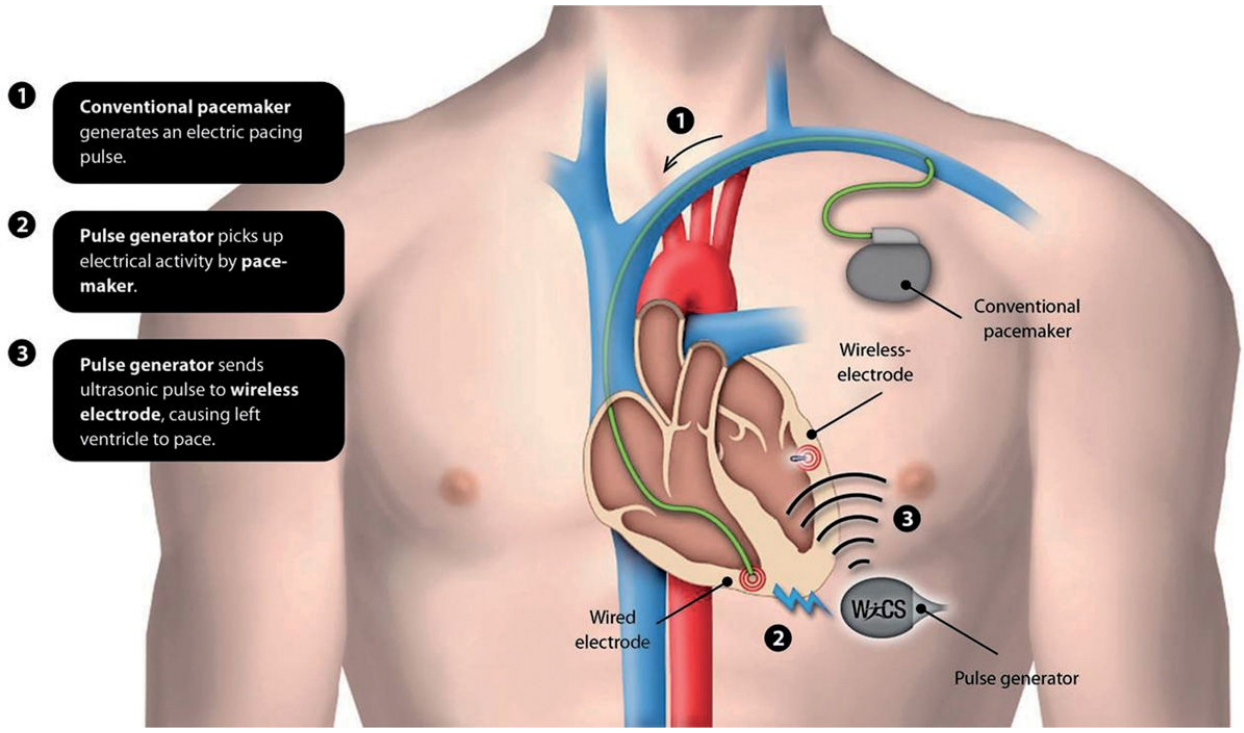

FIGURE 27.13 WiSE-CRT System.

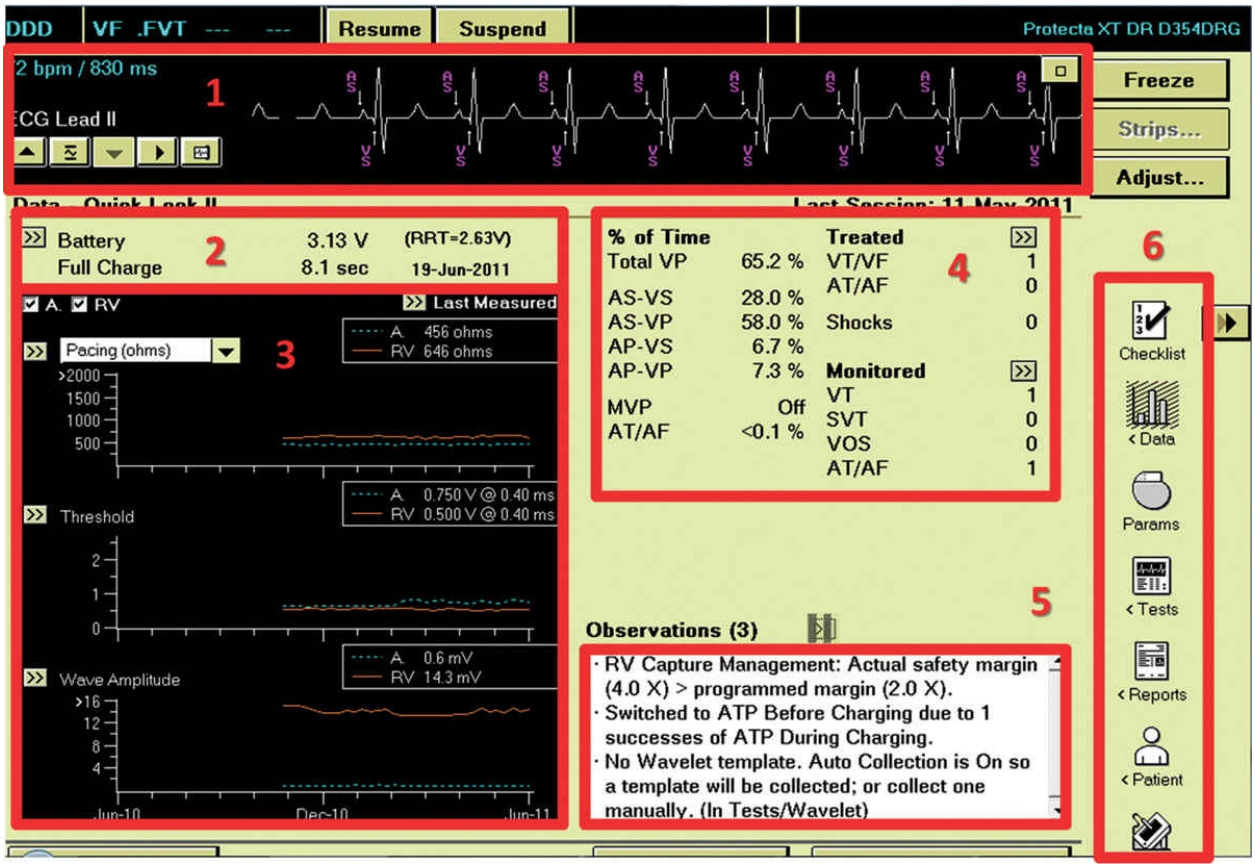
CONCLUSION

Implantable devices are an essential part of medical management for a large number of cardiac patients. Basic knowledge is needed to perform a complete and thorough device evaluation.

APPENDIX: LIMITED KEY GUIDE OF THE FIVE MAJOR DEVICE MANUFACTURER PROGRAMMERS

1. Medtronic CareLink Programmer (**Figure 27.14**)

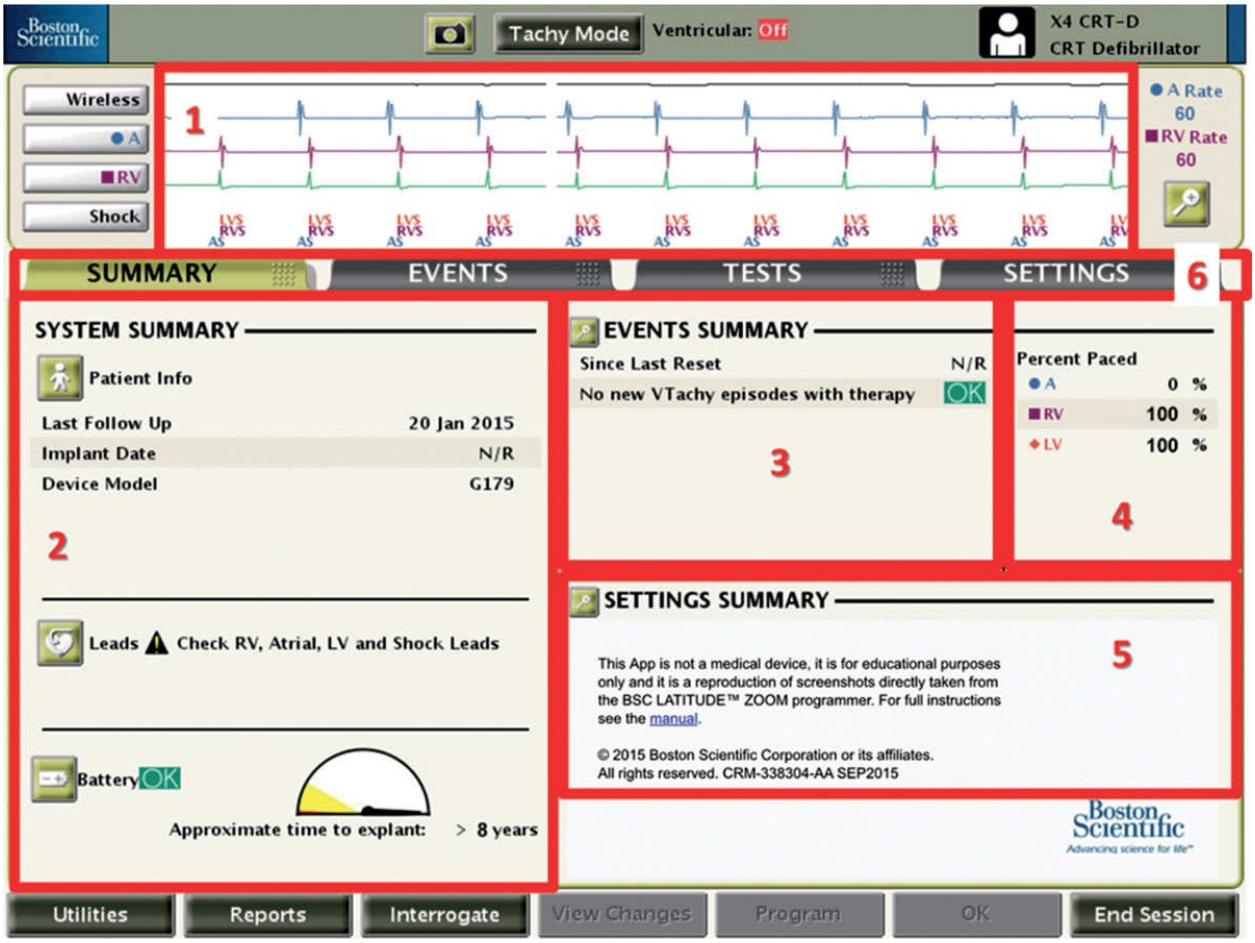


The initial screen of the Medtronic CareLink Programmer shows six main sections as marked in the figure.

1. Surface ECG
2. Battery management showing battery voltage as well as the marker for RRT
3. Trending section: This shows the trends overtime for measured amplitudes (sensing), thresholds, and lead impedances
4. Overview window for device statistics: This includes, percentage pacing over time, total atrial pacing (AP), and total ventricular pacing (VP). This section also shows the number of episodes of any arrhythmias including ventricular tachycardia/fibrillation (VT/VF), atrial tachycardia/fibrillation (AT/AF), and therapies if applicable for ICDs (shocks)
5. Observations window: This shows a short summary of most observation like fluid status (OptiVol), any thresholds issues (capture), or therapies
6. The sidebar set menu: This has a list of icons that help during the device interrogation, including checklist, statistical data, device setparameters, tests, reports and patient

FIGURE 27.14 Medtronic CareLink Programmer.

2. Boston Scientific ZOOM LATITUDE Programming System (**Figure 27.15**)



The initial screen of the Boston Scientific ZOOM LATITUDE Programming System shows six main sections as marked in the figure.

1. Surface ECG and intracardiac markers from the device leads (atrial, ventricular)
2. System summary window: This includes three sections, namely, patient information, leads notifications, and battery gauge showing indication of battery longevity with estimation for the time to explant
3. Events summary: This section shows the number of episodes of any arrhythmias, including ventricular tachycardia/fibrillation (VT/VF), atrial tachycardia/fibrillation (AT/AF), and therapies if applicable for ICDs (shocks)
4. Percentage paced: Total atrial pacing (AP) and total ventricular pacing (VP)
5. Setting summary: Device parameters setting
6. The upper ribbon tabs: These four tabs can take you directly to summary, events, tests, and device programmed settings. Reports printing can be selected by the button “reports” at the bottom of the screen

FIGURE 27.15 Boston Scientific ZOOM LATITUDE Programming System.

3. St. Jude Medical Merlin Programmer (**Figure 27.16**)

The initial screen of the St. Jude Medical Merlin Programmer shows eight main sections as marked in the figure.

1. Surface ECG and intracardiac markers from the device leads (atrial, ventricular)
2. Alerts windows: For any abnormalities, including lead issues, arrhythmia, or ICD therapy if applicable
3. Battery management window: This shows battery voltage as well as a graph depicting the estimated longevity
4. Daily test results summary window: This shows capturing thresholds, sensing amplitude, and lead impedances from most recent test check
5. Device setting summary
6. Percentage paced: Total atrial pacing (AP) and total ventricular pacing (VP)
7. Mode switching: This describes a percentage of automatic mode switching that occurs due to atrial arrhythmia. Mode-switching algorithms are designed to alleviate symptoms related to tracking of atrial arrhythmias
8. The sidebar set menu: This has a list of icons that help during the device interrogation, including FastPath summary, episodes, diagnostics, tests, parameters, and wrap-up overview from which reports are selected for printing

FIGURE 27.16 St. Jude Medical Merlin programmer.

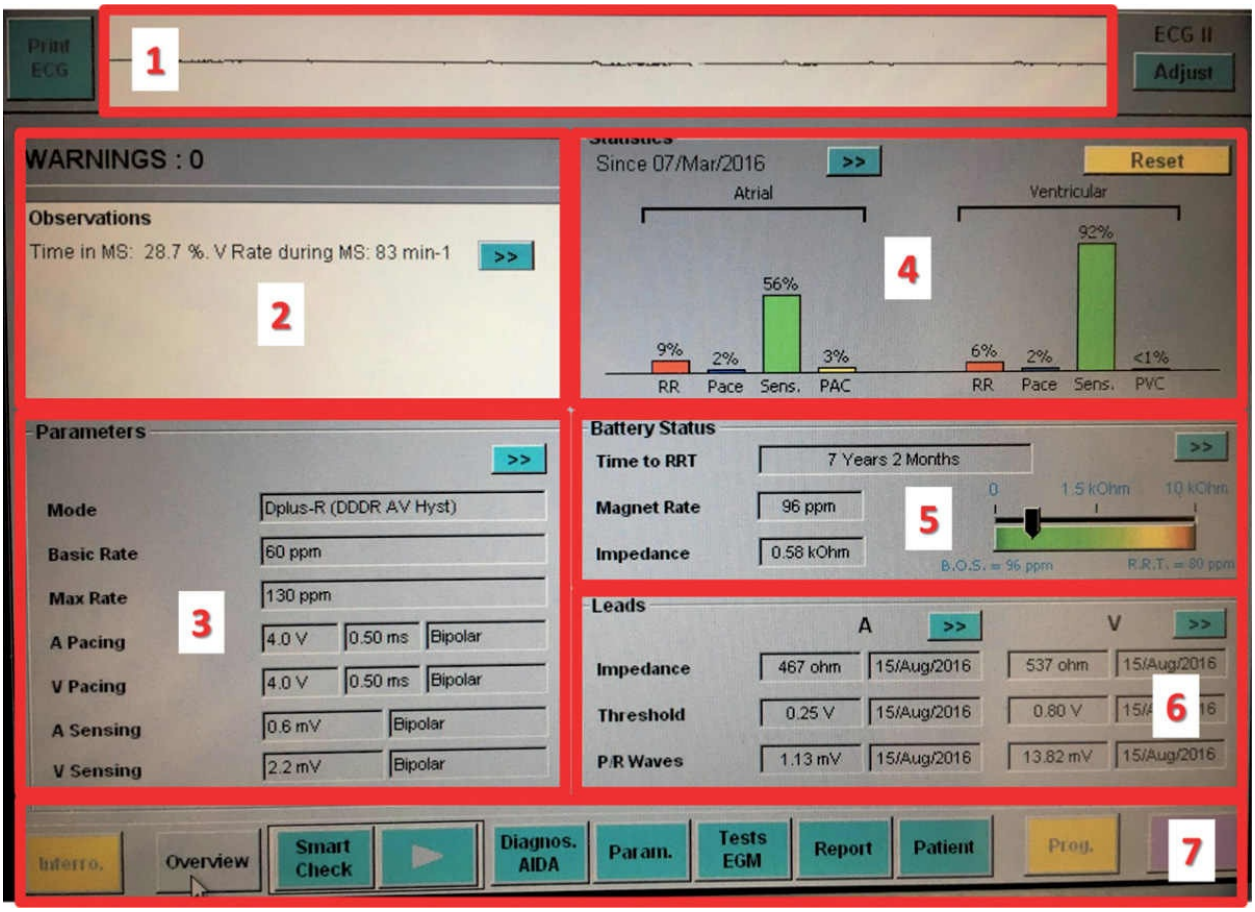
4. Biotronik Renaamic Programmer (**Figure 27.17**)

The initial screen of the Biotronik Renamic Programmer shows six main sections as marked in the figure.

1. Surface ECG and intracardiac markers from the device leads (atrial, ventricular)
2. Patient information, device parameters, and battery management window
3. Episodes windows: For any arrhythmia episodes SVT/VT/VF
4. Daily test results summary window: This shows capturing thresholds, sensing amplitude, and lead impedances from most recent test check
5. Diagnostics: Total percentage pacing for atrial pacing (A) and ventricular pacing (V) as well as atrial arrhythmia burden percentage
6. The sidebar set menu: This has a list of icons that help during the device interrogation, including follow-up, parameters, tests, recordings, diagnostics, and preferences. Reports printing can be selected by a button at the right lower part of the screen

FIGURE 27.17 Biotronik Renamic programmer.

5. Sorin Orchestra Plus Programmer (**Figure 27.18**)



The initial screen of the Sorin Orchestra Plus programmer shows seven main sections as marked in the figure.

1. Surface ECG and intracardiac markers from the device leads (atrial, ventricular)
2. Warnings and observations: This section also shows the number of episodes of any arrhythmias, including ventricular tachycardia/fibrillation (VT/VF), atrial tachycardia/fibrillation (AT/AF), and therapies if applicable for ICDs (shocks)
3. Device parameters and setting
4. Statistics: This shows the total percentage pacing for atrial pacing (A) and ventricular pacing (V) as well as atrial arrhythmia burden percentage
5. Battery management: This shows battery voltage and time to RRT
6. Leads: daily test results summary window: This shows capturing thresholds, sensing amplitude, and lead impedances from most recent test check
7. The lower bar menu: This has a list of buttons that help during the device interrogation, including interrogate, overview, smart check, diagnostics, parameters, tests, and reports

FIGURE 27.18 Sorin Orchestra Plus programmer.

Strategies for the Prevention of Sudden Cardiac Death

INTRODUCTION

Sudden cardiac death (SCD), also known as sudden cardiac arrest, is a major health problem worldwide.[1] According to the American Heart Association (AHA) Statistical Data from 2015, each year 326,000 people experience EMS-assessed out-of-hospital cardiac arrests in the United States and approximately 60% of out-of-hospital cardiac arrests are treated by EMS personnel.[2–3] It is usually defined as the cessation of cardiac mechanical activity, as confirmed by the absence of signs of circulation. Cardiac arrest is traditionally categorized as being of cardiac or noncardiac origin. A dynamic triggering factor usually interacts with an underlying heart disease, either genetically determined or acquired, and the final outcome is the development of lethal tachyarrhythmias or, less frequently, bradycardia.[4]

There is no comprehensible consensus on the definition of SCD, which is witnessed in only two-thirds of cases. Because the duration of symptoms preceding the terminal event usually defines the sudden nature of death, the World Health Organization defines SCD as unexpected death within 1 hour of symptom onset if witnessed or within 24 hours of the person having been observed alive and symptom free if unwitnessed.[5] Exclusion of noncardiac

causes, such as pulmonary embolus or drug overdose, is also critical because sudden cardiac arrhythmias may be the final common pathway in these disease states as well.

According to Framingham Heart Study, during a 20-year follow-up, 13% of the deceased have died of sudden death.[6] In more than 80% of cases, sudden death is caused by coronary disease.[7] The mechanism of sudden death is ventricular fibrillation (VF) in 65% to 85%, ventricular tachycardia (VT) in 7% to 10%, and electromechanical dissociation in 20% to 30%.

RISK FACTORS

About 80% of individuals who suffer SCD have coronary heart disease; the epidemiology of SCD to a great extent parallels that of coronary heart disease. On the basis of recent published data, the following variables have been associated with patients at higher risk of SCD: (1) syncope at the time of the first documented episode of arrhythmia, (2) NYHA class III or IV, (3) VT/VF occurring early after myocardial infarction (3 days to 2 months), and (4) history of previous myocardial infarction.[8] Other factors such as age, hypertension, left ventricular hypertrophy, intraventricular conduction block, elevated serum cholesterol, glucose intolerance, decreased vital capacity, smoking, relative weight, and heart rate are also postulated in identifying individuals at risk for SCD.[9–11] Even family history of myocardial infarction has been reported to be associated with the risk of primary cardiac arrest.[12] Another entity of patients at highest risk for early SCD are those with hereditary ion channel or myocardial defects, such as a long or short QT syndrome, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia (ARVD).

PATHOPHYSIOLOGY OF ARRHYTHMIA

The most common electric sequence of events in SCD is degeneration of VT (abnormal acceleration of ventricular rate) into VF, during which disorganized contractions of the ventricles fail to eject blood effectively, often followed by asystole or pulseless electrical activity.***7*** Polymorphic VT or torsade de pointes may be the initial arrhythmia in patients with genetic or acquired forms of structural heart disease.[13] Bradyarrhythmias or electromechanical dissociation

may be the primary electrical event in advanced heart failure or in the elderly patients.[14–15] Among patients with implantable cardioverter-defibrillators (ICDs), arrhythmic death accounts for 20% to 35% of deaths, and electromechanical dissociation after shock is a frequent cause of death. Asystole may be the first rhythm observed in the field, but this may be a marker of the duration of arrest because coarse VF ultimately degenerates into asystole.

MANAGEMENT

RISK STRATIFICATION

Current parameters for risk stratification of patients with CAD for SCD include medical history (presence of nonsustained VT or syncope), ejection fraction (EF), electrocardiogram (QRS duration, QT interval, QT dispersion), signal-averaged electrocardiogram, heart rate variability, and baroreflex sensitivity. However, the sensitivity and specificity of these parameters have not yet been studied in detail in large patient populations. The single major parameter associated with higher incidence and studied in many clinical trials is the left ventricular ejection fraction (LVEF). At present, only left ventricular (LV) dysfunction with reduced EF reliably defines “high risk” for SCD in patients with ischemic and nonischemic cardiomyopathy. The heart failure functional class and history of prior MI or CAD are also important prognostic risk factors along with sudden specific definite indications.[16]

PREVENTION

Prevention of sudden death means detection of high-risk patients and application of medical treatment in order to postpone it. The high risk of development of SCD is majorly attributed to fatal ventricular arrhythmias. Electrophysiologic anomalies in cells lead to development of ventricular ectopic activity or ventricular arrhythmias, which comes to the end with fibrillation and eventually death if not terminated in time. Because survival rates for out-of-hospital cardiac arrests are extremely low, ranging from 2% to 25% in the United States,[17] secondary prevention strategies only addresses a small portion of patient population at risk of SCD. The accumulated data have allowed guidelines to be formulated, which allow us to predict with more certainty patients at risk for

SCD and address the challenge to identify patients at risk before the first event as primary prevention. However, applying those guidelines in practice requires systems to structure the environment in which care is delivered so that "doing the right thing" becomes automatic.[18] This requires tools that simplify and provide focus by embedding the recommendations for evidence-based care into the care itself.

PHARMACOLOGIC THERAPY

β-Blockers

Of the different drugs that have been evaluated, only β-blockers have reduced sudden death in the myocardial infarction survivor.[19] The BHAT study showed that β-blockade with propranolol reduced all-cause mortality by 25% especially in patients with diminished LV function and/or ventricular arrhythmias.[20] A randomized trial of nearly 46,000 patients showed that, in the acute MI setting, early administration of high-dose β-blocker drugs orally has been shown to prevent VF.[21] In the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) trial, 3,991 patients with NYHA class II-IV heart failure and EF ≤ 40% were randomized to long-acting metoprolol with a dose-escalation protocol.[22] At 1-year follow-up, overall mortality was lower in the treated group compared with placebo (7.2% vs. 11% per patient-years of follow-up). There was also a 41% relative risk reduction in sudden death with long-acting metoprolol. These data provide unequivocal benefit of β-blockade in acute MI, post-MI, and congestive heart failure for prevention of mortality and SCD.

Antiarrhythmic Drugs

The sine qua non for efficacy of common antiarrhythmic drugs in prevention against SCD based on well-designed, placebo-controlled clinical trials have shown no added benefit.[19–23] Class I drugs (mexiletine, flecainide), calcium antagonists, and class III drugs (d-sotalol, dofetilide) all failed to reduce, or even increased, the incidence of SCD after a myocardial infarction.[24] Amiodarone has also been shown to have no definitive effect on mortality in patients after MI in preventing SCD, as manifested in the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT).[25]

Statins

The role of the statins has been well studied in the patients with CAD and has been shown to be extremely beneficial in reducing mortality but whether they play any significant role in preventing SCD remains controversial. A Multicenter Automatic Defibrillator Implantation Trial (MADIT II) substudy[26] demonstrated that, among patients treated with ICDs, those with background statin therapy had a lower rate of ventricular tachyarrhythmias. This finding was intriguing because it was unclear whether this observation was due to reductions in coronary events, decreased inflammation, unique antiarrhythmic properties, or unidentified confounders. Recently, the Cholesterol Lowering and Arrhythmia Recurrences After Internal Defibrillator Implantation (CLARIDI) study demonstrated that intensive lipid-lowering therapy using 80 mg of atorvastatin led to a 40% relative risk reduction (from 38% to 21%) in VT/VF recurrence in ICD patients during a 12-month follow-up. Yet, there are no definite guidelines supporting addition of statins as adjuvant therapy for prevention of SCD beyond conventional indications.

THE ROLE OF ICD DEVICES IN PRIMARY AND SECONDARY PREVENTION AGAINST SCD

Multiple prospective randomized multicenter clinical trials have documented improved survival with ICD therapy in high-risk patients with LV dysfunction due to either prior myocardial infarction or nonischemic cardiomyopathy. On a background of optimal medical therapy (with or without antiarrhythmic drug therapy), ICD therapy has been associated with a 23% to 55% mortality reduction due almost exclusively to a reduction in SCD. Superiority of an ICD over antiarrhythmic drug therapy for secondary prevention against SCD (predominantly amiodarone) was primarily noticed in the Antiarrhythmic Versus Implantable Defibrillator (AVID) trial.[27] The AVID trial enrolled 1,016 patients resuscitated from an episode of VT (if associated with hemodynamic collapse, cardiac symptoms, or occurring in the setting of an EF ≤ 40%) or VF. Patients were randomized to receive either medical therapy alone or in conjunction with an antiarrhythmic drug, which was most commonly amiodarone. The trial was stopped prematurely when a survival benefit was noted in patients receiving ICDs compared with those treated with sotalol or amiodarone. The unadjusted

survival rates for the ICD versus drug groups were 89% versus 82% at 1 year, 82% versus 75% at 2 years, and 75% versus 65% at 3 years. The major effect of the ICD was to prevent arrhythmic death (4.7% vs. 10.8% in patients treated with an antiarrhythmic drug). Results consistent with the AVID study were also reported from the CIDS[28] and the CASH[29] studies.

MADIT TRIAL

To test the efficacy of ICDs in prevention of SCD, the MADIT trial randomized 196 patients with ischemic cardiomyopathy,[30] EF ≤35%, a documented episode of nonsustained VT (NSVT), and inducible VT on electrophysiology study to ICD (n = 95) versus conventional medical therapy (n = 101). After a mean follow-up of 27 months, the relative risk reduction for all-cause mortality in the patients receiving ICDs was 54% (P = 0.009), thus showing the benefit of prophylactic ICD placement in a high-risk population.

MADIT II TRIAL

However, to make an impact on the overall population at risk for sudden death, high-risk patients need to be identified before an episode of VT or VF (primary prevention). The MADIT II study highlighted the possibility of preventing sudden death in patients with coronary artery disease (CAD). According to this trial, patients with a previous MI and low LVEF (≤30%) on optimal medical therapy were randomized to receive either an ICD or no ICD. Patients implanted with an ICD had a mortality rate of 14.2% versus 19.8% in the conventional therapy group (P = 0.016), with a 31% relative risk reduction in mortality during a follow-up period of 20 months. The survival benefit was entirely due to a reduction in the incidence of SCD and became apparent at 9 months after device implantation. This trial was novel in that there was no requirement for invasive electrophysiologic testing of prior ventricular arrhythmias. This trial expanded on the findings of MADIT I, which showed the superiority of ICD therapy in patients with CAD with an EF of 35% or less.

SCD-HEFT TRIAL

The significant role of ICD therapy in primary prevention against SCD in both ischemic and nonischemic cardiomyopathy patients was further clarified by the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT).[31] This trial enrolled

2,521 patients with New York Heart Association[32] class II or III CHF and an EF of ≤35%. Patients were randomized to receive optimal medical therapy alone (847 patients), optimal medical therapy along with amiodarone (845 patients), or optimal medical therapy along with a conservatively programmed, shock-only, single-lead ICD (829 patients). Placebo and amiodarone were administered in a double-blind fashion. The primary end point of the study was all-cause mortality with mean follow-up of 3.8 years. A 23% reduction in mortality ($P = 0.007$) was observed with the ICD; the benefit of ICD was similar in both ischemic (hazard ratio, 0.79; $P = 0.05$) and nonischemic cardiomyopathy (hazard ratio, 0.73; $P = 0.06$). In contrast, mortality was similar in patients either on medical therapy alone or when combined with amiodarone. The benefit of ICD therapy was comparable for ischemic and nonischemic cardiomyopathy.

DEFINITE TRIAL

The Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial was the MADIT II counterpart. This trial included 458 patients with nonischemic dilated cardiomyopathy, EF ≤35%, nonsustained VT or premature ventricular contractions, and NYHA class I, II, or III who were randomly divided to standard medical therapy or ICD.[33] At a 2-year follow-up, there was a trend in mortality reduction with ICD (7.9% vs. 14.1%; hazard ratio = 0.65, $P = 0.08$). The largest benefit was seen in NYHA Class III patients (hazard ratio = 0.37). In part on the basis of the results of this trial, the Centers for Medicare & Medical Services expanded coverage for ICD implementation to patients with nonischemic cardiomyopathy for more than 9 months in duration who have NYHA class III or IV heart failure and EF ≤35%.

TIMING OF ICD IMPLANTATION

CABG PATCH TRIAL

In the CABG Patch study, 900 patients with LVEF of <36% and abnormal signal-averaged ECG who were undergoing elective coronary bypass surgery were randomized to ICD or no antiarrhythmic therapy.[34] This trail showed no difference in survival between the two groups at an average of 32-month follow-up. Of note, 88 patients enrolled were not randomized because they were deemed too unstable at the time of surgery for ICD placement. Additionally, EFs of these patients were not assessed postoperatively. Nevertheless, results suggest

that revascularization should be performed when feasible and SCD risk stratification should be performed after revascularization.

DINAMIT TRIAL

In this randomized, open-label trial comparing ICD therapy to optimal medical therapy, 674 high-risk patients (defined by an EF <35%) were enrolled 6 to 40 days after myocardial infarction.[35–36] The primary end point was death from any cause; death from arrhythmia was a secondary end point. During a mean follow-up of 30 months, there was no difference in overall mortality between two treatment groups. A reduction in arrhythmia was balanced by an increase in overall mortality (cardiac but nonarrhythmogenic) in the ICD group. The reason for this surprising finding is unclear but may be related to impaired cardiac autonomic function early after MI. The benefits of ICD therapy for prevention of SCD may not become evident until years after myocardial infarction and may not have been captured in the mean 30-month follow-up of DINAMIT Trial. Current guidelines therefore recommend deferring ICD implantation for at least 40 days following MI.

Aggressive treatment of myocardial ischemia, including revascularization, is the main treatment in these patients, and early implantation of ICD does not reduce overall mortality after early MI (the DINAMIT study). Implantation of ICD should be deferred in these cases as is currently recommended, with reassessment of LV function after 40 days to determine whether ICD is still required for primary prevention of SCD (if LVEF <35%), although in some individual circumstances it may be considered (eg, in patients with recurrent, sustained arrhythmias).

CARDIAC RESYNCHRONIZATION THERAPY

Cardiac resynchronization therapy (CRT), or biventricular pacing, can improve cardiac pump function in advanced heart failure by simultaneous activation of the left and right ventricles in those with underlying or pacing-induced bundle branch block. CRT[37] is approved in the United States for EF ≤ 35%, evidence of dyssynchrony, and class III–IV heart failure despite optimal medical therapy. A brief review of the clinical data supporting their current use follows.

COMPANION TRIAL

CRT with either a pacemaker or a pacemaker-defibrillator has been shown to be very beneficial in the COMPANION trial,[38] which randomized patients with class III or IV heart failure, normal sinus rhythm, LVEF <35%, LV end diastolic volume > 60 mm, and QRS interval > 120 milliseconds. In this trial CRT with a pacemaker decreased the risk of the primary end point (hazard ratio, 0.81; P = 0.014), as did CRT with a pacemaker-defibrillator (hazard ratio, 0.80; $P < 0.01$). The risk of the combined end point of death or hospitalization for heart failure was reduced by 34% in the pacemaker group ($P < 0.002$) and by 40% in the pacemaker-defibrillator group ($P < 0.001$). A pacemaker reduced the risk of the secondary end point of death from any cause by 24% (P = 0.059), and a pacemaker-defibrillator reduced the risk by 36% (P = 0.003).

CARE-CHF TRIAL

The Cardiac Resynchronization in Heart Failure Study (CARE-HF) trial was a nonblinded European trial, which enrolled patients with class III or IV heart failure, LVEF <35%, LV end diastolic volume >30 mm, QRS interval >150 milliseconds, or QRS >120 milliseconds with echocardiographic parameters of dyssynchrony.[39] This trial confirmed earlier trials that the benefits of CRT are in addition to those achieved with standard pharmacologic therapy in patients with moderate-to-severe heart failure due to LV systolic dysfunction with evidence of cardiac dyssynchrony. CARE-HF is the first study to show benefit with CRT with respect to survival and the first to show benefit and continued improvement for a period of over 2 years.

MADIT-CRT

In a large randomized study of NYHA Class I and II patients, the primary endpoint showed that CRT-D were associated with 34% relative reduction in the risk of all-cause mortality or first heart failure event; in addition, there were 41% relative reduction of heart failure events compared with ICD patients. One-year follow-up confirmed an improvement of 11% in LVEF compared with 3% improvement for ICD patients.[40] The trial showed the best benefit were for patients with left bundle branch block or with non–left bundle branch with QRS > 150 msec, which led to an update in the guidelines that was published in 2012.[42]

A GENERALIZED SIMPLE SYSTEMATIC APPROACH TOWARD PREVENTION OF SCD (ESCAPE PATHWAY)

Multiple pathways have been developed in recent past to address these complex issues faced in the management of SCD; however, most of them lack simplicity, and practicality of implementation, which in turn affect their overall outcome and patient care. Here, we describe the ESCAPE pathway,[41] which is a simple novel pathway for primary and secondary prevention of sudden cardiac arrest aiming to increase physician awareness and incorporate a tool for appropriate referral for ICD evaluation (**Figure 28.1**).

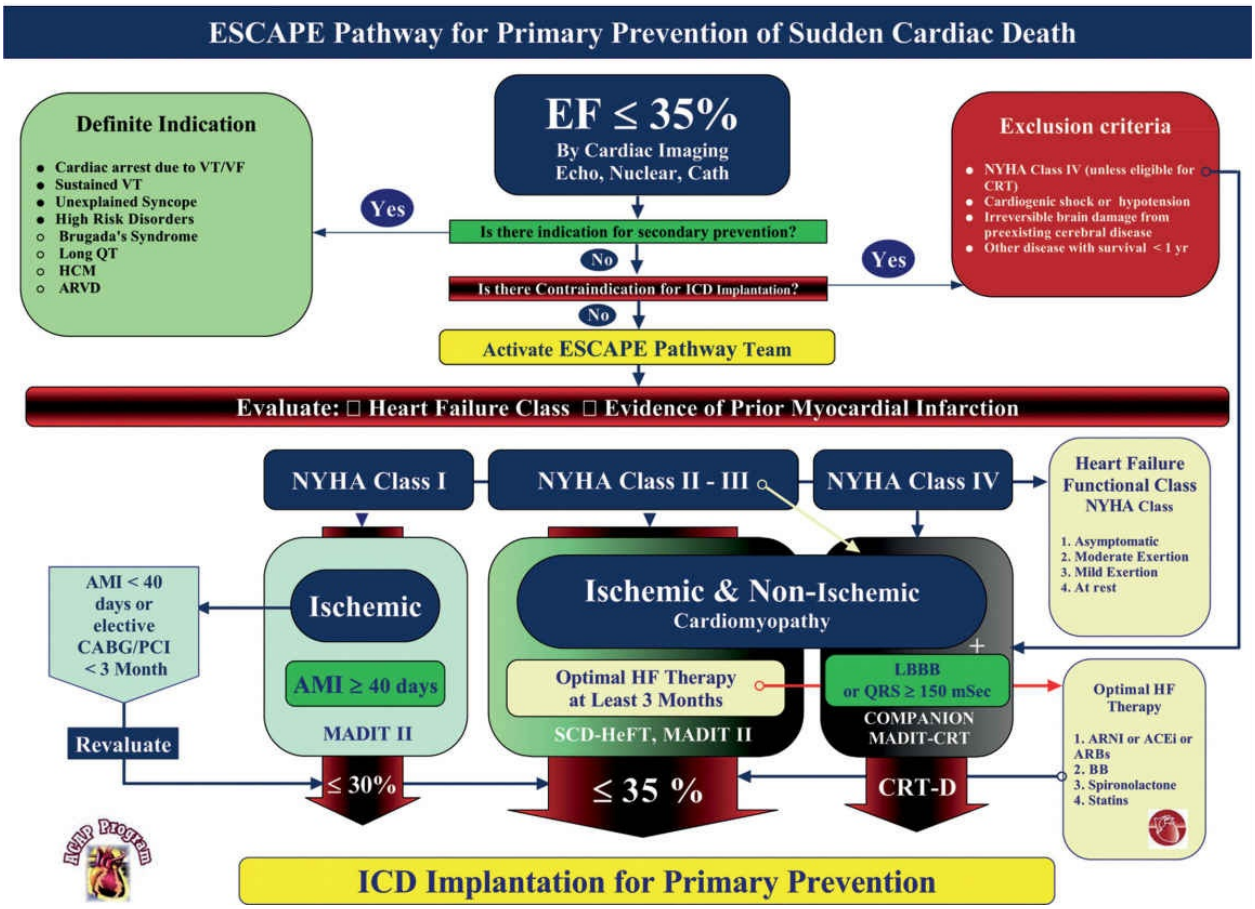

FIGURE 28.1 The ESCAPE pathway for prevention of sudden cardiac death.

STEP A: INITIAL EVALUATION OF PATIENTS

The initial and foremost thing to observe while assessing for the prevention against SCD is the EF. The ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of SCD criteria include patients with either ischemic or nonischemic cardiomyopathy with EF ≤ 35%, or NYHA class II or III heart failure.

On the basis of the initial evaluation of the patients with EF ≤ 35%, they can be divided into three subgroups: (A) patients with a clear indication for secondary cardiac arrest prevention, (B) patients who have a contraindication to ICD or have no proven benefit from ICDs for SCD prevention as per clinical data available to date, and (C) patients who neither have any indication for ICD placement at this time as a part of secondary prevention of SCD nor have any contraindication.

Group A involves the following patients (**Figure 28.2**):

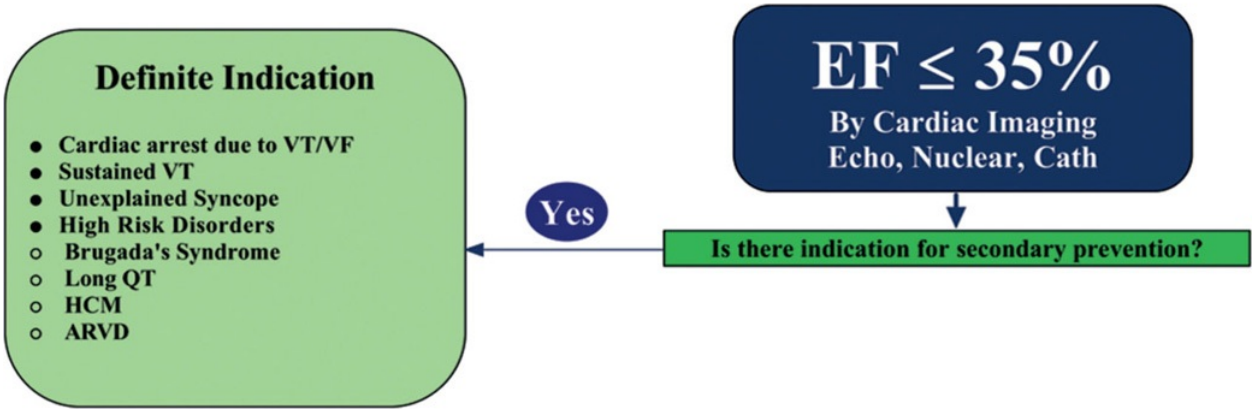

FIGURE 28.2 Indications for ICD implantation as secondary prevention of sudden cardiac death.

- Survivors of sudden cardiac arrest due to VT/VF
- Those with a previous documented episode of hemodynamically destabilizing sustained VT
- Those with unexplained syncope in the setting of underlying structural heart disease
- Those with high-risk short or long QT syndrome (LQTS or SQTS)
- Those with high-risk Brugada syndrome
- Those with high-risk hypertrophic cardiomyopathy
- Those with arrhythmogenic right ventricular dysplagia (ARVD)

This group of patient population on presentation should be referred directly for ICD implantation for secondary prevention against SCD.

Group B involves patients with a contraindication for ICD implantation and include the following (**Figure 28.3**):

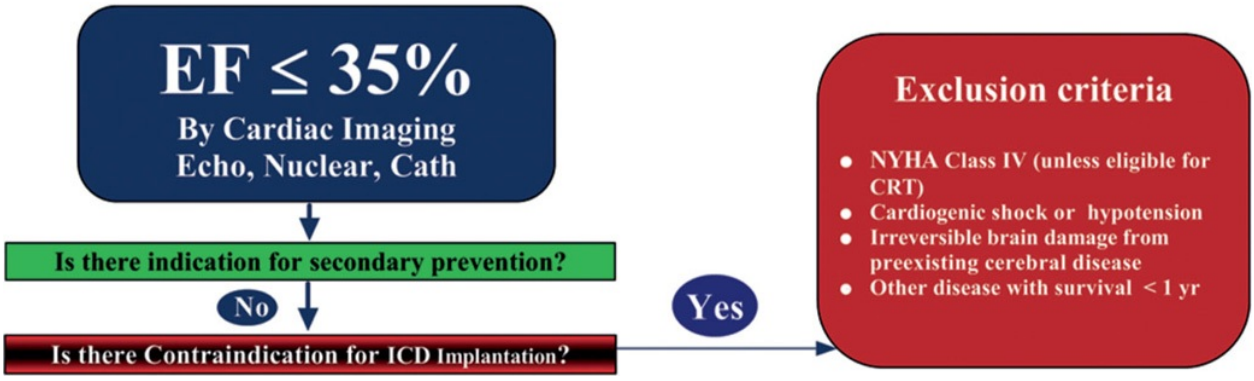

FIGURE 28.3 Contraindication for ICD implantation.

- NYHA class IV patients (unless QRS ≤ 120 milliseconds who are eligible for CRT)
- Those with cardiogenic shock or hypotension
- Those with irreversible brain damage from preexisting cerebral disease
- Those with other disease (eg, cancer, uremia, liver failure), associated with a likelihood of survival of less than 1 year

Group C patients need further work-up to decide whether or when they should get ICDs and should enter into step B.

STEP B: EVALUATION OF HEART FAILURE CLASSES

To determine the best course of therapy, these patients require assessment of the stage of heart failure according to the NYHA classification (**Figure 28.4**).[42–43]

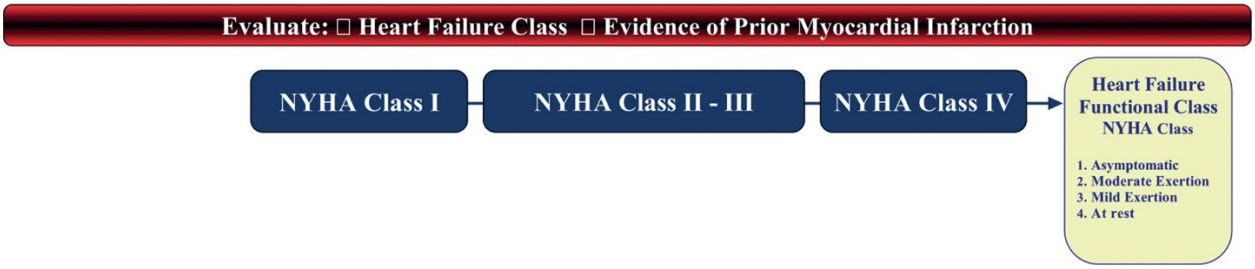

FIGURE 28.4 Evaluation of New York Heart Association classes.

- Class I: No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea (shortness of breath).
- Class II: Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea.
- Class III: Marked limitation of physical activity. Comfortable at rest, but less-than-ordinary activity causes fatigue, palpitation, or dyspnea.
- Class IV: Unable to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency at rest. If any physical activity is undertaken, discomfort is increased.

STEP C: EVALUATION OF CAD OR PRIOR MI IN NYHA CLASS I PATIENT

Evaluation for any evidence of prior MI or CAD requiring intervention is further necessary (**Figure 28.5**).

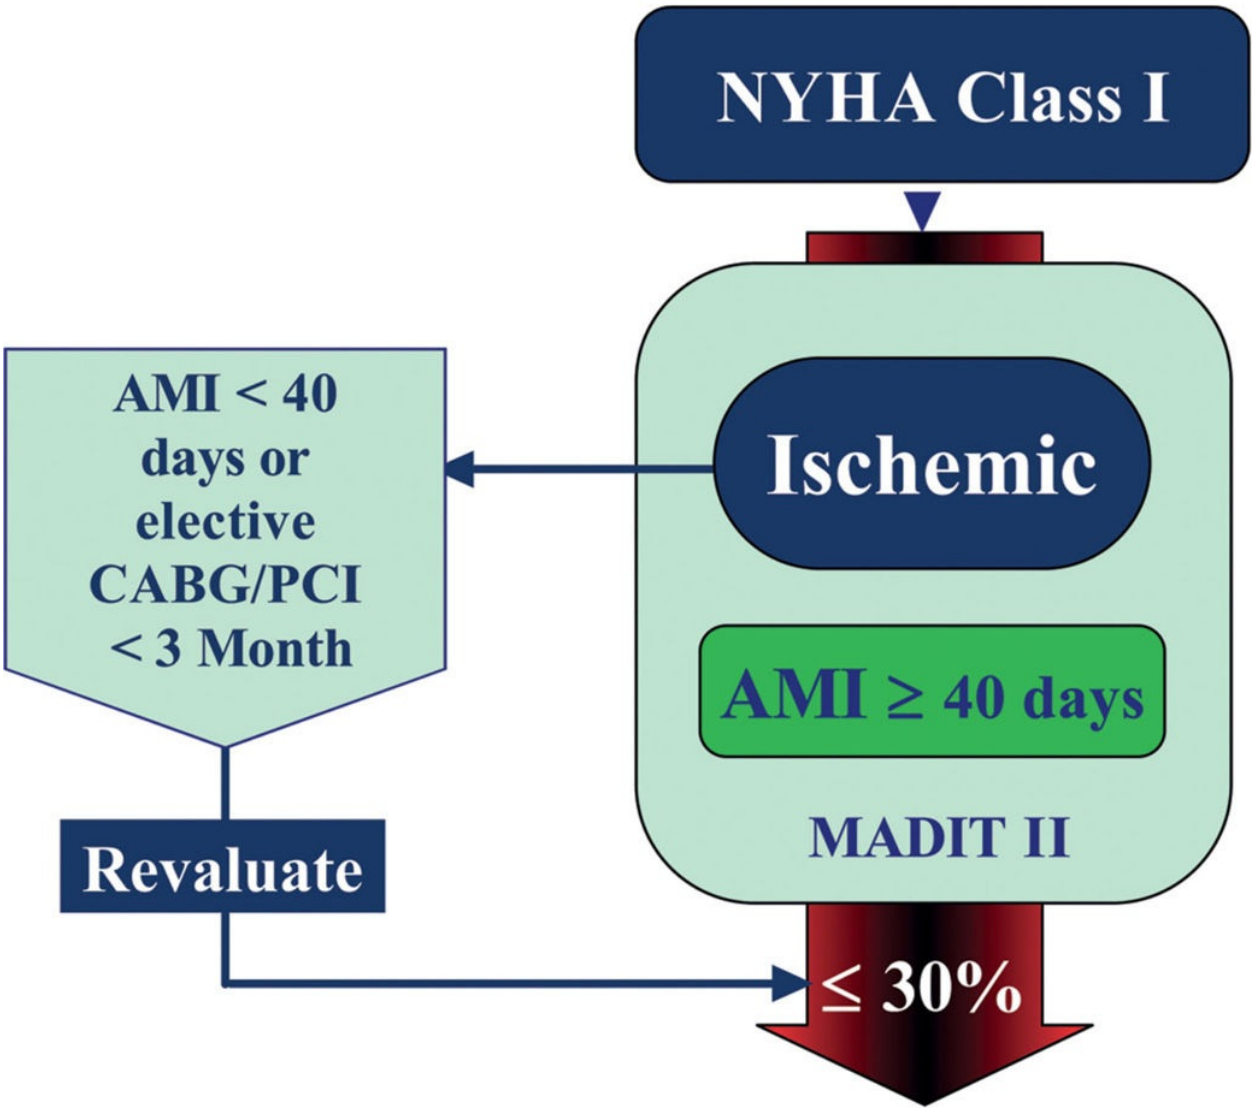

FIGURE 28.5 Evaluation of coronary artery disease or prior myocardial infarction in NYHA class I patients.

- Patients with NYHA class I heart failure whose EF is lower or equal to 30% and who are at least 40 days post-MI should be referred for an ICD implantation according to MADIT II trial.
- Patients with low EF and are ≤40 days post-MI should be managed medically for their heart failure at present.[44] If repeat imaging at 40 days confirms EF ≤ 30% (or ≤35% in patients with class II or III NYHA class CHF), these patients should be referred for an ICD implantation.
- Patients with low EF who underwent elective revascularization either by

percutaneous intervention or coronary bypass surgery in ≤3 months should be managed medically with optimal therapy for heart failure and if repeated imaging at 3 months confirms EF ≤ 30% (or ≤35% in patients with class II or III NYHA class CHF), these patients should be referred for an ICD implantation.

STEP D: PRIMARY PREVENTION OF SCD IN NYHA CLASS II–III PATIENTS WITH LOW EF

According to the ACC/AHA/HFSA Focused Update on New Pharmacological Therapy for Heart Failure: An Update of the 2016 ACCF/AHA Guideline for the Management of Heart Failure[43] (**Figure 28.6**),

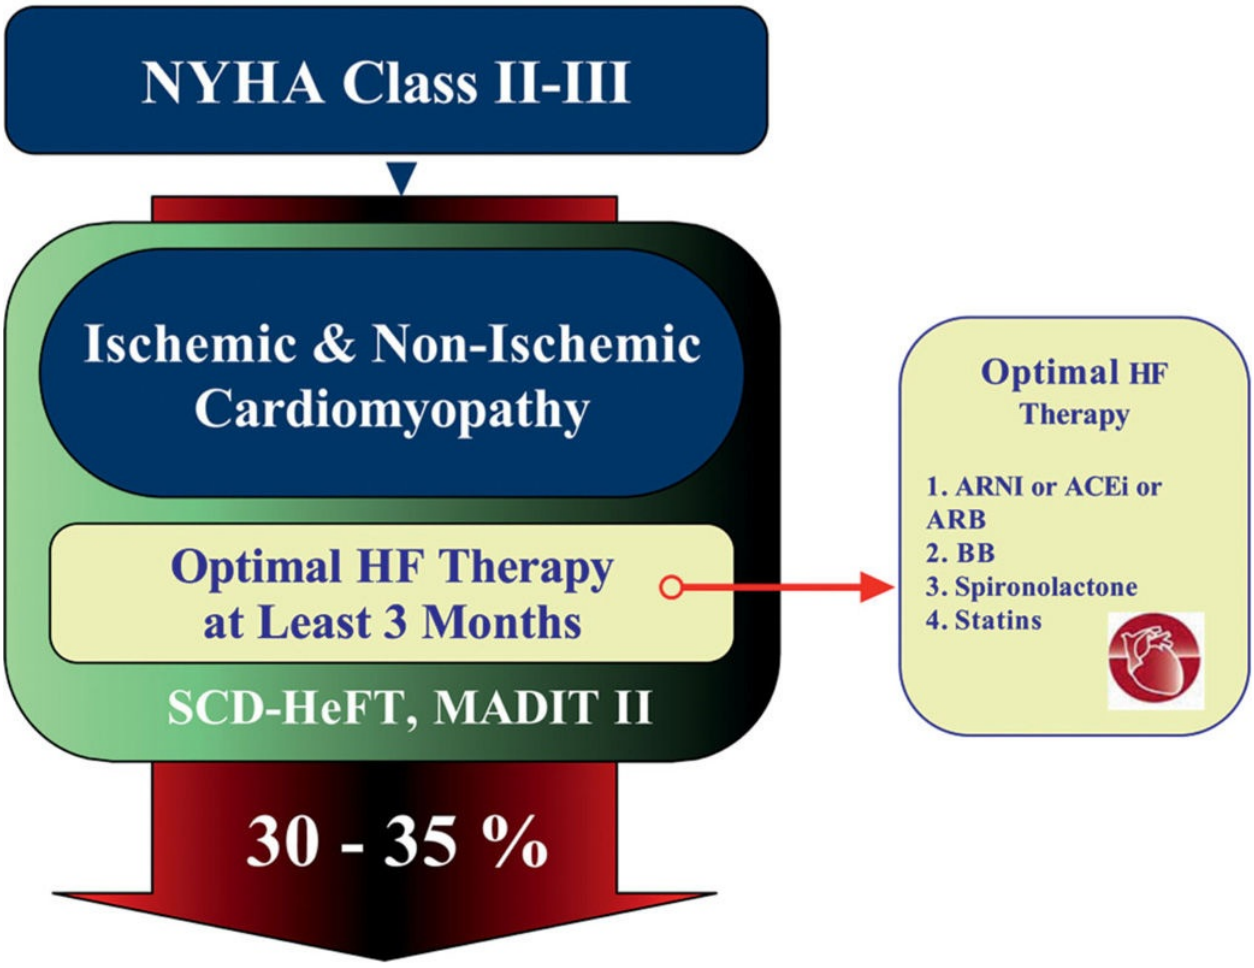

FIGURE 28.6 Primary prevention of sudden cardiac death in NYHA class II–III patients with low ejection

fraction.

- Angiotensin-converting enzyme (ACE) inhibitors are recommended for routine administration to symptomatic and asymptomatic patients with LVEF ≤40% (strength of evidence = A).
- β-Blockers shown to be effective in clinical trials of patients with HF are recommended for patients with an LVEF ≤ 40% (strength of evidence = A).
- Angiotensin-receptor blockers (ARBs) are recommended for routine administration to symptomatic and asymptomatic patients with an LVEF ≤40% who are intolerant to ACE inhibitors for reasons other than hyperkalemia or renal insufficiency (strength of evidence = A).
- Angiotensin-receptor/neprilysin inhibitor (ARNI), Valsartan/sacubitril may be used instead of an ACE inhibitor or an ARB in people with heart failure and a reduced LVEF (strength of evidence = A).
- Administration of an aldosterone antagonist should be considered in patients following an acute MI, with clinical HF signs and symptoms and an LVEF ≤40%. Patients should be on standard therapy, including an ACE inhibitor (or ARB) and a β-blocker (strength of evidence = A).

If repeated imaging at 3 months confirms EF ≤35% and still in NYHA class II to III, these patients will be referred for an ICD implantation.

STEP E: PRIMARY PREVENTION OF SCD IN NYHA CLASS III AND IV HEART FAILURE PATIENTS WITH LEFT BUNDLE BRANCH BLOCK OR NON–LEFT BUNDLE WITH PROLONGED QRS (≥150 MILLISECONDS)

Patients with left bundle branch block or non–left bundle with QRS ≥150 milliseconds and in NYHA class (II, III, and IV) according to COMPANION, CARE-HF, and MADIT-CRT trials will be referred for CRT with an ICD (CRT-D), whereas patients with NYHA class IV but QRS > 120 milliseconds should be treated with optimal medical therapy (**Figure 28.7**).[19]

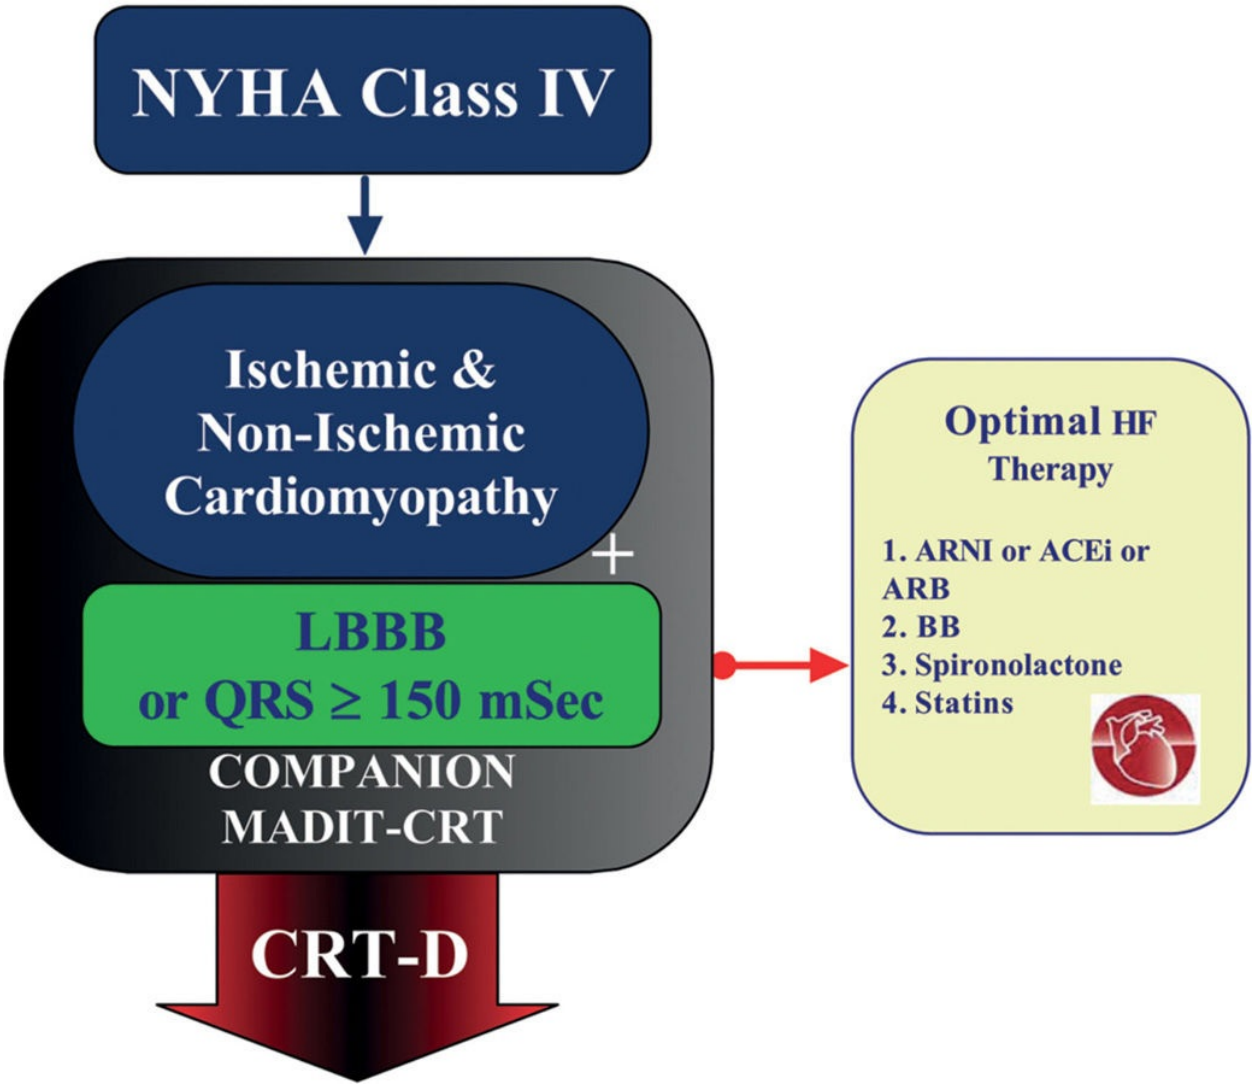

FIGURE 28.7 Primary prevention of sudden cardiac death in NYHA class III–IV heart failure patients with left bundle branch block (LBBB) or non-LBBB with prolonged QRS ≥150 ms.

CONCLUSION

Over the last three decades, revolutionary advances in the understanding and treatment of SCD have been accomplished. Structural and electrical mechanisms of terminal arrhythmias have been elucidated. Over two-dozen genetic mutations and polymorphisms have been identified, which in turn have increased our understanding of ion channel structure and function. At the same time, randomized trials that demonstrated harm from antiarrhythmic drugs have

curtailed the use of such drugs alone in the prevention of SCD. The ICD was developed and has proven to be a highly effective therapy in the prevention of SCD to date. However, most cases of SCD occur in patients without these high-risk features, and the biggest challenge still remains: to accurately identify patients at risk for SCD for primary prevention.

Cardiopulmonary Resuscitation and Cardiocerebral Resuscitation Using Therapeutic Hypothermia

DEFINING SUDDEN CARDIAC ARREST

Cardiac arrest is defined as the cessation of cardiac mechanical activity, as confirmed by the absence of signs of circulation. Cardiac arrest is traditionally categorized as being of cardiac or noncardiac origin. An arrest is presumed to be of cardiac origin unless it is known or likely to have been caused by trauma, submersion, drug overdose, asphyxia, exsanguination, or any other noncardiac cause as best determined by rescuers.[1]

It is challenging to define what “unexpected” or “sudden” death is. Current practice defines sudden cardiac death as unexpected death without an obvious noncardiac cause that occurs within 1 hour of symptom onset (witnessed) or within 24 hours of last being observed in normal health (unwitnessed).[2]

EPIDEMIOLOGY OF OUT-OF-HOSPITAL CARDIAC ARREST

Based on the American Heart Association (AHA) Statistical Data from 2015[1]

- Each year, 326,000 people experience emergency medical services (EMS)–assessed out-of-hospital cardiac arrests in the United States.
- Approximately 60% of out-of-hospital cardiac arrests are treated by EMS personnel.[3]
- Twenty-five percent of those with EMS-treated out-of-hospital cardiac arrest have no symptoms before the onset of arrest.[4]
- Among EMS-treated out-of-hospital cardiac arrests, 23% have an initial rhythm of ventricular fibrillation (VF) or ventricular tachycardia (VT) or are shockable by an automated external defibrillator (AED).[5]
- The incidence of cardiac arrest with an initial rhythm of VF is decreasing over time; however, the incidence of cardiac arrest is not decreasing.[6]
- The median age for out-of-hospital cardiac arrest is 66 years.[7]
- Cardiac arrest is witnessed by a bystander in 38.7% of cases, by an EMS provider in 10.9% of cases, and is unwitnessed in 50.4% of cases.[7]
- In the Cardiac Arrest Registry to Enhance Survival (CARES) registry, 31,127 out-of-hospital cardiac arrests were treated in 2013. Survival to hospital discharge was 10.6%, and survival with good neurologic function (Cerebral Performance Category 1 or 2) was 8.3%. For bystander witnessed arrest with a shockable rhythm, survival to hospital discharge was 33.0%.[7]
- According to the CARES registry, in 2013 the majority of out-of-hospital cardiac arrests occurred at a home or residence (69.5%).[7]
- A family history of cardiac arrest in a first-degree relative is associated with a 2-fold increase in risk of cardiac arrest.[8, 9]

EPIDEMIOLOGY OF IN-HOSPITAL CARDIAC ARREST

Based on the AHA Statistical Data from 2015[1]:

- Each year, 209,000 people are treated for in-hospital cardiac arrest in the United States.[10]
- According to the Get With The Guidelines (GWTG)-Resuscitation database from 2014, 25.5% of adults who experienced in-hospital cardiac arrest with any first recorded rhythm in 2013 survived to discharge.[1]

- In the United Kingdom National Cardiac Arrest Audit database between 2011 and 2013, the overall unadjusted survival rate was 18.4%. Survival was 49% when the initial rhythm was shockable and 10.5% when the initial rhythm was not shockable.[11]

CARDIOPULMONARY RESUSCITATION GUIDELINE EVOLUTION

The initial attempts to treat cardiac arrest focused on chest compressions. Closed chest defibrillation and closed chest cardiac massage were first described in the 1960s.

In the initial publication, some patients were treated with chest compression without positive pressure. However, with time, ventilation gradually became an essential pillar of cardiopulmonary resuscitation.

Given the prevalence and lethality of cardiac arrest, the AHA disseminated cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) information to health care professionals and the lay public in the 1970s.

The International Liaison Committee on Resuscitation (ILCOR) was formed in 1993. In 1999, the AHA hosted the first ILCOR conference to evaluate resuscitation science and develop common resuscitation guidelines. Since 2000, researchers from the ILCOR member councils have evaluated and reported their International Consensus on CPR and ECC Science With Treatment Recommendations(CoSTR) in 5-year cycles.[12]

HIGHLIGHTS OF THE 2015 AMERICAN HEART ASSOCIATION GUIDELINES UPDATED FOR CARDIOPULMONARY RESUSCITATION AND EMERGENCY CARDIOVASCULAR CARE

BASIC LIFE SUPPORT

Systems of Care

The 2015 AHA Updated Guidelines highlighted a new perspective on systems of care, differentiating in-hospital cardiac arrests (IHCAs) from out-of-hospital

cardiac arrests (OHCAs).[13]

The care for all post–cardiac arrest patients, regardless of the location of the arrests, converges in the hospital, generally in an intensive care unit (ICU) where post–cardiac arrest care is provided. The systems of care before that convergence are very different for the two settings. Patients who have an OHCA depend on their community for support. Lay rescuers must recognize the arrest, call for help, initiate CPR, and provide defibrillation (ie, public-access defibrillation [PAD]) until EMS assumes responsibility and transports the patient to an emergency department (ED) and/or cardiac catheterization lab. The patient is ultimately transferred to a critical care unit for continued care.

In contrast, patients who have an IHCA depend on a system of appropriate surveillance (ie, rapid response or early warning system) to prevent cardiac arrest. If cardiac arrest occurs, patients depend on the smooth interaction of the institution's various services and a multidisciplinary team of professional providers, including physicians, nurses, and respiratory therapists, among others.

Community Lay Rescuer Automated External Defibrillator Programs

It is recommended that PAD programs for patients with OHCA be implemented in public locations where there is a relatively high likelihood of witnessed cardiac arrest (eg, airports, casinos, sports facilities).

There is clear and consistent evidence of improved survival from cardiac arrest when a bystander performs CPR and rapidly uses an AED. Thus, immediate access to a defibrillator is a primary component of the system of care. The implementation of a PAD program requires 4 essential components: (1) a planned and practiced response, which, ideally, includes identification of locations and neighborhoods where there is high risk of cardiac arrest, placement of AEDs in those areas, and ensuring that bystanders are aware of the location of the AEDs, and, typically, oversight by an HCP; (2) training of anticipated rescuers in CPR and use of the AED; (3) an integrated link with the local EMS system; and (4) a program of ongoing quality improvement.

Figure 29.1 outlines the 2015 guidelines recommendations for the initial approach to a patient who is unresponsive.

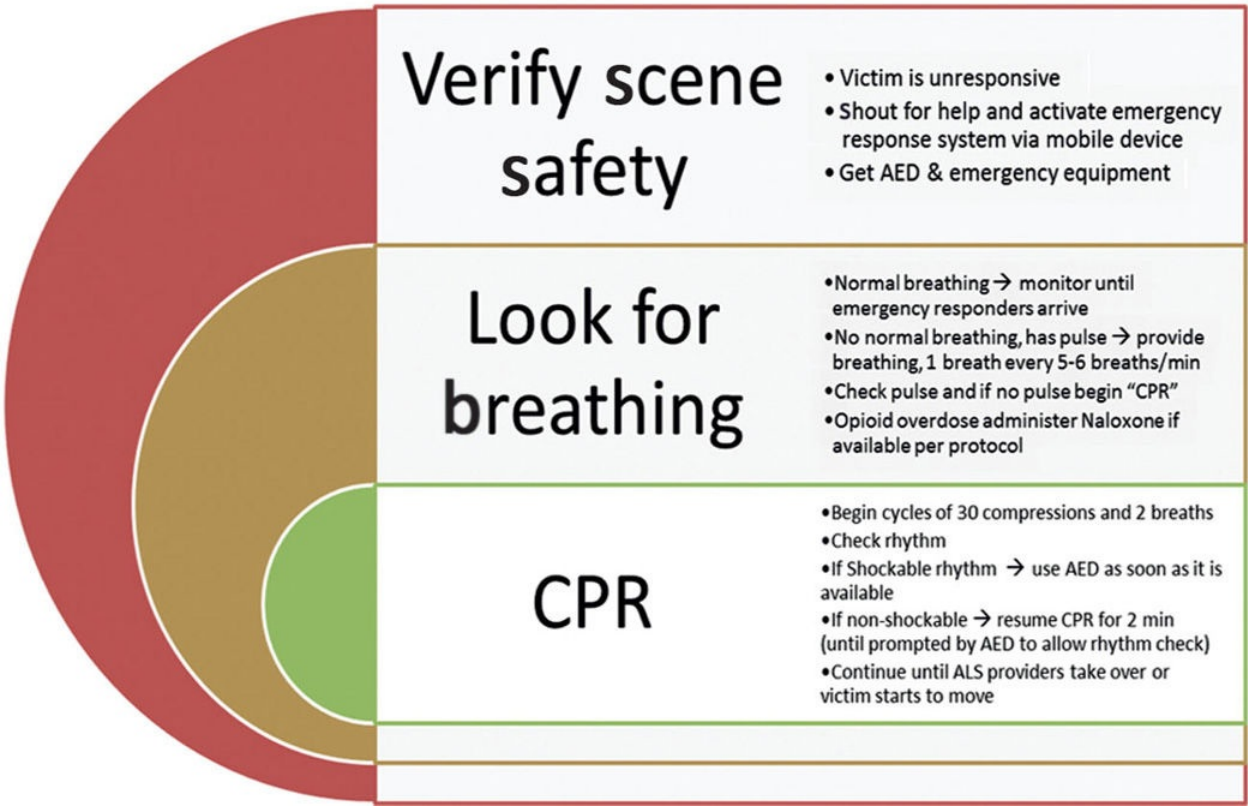

FIGURE 29.1 Updated 2015 guidelines recommendation for unresponsive patient management. AED, automated external defibrillator; ALS, advanced life support.

Chest Compressions

Untrained lay rescuers should provide compression-only (hands-only) CPR, with or without dispatcher guidance, for adult victims of cardiac arrest. The rescuer should continue compression-only CPR until the arrival of an AED or rescuers with additional training. All lay rescuers should, at a minimum, provide chest compressions for victims of cardiac arrest. In addition, if the trained lay rescuer is able to perform rescue breaths, he or she should add rescue breaths in a ratio of 30 compressions to 2 breaths. The rescuer should continue CPR until an AED arrives and is ready for use, EMS providers take over care of the victim, or the victim starts to move.

Chest Compression Rate

In most studies, more compressions are associated with higher survival rates, and fewer compressions with lower survival rates.

New to the 2015 Guidelines Update are upper limits of recommended compression rate and compression depth, based on preliminary data suggesting

that excessive compression rate and depth adversely affect outcomes.

For the critical outcome of survival to hospital discharge, evidence exists from two observational studies [14, 15] representing 13 469 adult patients. They compared chest compression rates of greater than 140/min, 120 to 139/min, less than 80/min, and 80 to 99/min with the control rate of 100 to 119/min. When compared with the control chest compression rate of 100 to 119/min, there was a 4% decrease in survival to hospital discharge with compression rates of greater than 140/min, a 2% decrease in survival to hospital discharge with compression rates of 120 to 139/min, a 1% decrease in survival to hospita l discharge with compression rates of less than 80/min, and a 2% decrease in survival to hospital discharge with compression rates of 80 to 99/min.

The study showed that chest compression depth declined with increasing chest compression rate. The relationship of reduced compression depth at different compression rates was as follows: for a compression rate of 100 to 119/min, 35% of compressions had a depth of less than 3.8 cm; for a compression rate of 120 to 139/min, 50% of compressions had a depth of less than 3.8 cm; and for a compression rate of 140/min or greater, 70% of the compressions had a depth of < 3.8 cm.

TREATMENT RECOMMENDATIONS

The 2015 guidelines recommend a manual chest compression rate of 100 to 120/min.

Chest Compression Depth

During manual CPR, rescuers should perform chest compressions to a depth of at least 2 inches (5 cm) for an average adult, while avoiding excessive chest compression depths (> 2.4 inches [6 cm]).

The reason for emphasis on accurate chest compression depth is the following: compressions create blood flow primarily by increasing intrathoracic pressure and directly compressing the heart, which in turn results in critical blood flow and oxygen delivery to the heart and brain. Rescuers often do not compress the chest deeply enough despite the recommendation to “push hard.” Although a compression depth of at least 2 inches (5 cm) is recommended, the 2015 Guidelines Update, as previously noted, incorporates new evidence about the potential for an upper threshold of compression depth (> 2.4 inches [6 cm]) beyond which complications may occur. Compression depth may be difficult to judge without use of feedback devices, and identification of upper limits of

compression depth may be challenging.

For the critical outcome of survival to hospital discharge, 3 observational studies [16–18] suggest that survival may improve with increasing compression depth. In the largest study (9,136 patients), a covariate-adjusted spline analysis showed a maximum survival at a mean depth of 4.0 to 5.5 cm (1.6 to 2.2 inches), with a peak at 4.6 cm (1.8 inches).[18]

Another important study showed injuries were reported in 63% with compression depth of more than 6 cm (more than 2.4 inches) and 31% with compression depth of less than 6 cm. Injuries were reported in 28%, 27%, and 49% with compression depths of < 5 cm (< 2 inches), 5 to 6 cm (2 to 2.4 inches), and > 6 cm (> 2.4 inches), respectively.[19]

Treatment Recommendations

The 2015 guidelines recommend a chest compression depth of approximately 5 cm (2 inches) while avoiding excessive chest compression depths (> 6 cm [> 2.4 inches] in an average adult) during manual CPR.

Compression–Ventilation Ratio

The critical outcome of survival with favorable neurologic outcome at discharge was studied in two observational studies.[20, 21] Of the 1,711 patients included, those who were treated under the 2005 guidelines with a compression–ventilation ratio of 30:2 had slightly higher survival than those patients treated under the 2000 guidelines with a compression–ventilation ratio of 15:2 (8.9% vs. 6.5%; RR 1.37 [0.98–1.91]).

The critical outcome of survival to hospital discharge was tested in 4 observational studies.[20–23] Of the 4,183 patients included, those who were treated under the 2005 guidelines with a compression–ventilation ratio of 30:2 had slightly higher survival than those patients treated under the 2000 guidelines with a compression–ventilation ratio of 15:2 (11.0% vs. 7.0%; RR 1.75 [1.32–2.04]).

For the critical outcome of survival to 30 days, 1 observational study[24] found that patients treated under the 2005 guidelines had slightly higher survival than those patients treated under the 2000 guidelines (16.0% vs. 8.3%; RR 1.92 [1.28–2.87]).

For the critical outcome of any return of spontaneous circulation (ROSC), 2 observational studies [20, 21] found that patients treated under the 2005 guidelines

had a ROSC more often than those patients treated under the 2000 guidelines (38.7% vs. 30.0%; RR 1.30 [1.14–1.49]).

Treatment Recommendation

The 2015 guidelines suggest a compression–ventilation ratio of 30:2 compared with any other compression–ventilation ratio in patients in cardiac arrest.

Ventilation During Cardiopulmonary Resuscitation with Advanced Airway

The 2015 guidelines suggest that it may be reasonable for the provider to deliver 1 breath every 6 seconds (10 breaths per minute) while continuous chest compressions are being performed (ie, during CPR with an advanced airway).

Bystander Naloxone in Opioid-Associated Life-Threatening Emergencies

New for the 2015 guidelines is that for patients with known or suspected opioid addiction who are unresponsive with no normal breathing but a pulse, it is reasonable for appropriately trained lay rescuers and basic life support (BLS) providers to administer intramuscular (IM) or intranasal (IN) naloxone in addition to providing standard BLS care.

In 2014, the naloxone autoinjector was approved by the US Food and Drug Administration for use by lay rescuers and HCPs.[3]

Shock First Versus Cardiopulmonary Resuscitation First

Numerous studies have addressed the question of whether a benefit is conferred by providing a specified period (typically 1½ to 3 minutes) of chest compressions before shock delivery, as compared to delivering a shock as soon as the AED can be readied. No difference in outcome has been shown.

For witnessed adult cardiac arrest when an AED is immediately available, it is reasonable that the defibrillator be used as soon as possible. For adults with unmonitored cardiac arrest or for whom an AED is not immediately available, it is reasonable that CPR be initiated while the defibrillator equipment is being retrieved and applied and that defibrillation, if indicated, be attempted as soon as the device is ready for use.

CPR should be provided while the AED pads are applied and until the AED is ready to analyze the rhythm.

Chest Recoil

On the basis of the 2015 guidelines, it is reasonable for rescuers to avoid leaning on the chest between compressions, to allow full chest wall recoil for adults in cardiac arrest.

Figure 29.2 summarizes the new 2015 guidelines recommendations for a high-quality CPR.

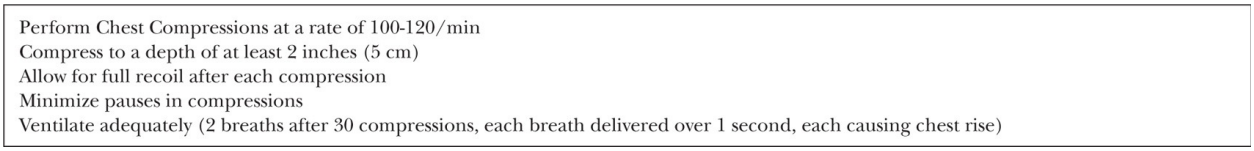

FIGURE 29.2 2015 guidelines recommendation for high-quality CPR.

ADVANCED LIFE SUPPORT

Mechanical Cardiopulmonary Resuscitation Devices

The 2015 updated guidelines recommend against the routine use of automated mechanical chest compression devices to replace manual chest compressions.[24]

For the critical outcome of survival to 1 year, 1 RCT[25] using the Lund University Cardiac Arrest System (LUCAS) device showed no benefit or harm when compared with manual chest compressions (survival 5.4% vs. 6.2%; RR, 0.87; 95% CI, 0.68–1.11).

For the critical outcome of survival to 180 days, 1 RCT[26] using a LUCAS device enrolling 2,589 OHCA patients showed no benefit or harm when compared with manual chest compressions when quality of chest compressions in the manual arm was not measured (survival 8.5% vs. 8.1%; RR, 1.06; 95% CI, 0.81–1.41).

Drugs During Cardiopulmonary Resuscitation

Epinephrine Versus Vasopressin

A single RCT[27] (n = 336) compared multiple doses of single- dose epinephrine (SDE) with multiple doses of standard-dose vasopressin in the ED after OHCA.

For the critical outcome of survival to discharge with favorable neurologic outcome (cerebral performance category [CPC] 1 or 2), there was no advantage with vasopressin (RR, 0.68; 95% CI, 0.25–1.82; P = 0.44).

For the important outcome of ROSC, there was no observed advantage with

vasopressin (RR, 0.93; 95% CI, 0.66–1.31; *P* = 0.67).

The 2015 guidelines suggest vasopressin should not be used instead of epinephrine in cardiac arrest.[24]

Epinephrine Versus Vasopressin in Combination with Epinephrine

For the critical outcome of survival to hospital discharge with CPC of 1 or 2, 3 RCTs [28–30] (*n* = 2,402) comparing SDE with vasopressin and epinephrine combination therapy showed no superiority with vasopressin and epinephrine combination (RR, 1.32; 95% CI, 0.88–1.98).

For the important outcome of ROSC, 6 RCTs [28–33] showed no ROSC advantage with vasopressin and epinephrine combination therapy (RR, 0.96; 95% CI, 0.89–1.04; *P* = 0.31).

The 2015 guidelines suggest against adding vasopressin to SDE during cardiac arrest.

Single-Dose Epinephrine Versus High-Dose Epinephrine

In adult patients in cardiac arrest in any setting, high-dose epinephrine (HDE) (at least 0.2 mg/kg or 5 mg bolus dose) was compared with SDE (1 mg bolus dose).

For the critical outcome of survival to hospital discharge with CPC 1 or 2, 2 RCTs comparing SDE with HDE [34, 35] (*n* = 1,920) did not show advantage with HDE (RR, 1.2; 95% CI, 0.74–1.96).

For the critical outcome of survival to hospital discharge, 5 RCTs comparing SDE with HDE (*n* = 2,859) did not show any survival to discharge advantage with HDE (RR, 0.97; 95% CI, 0.71–1.32).

The 2015 guidelines recommend against the routine use of HDE in cardiac arrest (weak recommendation, low-quality evidence).

Timing of Administration of Epinephrine

IN-HOSPITAL CARDIAC ARREST

For IHCA, for the critical outcome of survival to hospital discharge, one observational study[36] in 25,095 IHCA patients with a nonshockable rhythm showed an improved outcome with early administration of epinephrine. Compared to the reference interval of 1 to 3 minutes, adjusted OR for survival to discharge was 0.91 (95% CI, 0.82–1.00) when epinephrine was given after 4 to 6 minutes, 0.74 (95% CI, 0.63–0.88) when given after 7 to 9 minutes, and 0.63 (95% CI, 0.52–0.76) when given at more than 9 minutes after onset of arrest.

For IHCA, for the critical outcome of neurologically favorable survival at hospital discharge, an improved outcome was observed from early administration of epinephrine: compared with the reference interval of 1 to 3 minutes, adjusted OR was 0.93 (95% CI, 0.82–1.06) when epinephrine was given after 4 to 7 minutes, 0.77 (95% CI, 0.62–0.95) when given after 7 to 9 minutes, and 0.68 (95% CI, 0.53–0.86) when given at more than 9 minutes after onset of arrest.

For IHCA, for the important outcome of ROSC, an improved outcome from early administration of epinephrine: adjusted OR compared with reference interval of 1 to 3 minutes of 0.90 (95% CI, 0.85–0.94) when given after 4 to 7 minutes, 0.81 (95% CI, 0.74–0.89) when given after 7 to 9 minutes, and 0.70 (95% CI, 0.61–0.75) when given after 9 minutes.

Out-of-Hospital Cardiac Arrest

For the critical outcome of neurologically favorable survival at hospital discharge (assessed with CPC 1 or 2), 4 observational studies [37–40], involving more than 262,556 OHCAs, showed variable benefit from early administration of epinephrine.

For the important outcome of ROSC, there was very-low-quality evidence (downgraded for risk of bias, indirectness, and imprecision) from 4 observational studies, 38,41–43 of more than 210,000 OHCAs, showing an association with improved outcome and early administration of adrenaline. One study[42] showed increased ROSC for patients receiving the first vasopressor dose early (<10 vs. >10 minutes after EMS call): OR, 1.91 (95% CI, 1.01–3.63).

The 2015 guidelines recommendations for cardiac arrest with an initial nonshockable rhythm are that if epinephrine is to be administered, it should be given as soon as possible after the onset of the arrest.

Antiarrhythmic Drugs for Cardiac Arrest

Antiarrhythmic drugs can be used during cardiac arrest for refractory ventricular dysrhythmias. Refractory VF/pVT is defined differently in many trials but generally refers to failure to terminate VF/pVT with 3 stacked shocks, or with the first shock.

For the important outcome of ROSC, 1 RCT, involving 504 OHCA patients, showed higher ROSC with administration of amiodarone (300 mg after 1 mg of adrenaline) compared with no drug (64% vs. 41%; $P = 0.03$; RR, 1.55; 95% CI, 1.31–1.85).[44]

The 2015 guidelines recommendations for antiarrhythmia drugs for cardiac arrest suggest the use of amiodarone in adult patients with refractory VF/pVT to improve rates of ROSC.

The guidelines also suggest the use of lidocaine or nifekalant (a Class III antiarrhythmic drug) as an alternative to amiodarone in adult patients with refractory VF/pVT.

The 2015 guidelines recommend against the routine use of magnesium in adult patients.

CARDIOCEREBRAL RESUSCITATION

Brief History of Therapeutic Hypothermia

The use of therapeutic hypothermia (TH) to mitigate various types of injury, in particular, posthypoxic injury to the brain, has been studied since the late 1930s.[45] Interest was initially kindled by reports of survival after prolonged exposure to cold, or submersion in ice-cold water, indicating a possible protective effect of low temperature on hypoxic injuries.[46]

Use of hypothermia after cardiac arrest was first described in the late 1950s [47, 48], but proof that hypothermia could improve outcome in these patients remained elusive. [49, 50] At the time it was thought that protective effects of TH were purely a result of hypothermia-induced lowering of metabolism; therefore, it was presumed that very low temperatures (25–28°C) were needed to provide significant neuroprotection.

This perception changed in the late 1980s, when animal studies demonstrated that significant protective effects also occurred with mild hypothermia (30–34°C), with far fewer side effects, and that a variety of destructive mechanisms were moderated by hypothermia rather than just reductions in brain metabolism.[49] In the late 1990s, a number of small nonrandomized, clinical trials provided better evidence for the efficacy of TH. [51–54] This led to the initiation of 2 landmark multicenter RCTs to test TH treatment, the results of which were published side by side in 2002. [55, 56] Both reported clear and significant improvements in outcome in cardiac arrest patients treated with therapeutic cooling.

The largest study, performed in 11 centers in Europe, enrolled 275 patients with witnessed cardiac arrest and an initial rhythm of VF or pulseless VT. The authors observed a 15.8% absolute (35.1% relative) improvement in outcome in

the hypothermia group ($P < 0.01$).[55] The other RCT enrolled 77 patients across 4 centers in Australia, reporting an absolute improvement of 22.3% (relative improvement of 43.7%) in patients with witnessed VT/VF treated with hypothermia compared with controls ($P < 0.05$).[56] A meta-analysis calculated that 1 additional case of good neurologic outcome would be gained for every 6 patients treated with TH.[57] Guidelines from various medical societies such as the AHA, European Resuscitation Council (ERC), and Neurocritical Care Society (NCS) began recommending cooling after cardiac arrest. [58, 59]

A larger RCT, the Therapeutic Temperature Management (TTM) study, compared temperature management at 33.0°C to maintaining a core temperature of 36.0°C.[60] The study enrolled 939 patients with witnessed cardiac arrest regardless of initial rhythm, including those with persistent hypoxia and hypotension who had been excluded from previous studies, with predefined subgroup analyses to correct for various risk factors. The results of this study were negative.[60] Rates of survival with good neurologic outcome were 46.5% in the 33°C group versus 47.8% in the 36°C group ($P = 0.78$). The rate of survival with excellent outcome (no neurologic residual) was 41.6% versus 39.4%, whereas survival with mild neurologic impairment was 4.9% versus 8.4%.[60] The authors concluded that maintaining core temperature at 36°C has equally good outcomes as cooling to 33°C.

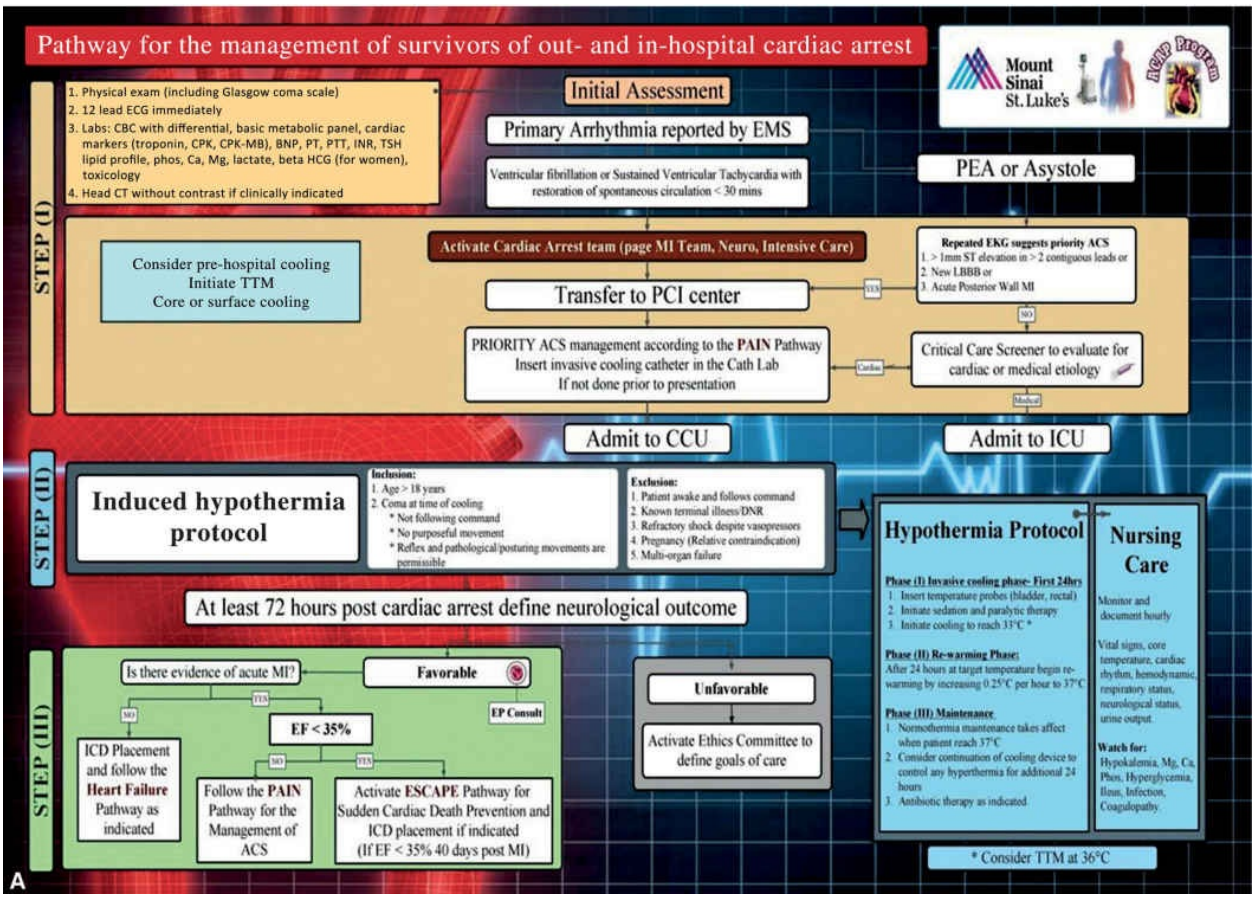
Pathways for the Management of Survivors of Out of and In-Hospital Cardiac Arrest

At our institution, similar to many tertiary medical centers, algorithms for the management of patients post–cardiac arrest have been developed.

Our first algorithm was published in 2010.[61] We continue to update it, as new scientific information and updated guidelines are published.[62]

The term therapeutic hypothermia has now been replaced with targeted temperature management(TTM).

Our 2015 updated TTM pathway is shown in **Figure 29.3A**.



Pathway for the management of survivors of out- and in-hospital cardiac arrest
Mount Sinai St. Luke's
ACHP Program
STEP (I)
1. Physical exam (including Glasgow coma scale)
2. 12 lead ECG immediately
3. Labs: CBC with differential, basic metabolic panel, cardiac markers (troponin, CPK, CPK-MB), BNP, PT, PTT, INR, TSH lipid profile, phos, Ca, Mg, lactate, beta HCG (for women), toxicology
4. Head CT without contrast if clinically indicated
Initial Assessment
Primary Arrhythmia reported by EMS
Ventricular fibrillation or Sustained Ventricular Tachycardia with restoration of spontaneous circulation < 30 mins
PEA or Asystole
Consider pre-hospital cooling
Initiate TTM
Core or surface cooling
Activate Cardiac Arrest team (page MI Team, Neuro, Intensive Care)
Repeated EKG suggests priority ACS
1. > 1mm ST elevation in > 2 contiguous leads or
2. New LBBB or
3. Acute Posterior Wall MI
YES
NO
Transfer to PCI center
PRIORITY ACS management according to the PAIN Pathway
Insert invasive cooling catheter in the Cath Lab
If not done prior to presentation
Cardiac
Critical Care Screener to evaluate for cardiac or medical etiology
Medical
Admit to CCU
Admit to ICU
STEP (II)
Induced hypothermia protocol
Inclusion:
1. Age > 18 years
2. Coma at time of cooling
* Not following command
* No purposeful movement
* Reflex and pathological/posturing movements are permissible
Exclusion:
1. Patient awake and follows command
2. Known terminal illness/DNR
3. Refractory shock despite vasopressors
4. Pregnancy (Relative contraindication)
5. Multi-organ failure
Hypothermia Protocol
Phase (I) Invasive cooling phase- First 24hrs
1. Insert temperature probes (bladder, rectal)
2. Initiate sedation and paralytic therapy
3. Initiate cooling to reach 33°C *
Phase (II) Re-warming Phase:
After 24 hours at target temperature begin re-warming by increasing 0.25°C per hour to 37°C
Phase (III) Maintenance
1. Normothermia maintenance takes affect when patient reach 37°C
2. Consider continuation of cooling device to control any hyperthermia for additional 24 hours
3. Antibiotic therapy as indicated
Nursing Care
Monitor and document hourly
Vital signs, core temperature, cardiac rhythm, hemodynamic, respiratory status, neurological status, urine output
Watch for:
Hypokalemia, Mg, Ca, Phos, Hyperglycemia, Ileus, Infection, Coagulopathy.
* Consider TTM at 36°C
At least 72 hours post cardiac arrest define neurological outcome
STEP (III)
Is there evidence of acute MI?
Favorable
EP Consult
NO
YES
EF < 35%
ICD Placement and follow the Heart Failure Pathway as indicated
Follow the PAIN Pathway for the Management of ACS
Activate ESCAPE Pathway for Sudden Cardiac Death Prevention and ICD placement if indicated (If EF < 35% 40 days post MI)
Unfavorable
Activate Ethics Committee to define goals of care
A

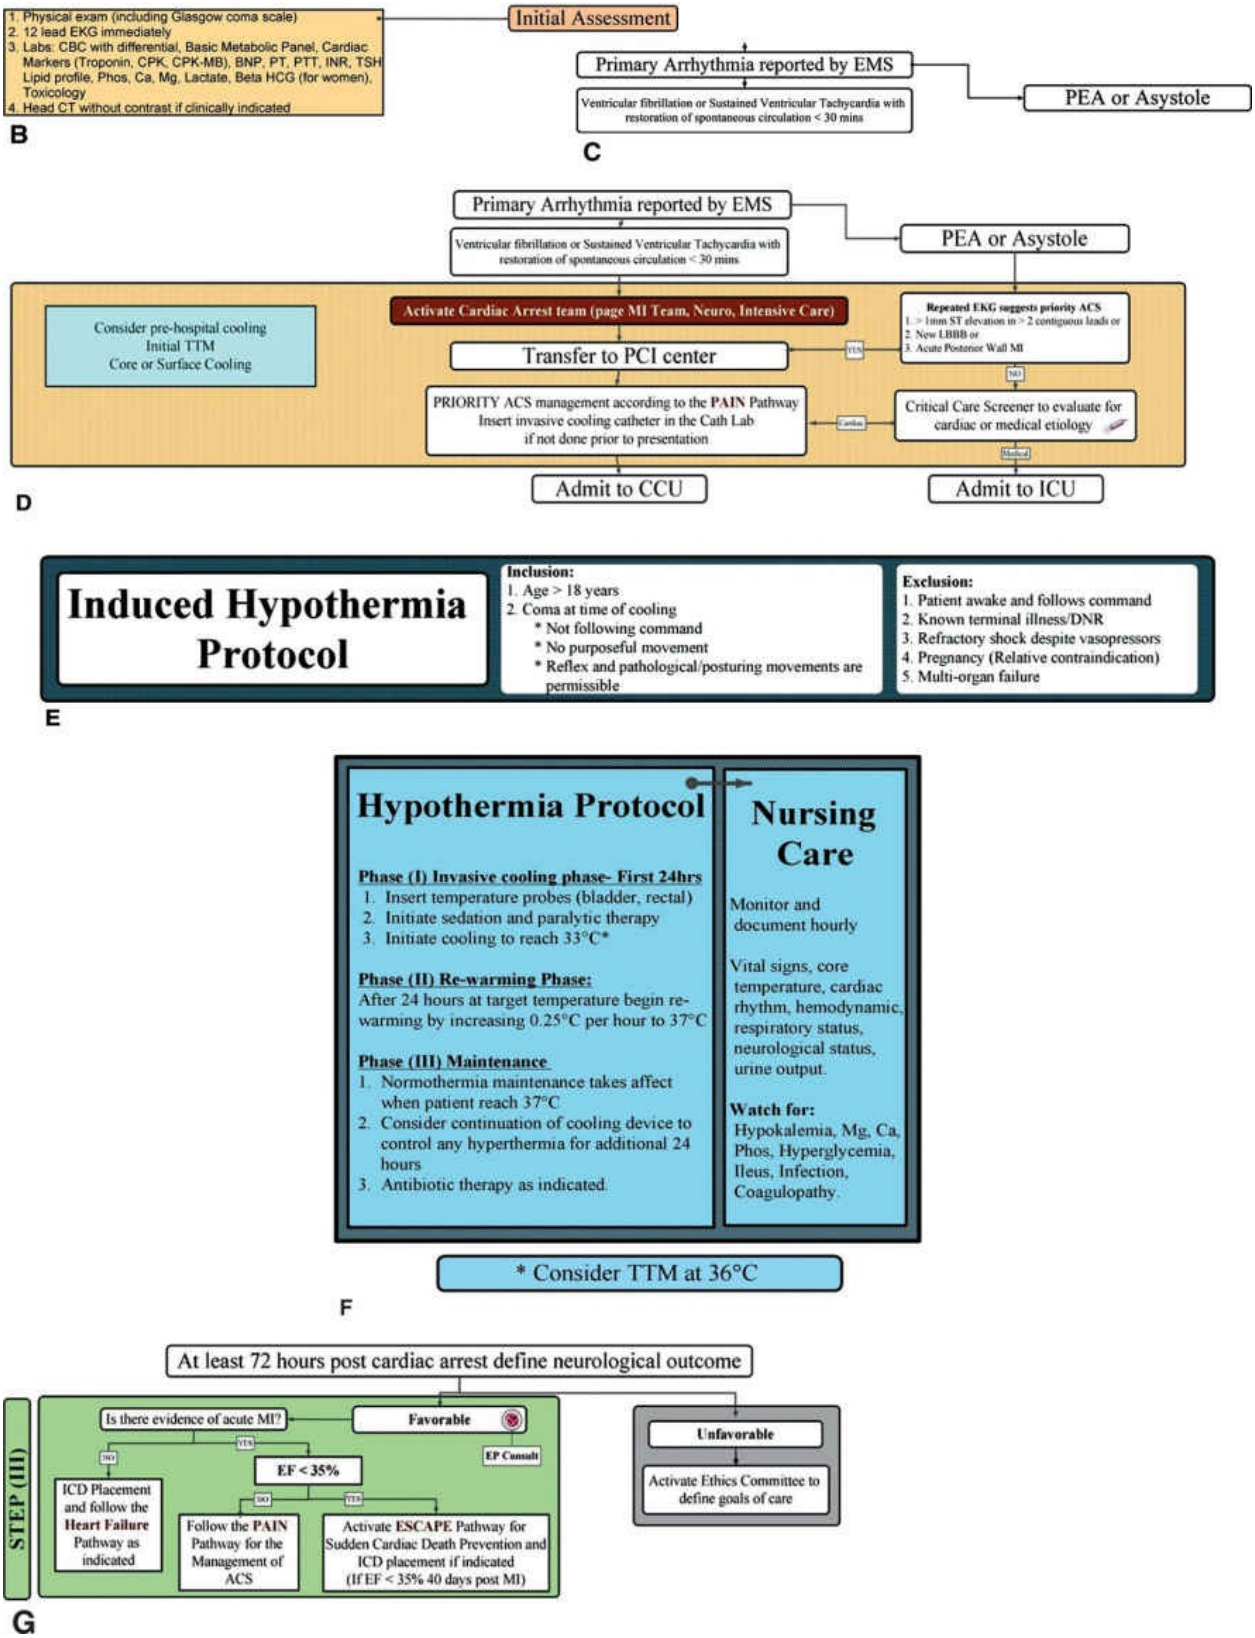


FIGURE 29.3 A, Pathway for management of survivors of out-of- and in-hospital cardiac arrest. B, Initial

assessment of patients who survive an out-of-hospital cardiac arrest. C, Identification of the primary arrhythmia that led to the cardiac arrest. D, Activation of the cardiac arrest team, transfer to percutaneous coronary intervention (PCI) center, and transfer to the critical care unit. E, Inclusion and exclusion criteria for patients who are candidates for the therapeutic hypothermia protocol. F, Induced therapeutic hypothermia protocol. G, Management of the post–rewarming phase including the recommendation for out-of-hospital therapy and the ethical decision to define goal of care.

The pathway is divided into three steps.

- Step I. From the field through the ED into the cardiac catheterization laboratory and to the critical care unit.
- Step II. Induced hypothermia protocol in the critical care unit.
- Step III. The management following the rewarming phase, including the recommendation for out-of-hospital therapy and the ethical decision to define goals of care.

STEP I

Presentation to the emergency department, proceeding to the cardiac catheterization laboratory and to the critical care unit.Upon arrival of a survivor of OHCA at the ED, the initial assessment (**Fig. 29.3B**) includes vital signs, physical examination, and neurologic examination with Glasgow coma score. Immediate 12-lead ECG is obtained and laboratory testing performed.

Initial laboratory testing includes complete blood count (CBC) with differential, basic metabolic panel, cardiac marker (troponin, CPK, CPK-MB), B-type natriuretic peptide (BNP), prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), lipid profile, phosphorus, calcium, magnesium, lactate, ß-HCG (for women), TSH, and toxicology screening. We recommend a head CT without contrast only if it is clinically indicated and will not delay transfer to the cardiac catheterization laboratory.

The patient is stabilized in the ED, where antiarrhythmic and vasopressor therapy may be administered, in addition to ventilator support.

The ED physician receives the emergency medical services (EMS) report of the primary rhythm and duration of cardiopulmonary resuscitation (CPR). This reported arrhythmia is the key decision point in our pathway.

The prognostically important distinction is between patients with documented VF or sustained VT who had a restoration of spontaneous circulation (ROSC) in <30 minutes and patients with reported asystole or pulseless electrical activity (PEA) (**Figure 29.3C**).

1. If the initial rhythm was VF or VT with an ROSC of ≤30 minutes, the cardiac arrest team is activated, and the patient will proceed to the cardiac catheterization laboratory (**Figure 29.3D**).
2. If the initial reported arrhythmia was PEA or asystole, the next step will depend on the ECG performed in the ED. If the ECG performed in the ED is suggestive of priority acute coronary syndrome (ACS), including ST elevation myocardial infarction (STEMI), left bundle branch block, or acute posterior wall MI, the MI team should be activated, and the care is similar to those patients with reported VF or VT arrest.
3. If priority ECG findings are not seen but the etiology of the arrest is most likely due to primary cardiac disease, the cardiology fellow will admit the patient to the cardiac care unit. We recommend an emergency echocardiogram.
4. If the etiology is likely noncardiac, the patient will be admitted to the medical ICU.

The cardiac arrest team includes the following 10 people.

The traditional (acute coronary syndrome) ACS-MI team comprises the following members:

1. Interventional cardiologist on-call team leader
2. Coronary care unit (CCU) director
3. Cardiology fellow on-call
4. Interventional cardiology fellow on-call
5. Cath lab nurse on-call
6. Cath lab technician on-call
7. CCU nurse manager on-call

In addition, the following personnel form the team:

8. The neurologist on-call
9. The critical care attending on-call
10. The medical resident screener

The MI team is activated by a single page to the central call center by the ED physician.

STEPS IN THE EMERGENCY DEPARTMENT

1. Decision to initiate induced hypothermia is made jointly by the ED physician and the cardiology or critical care physician. It is very important to review the hospital center's inclusion and exclusion criteria and decide whether the patient is a candidate for the TH protocol (**Figure 29.3E**).
2. The physician places an order to initiate hypothermia protocol.

Our goal is to transfer the patient to the percutaneous coronary intervention (PCI) center as soon as possible with a target door-to-balloon time of <90 minutes.

The management of the patient at this point is according to our Priority risk, Advanced risk, Intermediate risk, and Negative/low risk (PAIN) pathway following the priority ACS algorithm.[63]

Following cardiac catheterization, several steps occur while the patient is still in the catheterization laboratory:

1. The femoral arterial sheath can be maintained as an arterial catheter, which may be necessary to obtain blood pressure readings and arterial blood gas analyses.
2. The intravascular hypothermia catheter is inserted under strict aseptic technique (if it was not done earlier).

All patients are then transferred from the catheterization laboratory to the CCU where invasive hypothermia is initiated.

STEP II

Induced TH protocol in the critical care unit. The clinicians review the case and confirm the appropriateness of induced hypothermia (**Figure 29.3E**).

In summary, we recommend induced hypothermia for patients >18 years of age, who sustained a cardiac arrest and remain in coma. The patient must be comatose, not following commands or demonstrating purposeful movements. Patients excluded from the hypothermia protocol include patients who are awake, suffered prolonged ischemic times, experience refractory shock, demonstrate multiorgan failure, or have severe underlying illnesses, including terminal illnesses and do-not-resuscitate (DNR) status.

The hypothermia protocol is divided into three phases, as seen in **Figure 29.3F**:

Phase 1: Cooling phase for the first 24 hours

Phase 2: Rewarming phase

Phase 3: Maintenance phase

Phase 1: Cooling phase for the first 24 hours. We recommend 24 hours of the cooling therapy at a temperature goal of 33°C.

As will be discussed later in this chapter, the dose of the temperature management is controversial, and some centers cool patients to 36°C.

Endovascular catheters are an effective method of inducing TH (if a core cooling method is chosen). The catheters are usually inserted into the inferior vena cava through the femoral vein.

Continuous core temperature monitoring is required and generally accomplished using a temperature probe in the bladder (urinary catheter) or the rectum.

Monitoring of clinical condition and potential complications during the cooling phase.

As there are many physiologic effects of hypothermia, we recommend continuous monitoring and hourly documentation of vital signs; core temperature; cardiac rhythm; hemodynamic, respiratory, neurology status; and urine output. Common hemodynamic changes observed with cooling include hypertension, decreased cardiac output, and increased systemic vascular resistance. The hypertension and the increased systemic vascular resistance are believed to result from the cold-induced vasoconstriction.

Serum electrolyte imbalance is common during the cooling phase and results from the cooling-induced intracellular shifts of potassium, magnesium, calcium, and phosphate, leading to low levels of all these electrolytes. During the rewarming phase, these electrolytes shift back to the extracellular space.

Our protocol therefore recommends measurements of the basic metabolic panel every 4 hours for a total of 48 hours, measuring electrolytes (calcium, magnesium, and phosphate) PT, PTT, and INR, and a CBC every 12 hours up to 48 hours.

Additional possible side effects of cooling to be monitored include the following:

1. *Coagulopathy.* Coagulopathy is generally not significant with careful temperature monitoring and avoiding temperature of <33°C. If active bleeding occurs during the cooling phase, evaluation of coagulation factors and platelets should be performed and deficiencies corrected.
2. *Hyperglycemia. Hypothermia suppresses insulin release and causes insulin*

resistance. Our insulin infusion protocol for the management of hyperglycemia in critical care unit is used.[64]

3. *Infection.* Infection is usually multifactorial, including emergency intubation and intravenous catheter insertion and aspiration pneumonia at the time of arrest.

Furthermore, the hypothermia itself can suppress white blood cell production and impairs neutrophil and macrophage function. All measures to reduce ventilator-associated pneumonia are employed, including elevating the head of the bed.

4. *Shivering.* Our protocol aims to prevent shivering by administration of sedation and neuromuscular blocking agents on induction of hypothermia.

Phase 2: Rewarming phase. After 24 hours of the target temperature, the rewarming phase starts.

Controlled rewarming is a very important phase of this protocol.

Rewarming should be slow; at a rate of 0.25°C per hour, which we recommend, it typically requires 16 hours to rewarm to 37°C.

Potential complications during the rewarming phase include the following:

1. Hypotension—owing to peripheral vasodilation during the rewarming phase.
2. Electrolyte imbalance—increased levels of potassium, magnesium, calcium, and phosphate caused by intracellular shifting of these ions back to the serum during the rewarming phase.

Phase 3: Maintenance of normothermia phase. The maintenance phase is the last phase of the TH protocol.

Normothermia maintenance takes effect when the patient's temperature reaches 37°C.

We recommend continuation of the cooling device to maintain a temperature of 37°C and avoidance of fever that can potentially worsen a cerebral injury.

The duration of the additional maintenance phase is usually between 24 and 48 hours.

STEP III

The management following hypothermia and rewarming depends on the neurologic prognosis (**Figure 29.3G**).

At least 72 hours after cardiac arrest, the neurologic examination is performed by the neurology team. The neurologic examination may be affected by the

hypothermia protocol, including requirements for sedation and therapeutic paralysis, so the formulation of a neurologic prognosis may be delayed. In general, we defer neurologic prognostication until 6 days postarrest in patients undergoing hypothermia protocol.

Pathways for the patients will divide depending on whether the patient has a favorable neurologic prognosis or an unfavorable neurologic prognosis. An unfavorable neurologic prognosis would be defined as expectation of a persistent coma or vegetative state, or severe disability.

If the prognosis appears unfavorable, we recommend activating the ethics committee to meet with the family and clinicians to define the goals of care. From our experience, in most instances, life support is limited or withdrawn in such patients.

If the neurologic prognosis appears favorable, then the key question regarding further therapy is based on whether the cardiac arrest was because of MI.

If there is no evidence of acute MI (negative cardiac markers), then we recommend electrophysiology service consultation for consideration of implantable cardioverter defibrillator (ICD) placement and treatment of heart failure based on our heart failure pathway.[65]

If acute MI is confirmed by positive cardiac markers, we advise care based on the LV ejection fraction (LVEF) as it is defined by echocardiography or other imaging modalities. If LVEF ≤35%, we recommend activation of the ESCAPE pathway for sudden cardiac death prevention[66] and to consider ICD placement if EF ≤35% at 40 days post-MI. Also, we recommend managing heart failure according to our heart failure pathway.[65]

If EF >35%, we recommend following our PAIN pathway for the management of ACS,[63] including the following:

- Lifestyle modification
- Cardiac rehabilitation
- Secondary prevention medication (dual oral antiplatelet, ß-blocker, high-dose statin, ACE inhibitor/ARB)

Unresolved Practical Questions Regarding TTM

How Low Should We Go?

As mentioned earlier, the TTM study compared temperature management at 33°C to maintaining a core temperature of 36°C[60] and concluded that

maintaining core temperature at 36°C has outcomes that are as good as cooling to 33°C.

This observation seems to contradict the findings of all previous studies and may have been a result of selection bias.

Our group hypothesizes that a potential difference in outcome based on degree of cooling will depend on the severity of brain injury.

Our group opinion regarding this difference in outcome depending on the selection of patients for TTM appears in **Figure 29.4**.

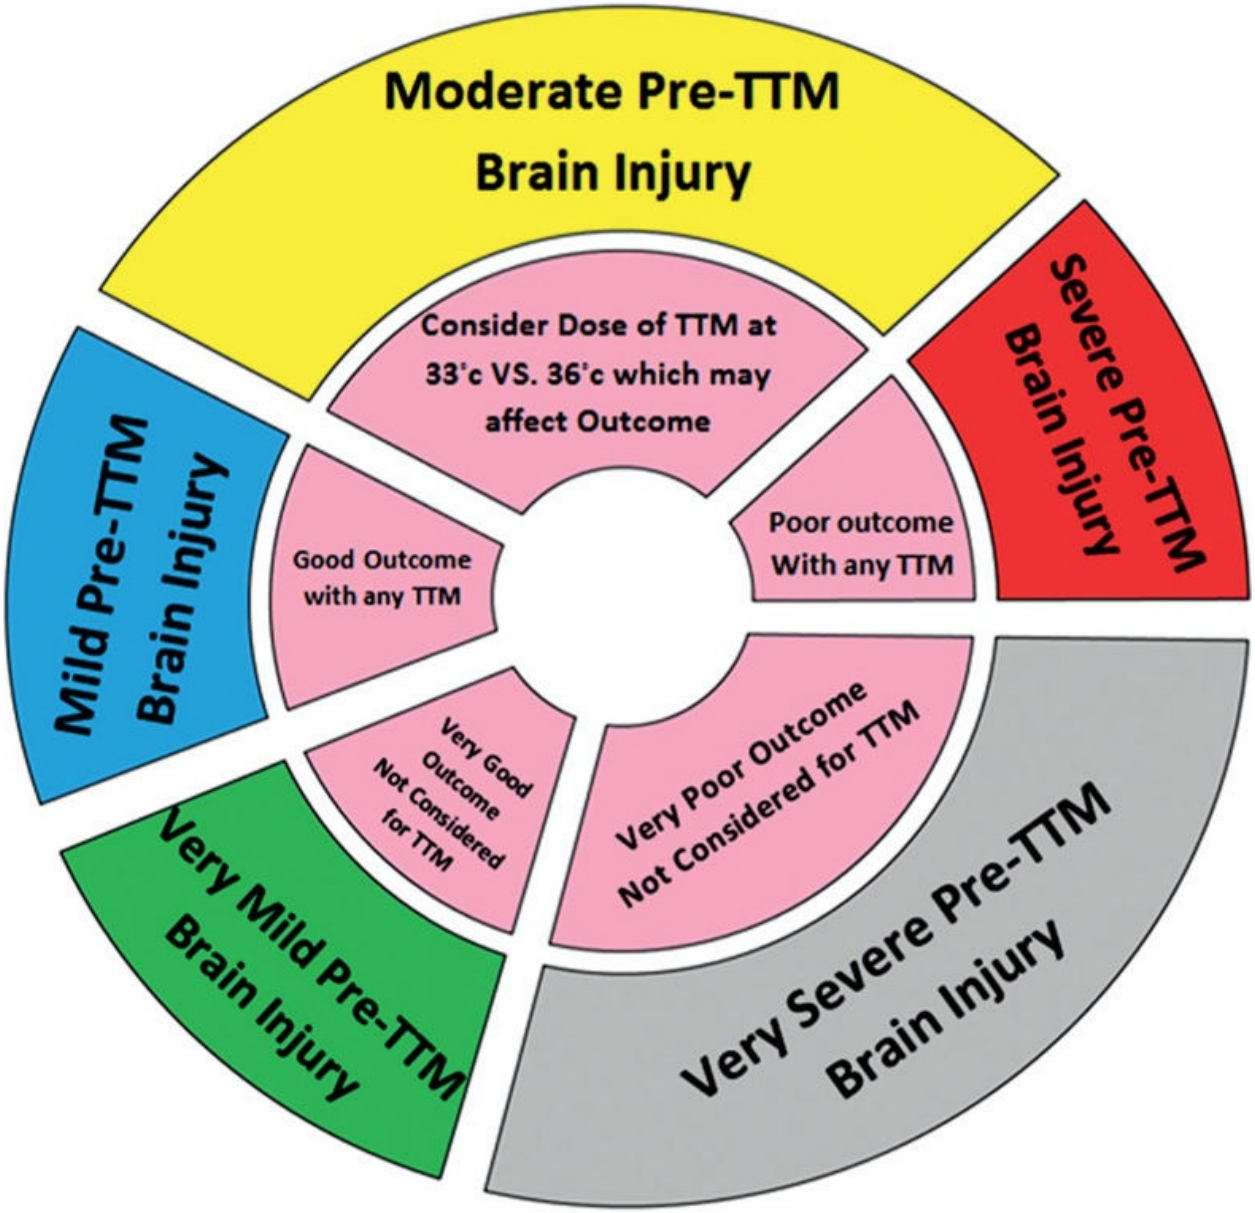

FIGURE 29.4 Degree of postarrest brain injury and proposed decision for Therapeutic Temperature

Management (TTM).

As seen in this figure, we can divide patients who survive cardiac arrest into 5 groups based on the degree of their postarrest brain injury.

1. Very severe brain injury
2. Severe brain injury
3. Moderate brain injury
4. Mild brain injury
5. Very minimal brain injury

Patients who fall into the first or the last category are unlikely to be considered for TTM in any health care system (as seen in the lower half of the figure).

- Patients who fall into groups 2, 3, and 4 are expected to have variable outcome.
- Patients in group 2, with severe brain injury, are expected to have poor outcome with any TTM.
- Patients in group 4 with mild brain injury are expected to have a good outcome with any TTM.

However, for patients in group 3, with moderate brain injury, the dose of TTM may affect outcome.

Our hypothesis is derived by applying Baye's theorem to the relationship between post-TTM degree of brain injury and pre-TTM degree of brain injury.

Our hypothesis is seen in **Figure 29.5**.

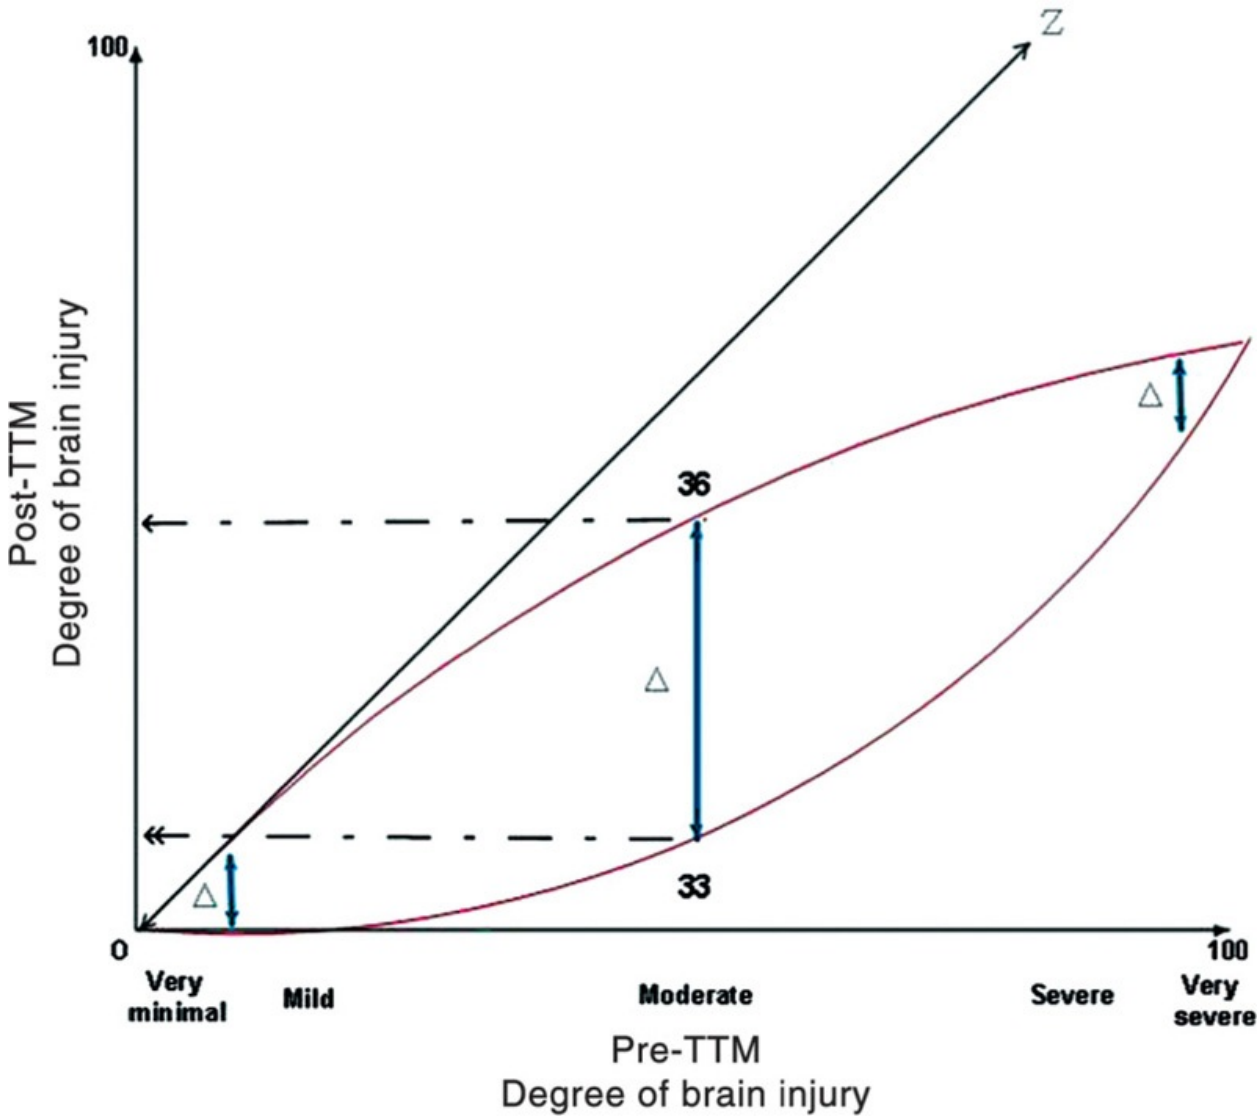

FIGURE 29.5 Applying Bayes' theorem to the relationship between post-TTM degree of brain injury and pre-TTM degree of brain injury. TTM, therapeutic temperature management.

In this figure, we have plotted the pre-TTM degree of brain injury on the x-axis, with score of 0 to 100 and the **post-TTM** degree of brain injury on the y-axis with score of 0 to 100, where a score of 0 mean no brain injury, and a score of 100 means irreversible brain injury.

As outlined earlier, we have five groups of patients based on their severity of brain injury:

- Very minimal, mild, moderate, severe, and very severe.
- The equivocal line (Z) represents where the pretreatment group brain injury is exactly the same as the posttreatment group brain injury.

- The other two lines represent the different temperature doses of 33°C and 36°C.
- It is the delta (Δ) between these lines that defines whether the therapy has potential benefits.

On the left end of this figure, the delta is very small for patients with very minimal or mild brain injury.

This is the same case for patients with severe or very severe brain injury where the delta between the two doses of therapy is very small.

However, for patients with moderate brain injury, the delta is quite large. In our hypothesized algorithm, there is a potential to reduce the post-TTM degree of brain injury from a high to a low score.

On the basis of this hypothesis, our group suggests that the dose of temperature management should be 33°C because it is difficult prognostically to determine moderate brain injury level.

We have to remember that this is only a hypothesis and larger studies enrolling solely patients with moderate brain injury should be conducted.

Our group believes that the Achilles heel of the field of TTM is our current limitations in the prognostication of postarrest brain injury.

Endovascular Versus Surface Cooling

Technologies can be broadly divided into invasive (core cooling) and noninvasive (surface cooling) methods.[67]

There is no evidence for a difference in outcome based on cooling method.

The advantages of invasive cooling over surface cooling are:

1. Greater speed of hypothermia/normothermia induction when core cooling is used; however, it is unclear whether more rapid induction improves outcome.
2. Fewer and smaller temperature fluctuations in the maintenance phase.
3. Continuous central temperature measurement in some types of endovascular catheter is possible.
4. No risk of surface cooling–induced skin lesions.
5. Ease of accessibility to patient, that is, no need to cover large areas of the skin to achieve cooling.
6. Less medication may be needed to control shivering because there is more effective shivering suppression with skin counterwarming (ie, the entire surface area can be warmed using warm air, leading to a significantly

diminished shivering response). [49,68,69]

The advantages of surface cooling over invasive cooling are as follows:

1. Ease of use; can be applied by nurses without the need for a physician to be present.
2. No invasive procedure required; therefore, no risk of mechanical complications.
3. Can be started immediately, without waiting for catheter insertion procedure, so potentially less delay in initiation of cooling.
4. No risk of catheter-induced thrombus formation.
5. Can be more easily applied outside the ICU setting.

A study by Deye and coworkers compared endovascular to surface cooling in a prospective, multicenter RCT.[70] The authors enrolled 400 patients; 203 were treated with endovascular cooling (using Zoll femoral Icy catheters) and 197 with external cooling (ice packs, fans, and a homemade tent). The main findings were as follows: significantly shorter time to target temperature (33°C), greater stability of temperature (defined as time within target ±1°C) in the maintenance phase, and reduced nursing workload (10 vs. 38 minutes, $P < 0.001$) in the endovascular group; more minor side effects in the endovascular group ($P = 0.009$); a nonsignificant trend toward more favorable outcome at 28 days (36.0% vs. 28.4%, OR 1.41 [0.93–2.16], $P = 0.107$; for shockable rhythm 53.7% vs. 37.1%, OR 1.97 [0.99–3.9], $P = 0.269$) and at 90 days (34.6% vs. 26.0%, OR 1.51 [0.96–2.35], $p = 0.07$) in the endovascular group; and fewer cases of severe overshoot (below 30°C) in the endovascular group ($n = 0$ vs. $n = 3$).[70] Strict fever control was maintained for a minimum of 3 days following rewarming in both groups.

This study had some limitations, especially the fact that newer and more powerful surface cooling devices such as the Arctic Sun system were not used and surface cooling was accomplished using fairly basic tools and devices.

We believe that the cooling method should be determined by institutional protocol.

Highlights from the 2015 Guidelines Recommendation for Post–Cardiac Arrest Care

Out-of-Hospital Cooling

Based on the 2015 guidelines: The routine prehospital cooling of patients with rapid infusion of cold IV fluids after ROSC is not recommended.[24]

Hemodynamic Goals After Resuscitation

It may be reasonable to avoid and immediately correct hypotension (systolic blood pressure < 90 mm Hg, mean arterial pressure < 65 mm Hg) during post–cardiac arrest care.[24]

Why: Studies of patients after cardiac arrest have found that a systolic blood pressure of < 90 mm Hg or a mean arterial pressure of < 65 mm Hg is associated with higher mortality and diminished functional recovery, whereas systolic arterial pressures of > 100 mm Hg are associated with better recovery. Although higher pressures appear superior, specific systolic or mean arterial pressure targets could not be identified because trials typically studied a bundle of many interventions, including hemodynamic control. Also, because baseline blood pressure varies from patient to patient, different patients may have different requirements to maintain optimal organ perfusion.

Early Coronary Angiography

Based on the 2015 guidelines: Coronary angiography should be performed emergently (rather than later in the hospital stay or not at all) for OHCA patients with suspected cardiac etiology of arrest and ST elevation on ECG. Emergency coronary angiography is reasonable for select (eg, electrically or hemodynamically unstable) adult patients who are comatose after OHCA of suspected cardiac origin but without ST elevation on ECG. Coronary angiography is reasonable in post–cardiac arrest patients for whom coronary angiography is indicated, regardless of whether the patient is comatose or awake.[24]

Targeted Temperature Management

All comatose (ie, lacking meaningful response to verbal commands) adult patients with ROSC after cardiac arrest should have TTM, with a target temperature between 32°C and 36°C selected and achieved, then maintained constantly for at least 24 hours.[24]

Continuing Temperature Management Beyond 24 Hours

Actively preventing fever in comatose patients after TTM is reasonable. In

observational studies, fever after rewarming from TTM is associated with worsened neurologic injury, although studies are conflicting. Because preventing fever after TTM is relatively benign and fever may be associated with harm, preventing fever is suggested.[24]

Prognostication After Cardiac Arrest

The earliest time to prognosticate a poor neurologic outcome using clinical examination in patients not treated with TTM is 72 hours after cardiac arrest, but this time can be even longer after cardiac arrest if the residual effect of sedation or paralysis is suspected to confound the clinical examination.[24]

Why: Clinical findings, electrophysiologic modalities, imaging modalities, and blood markers are all useful for predicting neurologic outcome in comatose patients, but each finding, test, and marker is affected differently by sedation and neuromuscular blockade. In addition, the comatose brain may be more sensitive to medications, and medications may take longer to metabolize after cardiac arrest. No single physical finding or test can predict neurologic recovery after cardiac arrest with 100% certainty. Multiple modalities of testing and examination used together to predict outcome after the effects of hypothermia and medications have been allowed to resolve are most likely to provide accurate prediction of outcome.

Organ Donation

All patients who are resuscitated from cardiac arrest but who subsequently progress to death or brain death should be evaluated as potential organ donors. Patients who do not achieve ROSC and who would otherwise have resuscitation terminated may be considered potential kidney or liver donors in settings where rapid organ recovery programs exist.[24]

Why: No difference has been reported in immediate or long-term function of organs from donors who reach brain death after cardiac arrest when compared with donors who reach brain death from other causes. Organs transplanted from these donors have success rates comparable to organs recovered from similar donors with other conditions.

Principles of Antiarrhythmic Drug Therapy

INTRODUCTION

Ion channels in cardiac cells that generate the action potential are the basis for most arrhythmias. Thus, it is critical to know their function in order to understand the mechanisms of most arrhythmias and their treatment.[1]

The action potential is a representation of the changes in voltage of a single cardiac cell plotted over time.

There are five phases of the normal action potential ***(Figure 30.1)***[2]*:*

1. **Phase (4):** is the resting potential, which is stable at –90 mV in working myocardial cells. It is principally permeable to potassium ions.
2. **Phase (0):** is the rapid depolarization where there is a rapid increase in sodium permeability that forces the membrane potential into the positive range.
3. **Phase (1):** is the initial repolarization phase of the action potential, which is the result of a rapid decline in the sodium permeability and increase in potassium and chloride ions permeability.
4. **Phase (2):** is the plateau phase of the action potential, which is the result of a

balance of residual inward sodium and calcium currents and outward components of current carried by potassium ions.

5. **Phase (3):** is the phase of rapid repolarization, which is the result of a sustained increase in potassium permeability.

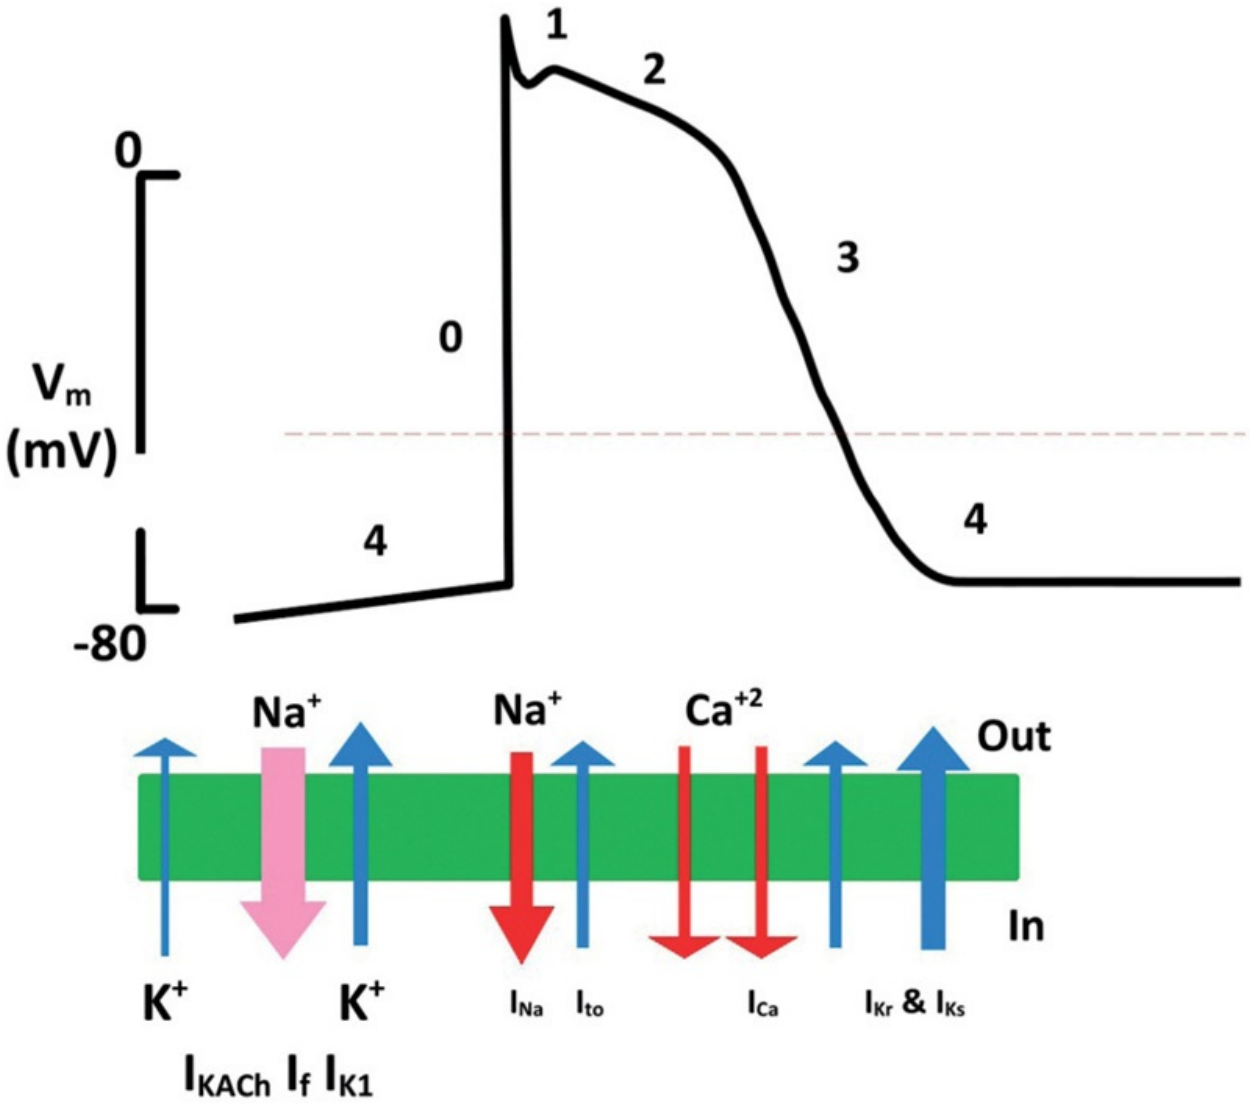

FIGURE 30.1 Action potential of cardiac cell depicting phases and ion movement across cell membrane. Downward arrows mark inward current; upward arrows mark outward current.

The pacemaker cells in the sinoatrial (SA) and atrioventricular (AV) nodes have significantly different action potential from the myocardial cells (**Figure 30.2**). Typically, phase (4) is resting at –50 mV and undergoes a slow depolarization that merges into phase (0). This is the effect of hyperpolarization-

activated current, I_F. Depolarization is much slower as a result of calcium ion carriers.

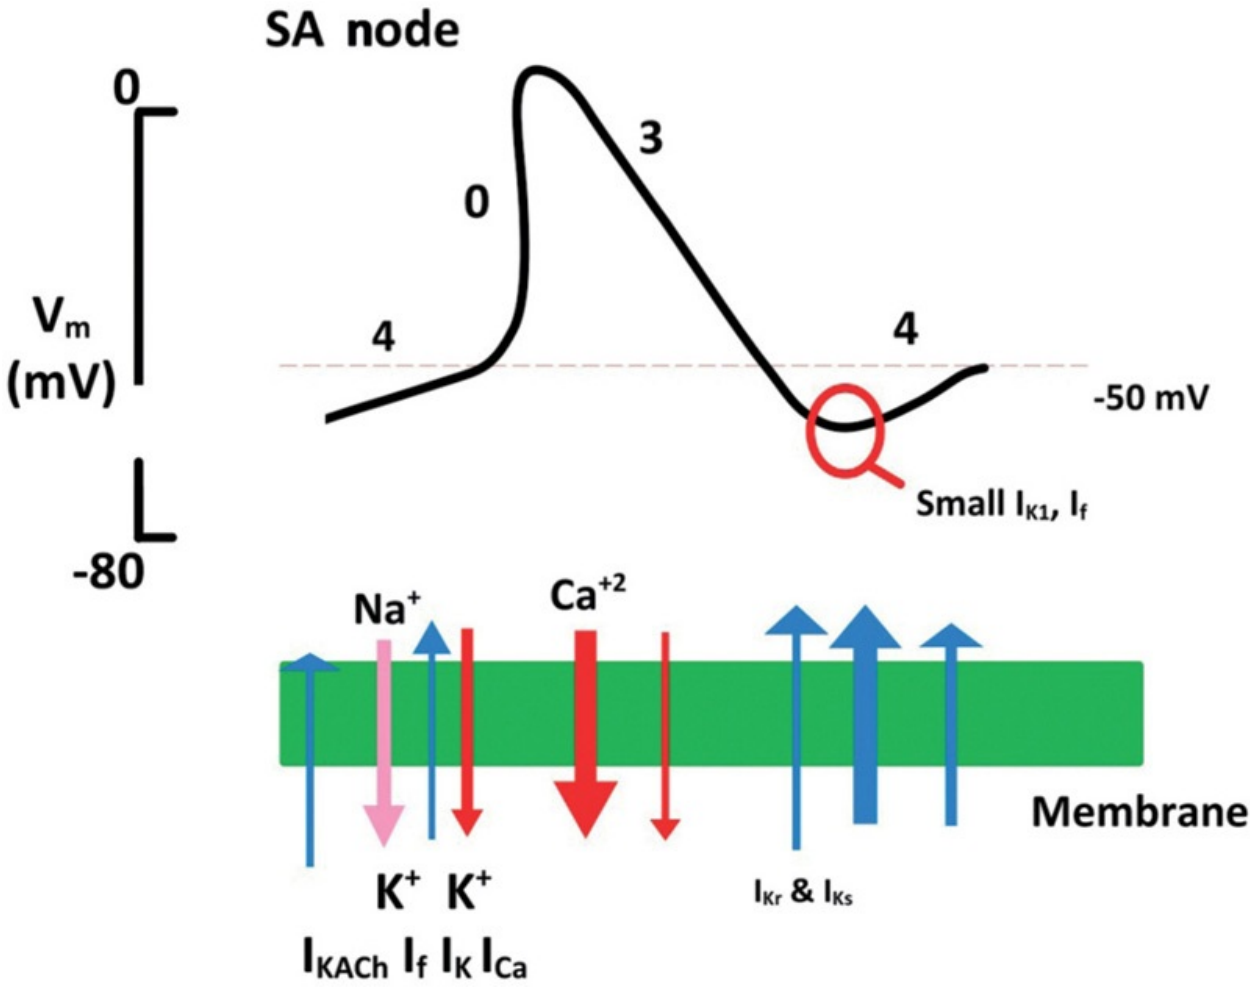

FIGURE 30.2 Action potential of cardiac pacemaker cells (SAN) depicting phases and ions movement across cell membrane. Downward arrows mark inward current; upward arrows mark outward current.

The sciences of ion channels are well correlated with the shape of the action potential, and this correlation is depicted in **Table 30.1**.

TABLE 30.1 Membrane Currents Controlling the Action Potential

Spontaneous depolarization of the SA node activates the neighboring atrial myocardium through electrotonic interactions. Elevation of the atrial membrane potential from its resting level to more positive values activates voltage-dependent Na^+ channels, giving rise to the peak Na^+ current (I_{Na}), which further depolarizes the membrane potential and produces the upstroke of the atrial action potential (AP). Subsequent activation of L-type Ca^{2+} channels produces a small influx of Ca^{2+} into the cell ($I_{Ca,\ L}$), which triggers a much larger Ca^{2+} release from the intracellular stores of the sarcoplasmic reticulum (SR) through the cardiac ryanodine receptor channels (RyR2), a process termed Ca^{2+}-induced Ca^{2+} release.[3] The Ca^{2+} released into the cytosol (Ca^{2+} transient) binds to the contractile machinery and initiates contraction, thereby linking electrical excitation and mechanical contraction (excitation–contraction coupling). The Ca^{2+} transient also feeds back to the L-type Ca^{2+} channels, causing Ca^{2+}-dependent inactivation to prevent excessive Ca^{2+} influx.[4] Relaxation of the atrial myocytes occurs as Ca^{2+} is extruded from the cell via both the electrogenic Na^+–Ca^{2+} exchanger (NCX1; giving rise to I_{NCX}) and plasmalemmal Ca^{2+}-ATPase, and is resequestered into the SR via the SR Ca^{2+}-ATPase (SERCA2a). The latter is controlled by the inhibitory proteins phospholamban (PLN) and sarcolipin.[5] The depolarizing Na^+ and Ca^{2+} currents are countered by repolarizing currents, predominantly carrying K^+ ions. The transient outward K^+ current (I_{to}) produces a rapid repolarization immediately following the AP upstroke. A concerted effort of delayed rectifier K^+ currents with slow, rapid, and ultrarapid kinetics (I_{Ks}, I_{Kr},

and I_{Kur}, respectively) and the Na^+–K^+ ATPase current (I_{NaK}) control AP duration (APD).

There is a change in the APD across the myocardium from endocardium to epicardium, with the action potential being the longest in the midmyocardial areas.[6] This dispersion can also be responsible for certain reentrant arrhythmias.

The average duration of the ventricular action potential is reflected in the QT interval on the surface electrocardiogram (ECG). It is this relationship that identifies the factors that produce QT-interval prolongation and the arrhythmias that are related to it, such as *torsade de pointes*.

Action potentials may be initiated within cells or groups of cells that have the property of automaticity. Diastolic depolarization during phase (4) of the AP is the basis of the automaticity in the SA and AV nodes. Abnormal automaticity may take other forms, such as early afterdepolarizations (EADs) and delayed afterdepolarizations (DADs), which are examples of triggered activity because they are dependent on the preceding action potential.[7] Action potential prolongation is essential for EADs, with a net membrane current shift from outward to inward that, in consequence, produces oscillations of the membrane potential that may reach threshold; an example of this is torsade de pointes in long QT.[8] EADs can be abolished by interventions that return the APD toward normal or block the sodium current (I_{Na}) and calcium current (I_{Ca}). This can be achieved by increasing the heart rate with pacing or isoproterenol infusion; or by blocking the I_{Na} and I_{Ca} with class IC and class IV antiarrythmics, respectively.

On the other hand, DADs are characteristics of conditions that lead to Ca^{2+} overload. Ca^{2+} antagonists can block these. An example of DAD-mediated arrhythmias are the tachyarrhythmias that occur with digitalis toxicity. Characteristics of the modulation of EADs and DADs are depicted in (**Figure 30.3**).

FIGURE 30.3 A, Early afterdepolarizations (EADs) are due to progressive prolongation of the action potential that results in oscillations at the plateau level of membrane potential. B, Delayed afterdepolarizations (DADs) are due to progressive prolongation of the action potential that results in oscillations during phase 4 of membrane potential.

CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

For the past two decades, antiarrhythmic drugs have been differentiated according to the well-known classification system developed by Vaughan Williams[9] and subsequently modified by Harrison.[10] The original system includes four major groups of antiarrhythmic drugs: classes I, II, III, and IV. **Table 30.2** summarizes all the pharmacodynamic and pharmacokinetic properties of these drugs.

TABLE 30.2 Vaughan Williams Antiarrhythmic Drugs Pharmacodynamics a Properties

DRUG	EFFECT ON ION CURRENTS, CHANNELS	ECG CHANGES	ELIMINATION	BIOAVAILABILITY (%)	TIME TO PEAK PLASMA CONCENTRATION (HR)
Procainamide	I_{Na}, I_{Kr}	↑ QT	Hepatic (40–70%) Renal (30–60%)	100	1
Quinidine	I_{Na}, I_{Kr}, I_{to}	↑ QT	Hepatic (50–90%) Renal (10–30%)	70	1.5–3
Disopyramide	I_{Na}, I_{Kr}	↑ QT	Hepatic (20–30%) Renal (40–50%)	80–90	1–2
Lidocaine	I_{Na}		Hepatic		
Mexiletine	I_{Na}		Hepatic	90	2–4

Propafenone	I_{Na}, βB	↑ PR, ↑ QRS	Hepatic	10–50	2–3
Flecainide	I_{Na}	↑ PR, ↑ QRS	Hepatic (70%) Renal (30%)	90–95	2
Amiodarone	I_{Kr}, I_{Ks}, IK_{Ach}, Ca, I_{Na}, βB	↑ PR, ↑ QRS ↑ QT	Hepatic	50	3–7 (onset of action may take weeks)
Dronedarone	I_{Kr}, I_{Ks}, IK_{Ach}, Ca, I_{Na}, βB	↑ PR, ↑ QT	Hepatic	4–15	3–6
Dofetilide	I_{Kr}	↑ QT	Renal	90	2–3
Sotalol	I_{kr}, βB	↑ QT	Renal	90	2.5–4
Ibutilide	I_{Kr}	↑ QT	Hepatic		
Vernakalant	I_{Kur}, HERG, I_{KAch}	↑ QRS ↑ QT	Hepatic		

VAUGHAN WILLIAMS CLASS I: SODIUM CHANNEL BLOCKADE

Class I antiarrhythmic drugs block the rapid inward sodium channel during phase 0 of the action potential, slowing the rate of depolarization. The Hodgkin and Huxley[11] model describes these channels as existing in one of three states (open, closed, and inactivated), giving a different affinity for each drug.[12] These characteristics explain the feature of use dependence of drugs in this class, whereby block increases with increasing rate of stimulation, that is to say, with increased stimulation more sodium channels are in an open or inactivated state. Drugs that have greater affinity for their receptor when the sodium channel is open or inactivated bind more readily at faster stimulation rates. Drugs also show different rates for association or dissociation from their receptor, which is the basis for the subclassification refinement for class I drugs to (IA, IB, and IC).

Drugs with class IA action (eg, quinidine, procainamide, and disopyramide) prolong the depolarization and the refractoriness of myocardial cells in addition to blocking the rapid inward sodium channels. Thus, they may increase QRS duration and QT intervals. Class IB drugs (eg, lidocaine and mexilitine) shorten the action potential, but produce a minimum inhibition of the inward sodium channels, thus having a minimal effect on the QRS and QT durations. Drugs with class IC action (eg, flecainide and propafenone) are important sodium channel blockers that slow its conduction velocity and could thus increase the QRS duration more than any of the other class I drugs.

Class IA

These drugs have an intermediate rate of association and dissociation from sodium channels. In addition to blocking the sodium channels, they also decrease automaticity and excitability in the atria, ventricles, and Purkinje fibers because of the blockade of the rapidly activating potassium channel $I_{Kr.}$[13]

Quinidine

Quinidine depresses conduction and excitability, slows repolarization, and lengthens the AP duration. Because of its I_{kr} channel blockade, it reduces the maximum reentry frequency and thus slows tachycardia. It also possesses an α-adrenergic blocking property that promotes vasodilation and, in turn, causes a reflex increase in the SA node rate. It also has a greater potassium channel blockade than procainamide; thus, these drugs should be avoided in patients with heart failure because of their proarrhythmic and negative inotropic effect. In addition, quinidine decreases the potassium current during phase 1 of the action potential by blocking the I_{to} current. This effect may prevent the heterogeneity in membrane potentials during phase 2, which is believed to underlie the ST-segment elevation in the right precordial leads and initiation of ventricular fibrillation seen in Brugada syndrome.[14] This characteristic has been postulated in some studies for the management of electrical storm in Brugada syndrome patients.[15–17] Quinidine is predominantly metabolized by the P450 enzyme CYP3A4, and thus requires a lower dosage in patients with liver dysfunction. Importantly, it reduces the renal clearance of digoxin and may lead to digoxin toxicity.[18, 19] Metabolism of quinidine is inhibited by cimetidine and increased by phenytoin, phenobarbital, and rifampin. The main side effects of quinidine include hypotension, thrombocytopenia, hepatitis, and cinchonism, whose

symptoms include tinnitus, blurred vision, headaches, and dizziness.[20] It also can worsen symptoms in patients with myasthenia gravis.[21]

Disopyramide

In addition to its class IA characteristics, it exerts marked cardiac antimuscarinic effects leading to sinus node suppression as well as slow AV nodal conduction. Because of this anticholinergic effect, this drug can cause urinary retention, dry mouth, blurred vision, and closed-angle glaucoma and should thus be avoided in patients with glaucoma and men with symptomatic prostatic hyperplasia. For the past few years, disopyramide has emerged as an important drug in the management of patients with obstructive hypertrophic cardiomyopathy,[22–24] which may be its only use nowadays. It is eliminated by both renal and hepatic routes. It should be titrated up gradually from low doses because of its characteristics of saturable protein binding that can lead to disproportionally increased levels of the free drug.
Dosage: 150 mg every 8 hours up to 1 gm/day.

Procainamide

It is a derivative of the local anesthetic agent procaine, and its active metabolite N-acetylprocainamide (NAPA) is the reason for its I_{kr} blockade. It is indicated for acute conversion of ventricular and atrial dysrhythmias, and although it is less effective in suppressing abnormal ectopic pacemaker activity, it has more effective Na^+ channel blockers in depolarized cells. Procainamide given intravenously in a maximal dose of 10 mg/kg body weight over a 5-minute period during sinus rhythm produced complete anterograde block in the accessory pathway.[25] The usual effective concentration of procainamide is 4 to 8 mcg/mL and NAPA 7 to 15 mcg/mL.[26] Because of its Variable hepatic metabolism in relation to NAPA, monitoring of both procainamide and NAPA levels is needed during initiation of the drug or up titration of dosage because each component reaches steady-state levels at different times. The QT interval should be monitored during initiation to assess the risk of torsade de pointes. Procainamide can cause a drug-induced lupus-like syndrome that appears in about 20% of patients, with positive antinuclear antibodies in all patients, these symptoms range from arthralgia, arthritis, fever, and malar rash to pleural and cardiac effusions. It is also associated with the development of agranulocytosis.[27] It certainly has negative inotropic properties that may lead to

hypotension with rapid IV infusion, and it is thus contraindicated in patients with heart failure.
Dosage: Acute: 17 mg/kg at 20 mg/min (50 mg/min, if urgent). Infusion: 1–4 mg/min (depends on renal function).

Class IB

These drugs block fast sodium channels, decreasing V_{max}, the rate of depolarization during phase 0 of the action potential. They are typically used in treatment of ventricular tachycardia because they have no significant effect on atrial tissue. Both lidocaine and mexiletine are metabolized in the liver by the P450 enzyme CYP2D6; thus drugs that inhibit this enzyme (ie, amiodarone, quinidine, citalopram, cimetidine) can increase their plasma levels and the risks of toxicity.

Lidocaine

It is indicated in acute management and treatment of ventricular arrhythmia and is administered intravenously only to treat arrhythmias associated with myocardial infarction.[28] It is rapidly acting exclusively on Na^+ channels and may slightly shorten action potential duration and effective refractory period of normal conducting tissues, thus prolonging diastole and extending the time to recovery. However, some studies have suggested a facilitation of subnodal block in patient with abnormal conduction[29]; thus, when it is used as a local anesthetic, it should be given with caution in patients with heart block.[30] Lidocaine can cause sinus node standstill, in addition to causing neurologic system toxicity, which can be manifested by paresthesias, tremor, nausea, lightheadedness, hearing disturbances, slurred speech, and convulsions.
Dosage: 1.0–1.5 mg/kg IV push over 1–2 min; repeat every 5–10 min with 0.5–0.75 mg/kg, as needed, until 3 mg/kg total dose. Typical maintenance dose: 1.0 to 4.0 mg/min.

Mexilitine

It is an overall analog of lidocaine and can be safely used in patients with severe systolic dysfunction. It has an approximately 90% bioavailability, with only 1% of total body content within the plasma. Side effects of mexilitine include severe gastritis, tremor, blurred vision, nausea, dysphoria, dizziness, and agranulocytosis.

Dosage: 200 mg every 8 hours; consider lower dose in renal dysfunction patients.

Class IC

Flecainide and propafenone slow conduction velocity and V_{max} by blockade of sodium channels, with slow association/dissociation channel kinetics, resulting in marked use-dependent characteristics. Both prolong the PR and QRS durations, although flecainide can slightly increase the QT interval. The concomitant use of a β-blocker or nondihydropyridine calcium channel antagonist is generally recommended to prevent rapid atrioventricular conduction in the event of atrial flutter. Both can be effective at maintaining sinus rhythm with recurrence rates of 31% to 70%, as seen in the RAFT trial.[31]

Flecainide

It slows conduction in all cardiac tissue, has negative inotropic effect, and is shown to block the delayed rectifier potassium channels.[32] It is used primarily in patients with supraventricular tachycardia and atrial fibrillation (AF). It should be avoided in patients with coronary artery disease, reduced ventricular function, and ventricular arrhythmia, as seen in clinical trials, including the Cardiac Arrhythmia Suppression Trial (CAST)[33] and the Cardiac Arrest Study Hamburg (CASH).[34]

Flecainide can cause sinus node dysfunction and can increase pacing thresholds as well as increased levels of digoxin.

Dosage: 100 to 200 mg every 12 hours.

Propafenone

It blocks both open and inactivated sodium channels; in addition, it blocks both voltage-dependent calcium currents and potassium currents such that the action potential duration is essentially unchanged.[35] It has β-blocking properties that are particularly obvious in patients who poorly metabolize propafenone to 5-hydroxy propafenone. It is metabolized in the liver by enzyme CYP2D6 and thus increases the levels of digoxin, metoprolol, and warfarin.

Dosage: 450–900 mg every 8 hours.

Pill-in-the-Pocket

Class IC medication has been tested for safety and efficacy to be used in the emergency room with patients who have recent-onset atrial fibrillation; treatment was successful in 94% of the episodes occurring during the 15 months' follow-up, with conversion occurring over the mean of two hours.[36] The major concern of this approach was the possibility of ventricular tachyarrhythmias that ranged up to 5%. The pill-in-the-pocket approach should be considered an outpatient self-administration of single oral loading dose only in patients with lone AF and normal hearts, after being initially used in an in-hospital monitor setting that proved to have a safe response to single-dose therapy[37] with reported conversion rates of 70% to 80%.[38]

Dosage: depending on patient weight < 70 kg: immediate-release propafenone 450 mg once and flecainide 200 mg once, for weight ≥ 70 kg: 600 mg once and 300 mg once, respectively.

VAUGHAN WILLIAMS CLASS II: β-RECEPTOR BLOCKADE

This class of medications include those that selectively block receptors in cardiac tissue (β_1) or nonselectively including receptors in the lung and the blood vessel (β_2). Their predominant actions include a reduction in automaticity in cardiac tissue and conduction through the AV node. B_1 selective drugs like metoprolol, bisoprolol, and atenolol are better rate control drugs particularly in patients with heart failure.[39] Nonselective drugs that block both β_1 and β_2 receptors include propranolol, nadolol, and carvedilol, which, in addition, block α_1-adrenergic receptor, making it a great drug for rate control in patients with heart failure and hypertension.[40]

VAUGHAN WILLIAMS CLASS III: POTASSIUM BLOCKADE

Medications in this class block potassium channels, resulting in prolongation of the action potential. This group includes amiodarone, dronadarone, sotalol, ibutilide, and dofetilide. Vernakalant is a new agent that blocks potassium channels selectively in the atrial tissue.

Agents that block the rapidly activating inward rectifying potassium channels (I_{kr}) display reverse use dependence, wherein block is greater at slower heart rate. Therefore, drugs that block I_{kr} result in delays in repolarization and QT prolongation predominantly at slower heart rate (eg, dofetilide).

Amiodarone

It is the most commonly used antiarrhythmic drugs by far because it exerts effects across all Vaughan Williams classes. It increases the action potential duration and the refractory period via potassium channel blockade in a use-dependent manner, and noncompetitive inhibition of α- and β-receptors.[41] It increases the refractory period in all cardiac tissues, and decreases automaticity by slowing phase 4 depolarization. Although it might increase QT interval, torsade de pointes very rarely occurs (<1%).[42]

Amiodarone possesses class I effects by blocking activated sodium channels[43, 44] and also blocks L-type calcium channels. Amiodarone and dofetilide are second-line agents for patients without heart disease but are first-line agents for patients with heart failure. When given intravenously, it can cause hypotension that is related to the solvents polysorbate 80 and benzyl alcohol.[45] The iodine moiety in amiodarone is responsible for hypothyroid or hyperthyroid status. Iodine released from amiodarone in its metabolism directly inhibits thyroid function and hormone synthesis, producing a state of hypothyroidism.[46] Hyperthyroidism can occur in up to 10% of patients with two forms described.[47] Type-I hyperthyroidism, occurs in populations with an underlying thyroid pathology such as autonomous nodular goiter or Graves' disease. In these patients, there is accelerated thyroid hormone synthesis secondary to the iodide load from the amiodarone therapy (the Jod-Basedow phenomenon). In type-II hyperthyroidism, there is an inflammatory thyroiditis with release of stored thyroid hormone.[48, 49]

Amiodarone-induced pneumonitis may develop after several months or years, with cumulative prevalence estimated between 1% and 15%, depending on daily dose.[50] In addition, amiodarone may cause optic neuritis (0.1–2%), skin discoloration (4–9%), peripheral neuropathy (0.3%),[51] and hepatitis (0.6%), although an increase in transaminases can occur without it to hepatic toxic effect.[41]

It has a large volume of distribution, as a result of accumulation in fatty tissue and in the liver, lung, and spleen. Elimination is by excretion into bile, with a slow but valuable elimination rate and a half-life ranging between 13 and 103 days.[52]

There is a strong correlation between amiodarone and warfarin potentiation; thus, the warfarin dose should be reduced with close monitoring of the international normalized ratio. Other examples of drug-drug interactions are

those documented with digoxin, risk of rhabdomyolysis when given in combination with statins and prolongation of the QT interval when given with fluoroquinolone and macrolides.[41]

Dosage:

An oral dosing protocol

- 15 mg/kg/day × 1 week (~400 mg TID)
- 10 mg/kg/day × 2 weeks (~400 mg BID)
- 5 mg/kg/day (~400 mg QD)
- Eventually reduce to 100–200 mg daily

General IV load

- All arrhythmia: Monitor heart rate and blood pressure
  - 150 mg over 10 minutes
  - 1 mg/min × 6 hours
  - 0.5 mg/min × 18 hours or longer
- Ventricular fibrillation
  - 300 mg IVP; may repeat w/150 mg IVP
- Ventricular tachycardia
  - 150 mg over 10 min; repeat as needed to a total of 2.2 gm in 24 hours

For chronic use, the prescriber should consider at least twice yearly assessment of pulmonary, hepatic, eye, and thyroid function during amiodarone therapy.

Dronedarone

Dronedarone is, like amiodarone, a benzofuranyl compound with iodine removed and a methane sulfonyl group added. Removing iodine from the molecule was intended to eliminate or reduce iodine-related organ toxicity. Dronedarone retains many of amiodarone's electrophysiologic effects. It is a multichannel blocker with effects on the rapid and slow components of the delayed rectifier potassium channels (I_{Kr} and I_{Ks}), slow L-type calcium currents, ($I_{Ca\text{-}L}$), the inward sodium current (I_{Na}), and the inward rectifier potassium current (I_{K1}). It also inhibits the acetylcholine receptor–dependent K^+ current (I_{KAch})[53] and the pacemaker current (I_f) and is a noncompetitive α- and β-adrenergic antagonist,[54] thus reducing sinus rate and prolonging AV nodal conduction and refractoriness.[53] Dronedarone has been shown to prevent atrial

fibrillation/flutter (AF/AFl) recurrences in several multicenter trials.[55, 56] In addition to its rhythm control properties, dronedarone has rate control properties and slows the ventricular response during AF. In patients with decompensated heart failure, dronedarone treatment increased mortality and cardiovascular hospitalizations.[57] Results of the PALLAS trial suggested that dronedarone should not be used in the long-term treatment of patients with permanent AF.[58] As a result, the usage of dronedarone has fallen out of favor.[59] In our opinion, its use is limited only to cases when other medications are contraindicated, as in patients with atrial tachycardia who have underlying pulmonary disease. It is metabolized by CYP3A4 and thus subject to interactions with drugs that inhibit this enzyme such as verapamil, diltiazem ketoconazole, as well as macrolides, which could increase dronedarone levels and in turn worsen bradycardia or AV conduction block. It can increase digoxin levels by interacting with P-glycoprotein.[60]

Dosage: 400 mg every 12 hours.

Dofetilide

The most potent drug in this class,[61] it works by blocking the fast component of the delayed rectified potassium current, I_{kr}. Thus, it is indicated for chemical cardioversion as well as maintenance of sinus rhythm in patients with AF/AFl.[62] No negative inotropic effects are associated with this drug, and it could be used in patients with heart failure.[63] The EMERALD trial[61] showed that a full dose of dofetilide (500 mcg twice daily) was superior to low-dose dofetilide (250 mcg twice daily), low-dose sotalol (80 mg twice daily), and placebo.

The risk for torsade de pointes at doses of 250 to 500 mcg twice daily was less than 1% but as high as 2.9% in the DIAMOND-MI trial[64] and 3.3% in DIAMOND-CHF.[65] For this reason, the FDA recommends that dofetilide therapy be initiated in the hospital over a period of 3 days. It is excreted mainly by the kidneys (80%) through both glomerular filtration and cationic renal (active tubular) secretion, which is inhibited by cimetidine, ketoconazole, trimethoprim, prochlorperazine, and megestrol. Dofetilide carries a black box warning. Verapamil has a relative contraindication because it increases peak plasma level of dofetilide by 42% and was shown in the DIAMOND trial to increase the risk of torsade de pointes. Thiazide diuretics also have a block box warning in view of the risk of hypokalemia because they were shown to increase dofetilide AUC by 27% and further increased the QTc over time by 197%. In

addition, any other drug that prolongs the QT interval or promotes hypokalemia or hypomagnesemia should be avoided with dofetilide.

As previously mentioned, the FDA recommends that dofetilide therapy be initiated in the hospital over a period of 3 days and prescribed and dispensed by certified personnel. Generally, three half-lives should be used after stopping a previous antiarrhythmic before starting dofetilide. However, in the case of amiodarone, a waiting period of 3 months should be allowed (or until amiodarone concentration < 0.3 mcg/mL is reached).

Dosage is determined on the basis of renal function, calculated by creatinine clearance.

Dosage:

> 60 mL/min	500 mcg twice daily
40 – 60 mL/min	250 mcg twice daily
20 – 39 mL/min	125 mcg twice daily
< 20 mL/min	contraindicated (or if QTc is >440 msec)

If the QTc increases by more than 15% after the drug initiation, dofetilide dose is to be decreased by 50%; while, if the QTc exceeds 500 msec after the second dose, dofetilide should be stopped entirely.

Sotalol

It is prepared as a mixture of d- and l-isomers, of which the l-isomer is responsible for β-blockade. Both isomers block the rapid component of the delayed potassium rectifier channel (I_{Kr}). The initial d-Sotalol drug was found to have a higher mortality in patients with a history of myocardial infarction, as seen in the SWORD trial[66]; however, the racemic mixture of d- and l-isomers does not increase mortality.[67]

It prolongs the action potential by prolonging the repolarization by blockade of I_{Kr} channels, in both atrial and ventricular tissue. As a result of both β-blockade and potassium channel blockades, there is an overall slowing of the heart rate, AV node conduction, conduction across accessory bypass tracts,[68] and increase in AV nodal refractory period.[69] Class III effects are seen at more than 160 mg daily; at dosages of up to 640 mg/d, the QT interval is increased by 40 to 100 msec and the corrected QT interval by 10 to 40 msec.[70] Sotalol carries a dose-related proarrhythmic risk of torsade de pointes, which increases in the

setting of bradycardia, female gender, history of heart failure, or preexisting QT prolongation. Sotalol is excreted by the kidneys, and thus caution is indicated in patients with renal dysfunction. Antacids should be avoided within 2 hours because they may reduce peak serum concentrations and area under the plasma concentration curve. For a creatinine clearance of 30 to 59 mL/min, sotalol should be administered at an interval of 24 hours, starting at a low dose of 80 mg. Because of its β-blocking effect, sotalol should be used with caution in asthmatic patients, or in patients with other drugs that affect AV conduction.
Dosage: 80 – 320 mg orally twice daily can also be administered intravenously at 75 mg IV over 5 hours.

Precautions:
- Do not initiate if QTc > 450 msec
- Accepted QTc < 500 msec the for first 3 days to keep the risk of torsades de pointes under 2%.
- QTc < 520 msec could be accepted thereafter.
- Dosage greater than 320 mg/day may be lead to a substantial increase in the incidence of torsades de pointes (as high as 11% in patients whose corrected QT interval exceeds 550 ms).

Ibutilide

Ibutilide has antiarrhythmic effects through blockade of the rapid component of the delayed rectified potassium current, I_{kr}, as well as enhancing the slow inward sodium current; therefore, it prolongs the action potential duration and the QT interval in proportion to its plasma concentration.[71] There is no significant effect on the heart rate, the PR interval, or QRS duration and no significant change in the cardiac output or the blood pressure. When administered as a 1 mg dose followed by a second dose of 0.5 or 1 mg, ibutilide converted 47% of patients compared with 2% of placebo.[71] The overall risk for torsade de pointes is about 5%,[72] and thus the patient should be monitored for 4 hours after administration of the drug. If ibutilide fails to convert, it may at least enhance the response to electrical cardioversion. Because it is extensively metabolized by first pass, it must be given intravenously. It can be administered to patients receiving digoxin, calcium channel blockers, or β-blockers without interaction; however, the risk of proarrhythmia may increase.
Dosage: 1 mg (0.01 mg/kg < 60 kg) over 10 min; repeat, if needed, after 10 min. In our practice, we preload the patient with magnesium to keep the magnesium

level above >2.

Vernakalant

Vernakalant is an atrial-selective, multiple ion channel blocker that is approved in Europe for the treatment of AF; however, the FDA judged that additional information was necessary for approval. Vernakalant blocks the rapidly activating delayed rectifier potassium channel I_{Kur}, which is present in higher density in the atria, making it relatively atrial selective. It also blocks other potassium currents (I_{to}, hERG, and $I_{KAch)}$ and exhibits rate- and voltage-dependent blockade of the fast inward sodium current I_{Na}. Vernakalant has, therefore, a much greater effect in fibrillating atria than in the ventricle and is less likely to be proarrhythmic.

In the ACT II trial[73] that was performed in patients with new-onset atrial fibrillation or flutter after cardiac surgery, 47% converted to sinus rhythm opted for infusions of Vernakalant, compared with 14% who received placebo with median time to conversion of 12 minutes. In a recently published controlled randomized trial, Vernakalant was found to have significant advantages: it achieved conversion to a normal sinus rhythm within an average of 10 minutes, compared to ibutilide with an average of 26 minutes. Approximately 90 minutes after treatment began, 69% of Vernakalant-treated patients were in sinus rhythm, compared to 43% of patients treated with ibutilide.[74] Most studies were performed on patients with recent-onset atrial fibrillation <7 days, and the conversion rate changed from 45% to 61% within the first 10 to 15 minutes after intravenous administration with the most commonly used regimen (2 mg/kg bolus followed by 3 mg/kg 30 minutes later if AF continued).[73, 75]

Vernakalant is hepatically metabolized by CYP2D6; it is not clear what effect abnormal liver function has on the metabolism of the drug. Differences in renal function, age, sex, race, blood pressure, and heart failure status have not been shown to affect the pharmacokinetics of Vernakalant.[76] The new European guidelines added IV Vernakalant as a first-line treatment for chemical cardioversion for recent-onset atrial fibrillation in patients with coronary artery disease, moderate heart failure, and left ventricular hypertrophy.[77]

VAUGHAN WILLIAMS CLASS IV: CALCIUM CHANNEL BLOCKADE

Diltiazem and verapamil block the L-type calcium channels, resulting in the

relaxation of arterial smooth muscle and vasodilation, and decreased contractility in cardiac myocytes. These drugs also slow AV nodal conduction and increase AV nodal refractoriness. Verapamil also blocks sodium channels, but this is not believed to be a clinically important effect. They are both well absorbed from the gastrointestinal tract and undergo significant first pass effects in the liver, giving a bioavailability of 20% for verapamil and about 40% of diltiazem. They are metabolized in the liver by CYP3 A4; levels can thus be increased in the presence of inhibitors of this P450 enzyme such as ketoconazole and human immunodeficiency virus antiviral agents.

OTHER ANTIARRHYTHMIC DRUGS

Ranolazine

Ranolazine has antianginal properties and is currently approved for use in chronic angina. It reduces myocardial ischemia by its effects on the late inward Na current (I_{NaL}). Ranolazine inhibits peak I_{Na} in the atrium but not the ventricle. This effect results in reduced atrial excitability and a rate-dependent increase in postrepolarization atrial refractoriness. Ranolazine has variable systemic availability after oral administration because of its extensive first pass metabolism in the gut and liver. Metabolism is mainly via CYP3A4 and, to a lesser extent, CYP2D6. The terminal elimination half-life is 7 hours. The recommended dosage in patients with angina is 500 to 1000 mg twice daily. Ranolazine results in a 2- to 6-ms mean increase in the QTc interval, but drug-induced polymorphic ventricular tachycardia has not been observed. The MERLIN-TIMI 36 trial showed significant decreases in the frequency of nonsustained ventricular and supraventricular tachycardia and in the trend toward less frequent new-onset atrial fibrillation.

Pearls

Greater caution should be used when treating women with antiarrhythmic drugs that prolong repolarization, especially when additional risk factors for developing torsade de pointes are present (**Table 30.3**). Patient synchronic class I a or class III drugs should have regular follow-up so that electrocardiogram can be checked for conduction changes or prolongation of the QT interval. Periodic monitoring of laboratory data is also important, including electrolytes, creatinine, and liver enzymes as appropriate for the particular antiarrhythmic

agent. Both sotalol and dofetilide are renally excreted, and their use should be carefully monitored in patients with renal disease.

TABLE 30.3 Risk factors for Developing Drug-induced Torsade De Pointes

Congenital long QT
Female gender
Electrolyte abnormalities (hypokalemia, hypomagnesemia, hypocalcemia)
Diuretic use
Bradycardia
Cardiac hypertrophy
Myocardial fibrosis
Congestive heart failure
Renal and liver insufficiency
Co-administration of drugs blocking P450 isoenzyme CYP3A4
High doses or rapid intravenous infusion of the drug
Baseline electrocardiographic abnormalities
Prolonged QT, T wave lability

Patient and Family Information for: PRINCIPLES OF ANTIARRHYTHMIC DRUG THERAPY

Antiarrhythmic drugs are medicines that are used to treat abnormal heart rhythms resulting from irregular electrical activity of the heart. Antiarrhythmics correct irregular heartbeats and slow down hearts that beat too fast. Normally, the heart beats at a steady, even pace. The pace is controlled by electrical signals that begin in one part of the heart and quickly spread through the whole heart. If something goes wrong with this control system, the result may be an irregular heartbeat, or an arrhythmia. Antiarrhythmic drugs control these irregular heartbeats. If the heart is beating too fast, these drugs will slow it down. By correcting these problems, antiarrhythmic drugs help the heart work more efficiently. These medications only control abnormal heart rhythms, not cure them, and therefore you may have to take them for life. There are many different types of antiarrhythmic drugs, and your doctor will decide what class and medication is best for you. We will explain the purpose and how to use the most commonly used medications here.

Antiarrhythmic medicines are split into four categories:

- **Class I antiarrhythmic** medicines are sodium channel blockers, which slow electrical conduction in the heart.
  - **Flecainide**: Take this medication by mouth with or without food, usually twice daily.
    - Supraventricular tachycardia: 100 to 200 mg/day every 12 hours
    - Paroxysmal atrial fibrillation: 50 to 300 mg/day taken 2 to 3 times daily
    - Should not be used in people with liver impairment

    - **Propafenone**: Generally needs to be started in a hospital setting to ensure ECG monitoring of the patient.
        - There are many different dosages of propafenone, depending on clinical presentation of the arrhythmia. The treatment is generally begun with relatively high dosages (450–900 mg/day), decreasing to near 300 mg/day.
        - This medicine works best when there is a constant amount in the blood. To help keep the amount constant, do not miss any doses. Also, it is best to take each dose at evenly spaced times day and night. For example, if you are to take 3 doses a day, doses should be spaced about 8 hours apart.
        - If you miss a dose of this medicine, take it as soon as possible. However, if it is almost time for your next dose, skip the missed dose and go back to your regular dosing schedule. Do not double doses.
    - These two drugs can be used as a "pill-in-the-pocket" method for use with single dosage in patients with lone AF episodes. This method can be utilized only in patients with normally structured hearts, with initial dose delivered in a hospital setting.
- **Class II antiarrhythmic** medicines are β-blockers, which work by blocking the impulses that may cause an irregular heart rhythm and by interfering with hormonal influences (such as adrenaline) on the heart's cells. By doing this, they also reduce blood pressure and heart rate.
    - **Metoprolol**: A β-blocker that works by blocking the effects of epinephrine, causing the heart to pump more slowly and with less force.
        - Metoprolol tartrate (short-acting) dosage: 50 to 200 mg taken every 12 hours.
        - Toprol XL (long-acting) dosage**:** 50 to 200 mg taken once daily
- **Class III antiarrhythmic** medicines slow the electrical impulses in the heart by blocking the heart's potassium channels.
    - **Amiodarone**: Most commonly used antiarrhythmic medication.
        - Maintenance dose: 100 to 200 mg daily
        - Avoid eating grapefruit or drinking grapefruit juice while using this medication unless your doctor instructs you otherwise. Grapefruit can increase the amount of this medication in your bloodstream.
        - Nausea, vomiting, constipation, loss of appetite, shaking, or tiredness may occur.
        - Tell your doctor right away if you have any of the following serious side

effects: easy bruising/bleeding, loss of coordination, tingling/numbness of the hands or feet, uncontrolled movements, new or worsening symptoms of heart failure (such as ankle/leg swelling, increased tiredness, increased shortness of breath when lying down).
    - Amiodarone may rarely cause thyroid problems. Either low thyroid function or overactive thyroid function may occur. Tell your doctor right away if you develop any symptoms of low or overactive thyroid, including cold or heat intolerance, unexplained weight loss/gain, thinning hair, unusual sweating, nervousness, irritability, restlessness, or lump/growth in the front of the neck (goiter).
    - Amiodarone has many interactions with medications, so be sure to discuss all the medications you are taking with your doctor.
    - Many patients who are prescribed amiodarone are also on the blood thinner coumadin, also known as warfarin. The blood levels of coumadin are higher when used with amiodarone, and therefore the dose of coumadin will need to be adjusted.
    - Digoxin dose will also most likely need to be lowered to prevent levels of digoxin in the blood from being too high.
    - Muscle breakdown can happen when taking amiodarone with cholesterol medications.
    - Amiodarone can cause other electrical disturbances within the heart when taken with certain antibiotics, so be sure to inform any primary care provider before taking any additional medication when treating an infection.
- **Sotalol**: Maintaining a normal heartbeat in patients who have AF or AFl.
    - Dosage: take one tablet 80 to 320 mg every 12 hours.
    - Patients who begin taking or restart sotalol should be observed in a hospital or similar setting in which heart and kidney function monitoring may be performed for at least 3 days after starting sotalol. Close monitoring of your heart or kidney function may also be needed if your dose is changed.
    - Sotalol may sometimes cause a new or worsened irregular heartbeat (prolonged QT interval), which could be life threatening. Talk with your doctor if you have prolonged QT interval or kidney problems.
    - Sotalol has many drug and herbal interactions, so be sure to go over everything you are taking and have recently taken with your health care provider before starting sotalol.

- **Dofetilide**: Used for the maintenance of sinus rhythm in individuals prone to the occurrence of AF and AFl arrhythmias, and for chemical cardioversion to sinus rhythm from AF and AFl.
  - There is risk of fatal heart rhythm when starting this medication, and therefore it must be initiated in a hospital setting where heart and kidney monitoring can occur for 3 days.
  - If you have been taking amiodarone, it should be stopped for 3 months before starting dofetilide.
  - There is a very specific dosing regimen when initiating dofetilide, which will be carried out by a trained professional in the hospital. The home dose is 500 mcg twice daily.
- **Class IV antiarrhythmic** medicines slow the electrical impulses in the heart by blocking the calcium channels in the heart.
  - **Diltiazem**: This medication is used to treat high blood pressure and chest pain as well as heart rhythm problems. Diltiazem affects the movement of calcium ions within heart tissue that occur during each heartbeat. This helps to relax the muscles of the heart and also open up blood vessels around the heart. It is known as a calcium channel blocker.
    - Diltiazem should not be used if you have heart failure.
    - Extended release tablets dosage: 180 to 480 mg daily.

Modern Anticoagulation Therapy

BACKGROUND

Atrial fibrillation (AF) is among the most common sustained cardiac tachyarrhythmia in hospitalized patients.[1] The lifetime rate of developing AF in individuals 40 years and older is approximately 25%; with an estimated 16 million Americans with AF by 2050. There is about a 5-fold increased risk in developing an acute ischemic stroke in patients with AF.[1] In a meta-analysis, the rate of ischemic stroke in patients managed for AF with adjusted-dose warfarin reduced by 66% and antiplatelet agents by 22%.[2] To that end, adjusted-dose warfarin has traditionally been the gold standard in those with AF who are at risk for stroke.

Warfarin, however, is a complicated anticoagulant to manage, with a diverse mechanism of action profile on the clotting cascade.[3] Therefore, to improve the effectiveness of antithrombotic therapy in AF and reduce the relative risks of bleeding, newer modern anticoagulants have been developed with more direct-acting mechanisms on the clotting cascade that yield a more predictable anticoagulant effect.[3] As such, the purpose of this chapter is to provide clinicians with an overview of the evolving field of anticoagulation therapy as it pertains to AF, particularly when cardiac valves are not involved, such as mechanical valve repairs and replacements.

As research advances and the understanding of the incidence and etiologies of AF evolves in the context of valvular conditions, we recognize that at the time this chapter was developed, there were established differences in the worldwide definition of nonvalvular atrial fibrillation (NVAF) that only recently emerged.[4, 5] The American College of Cardiology (ACC), American Heart Association (AHA), and the Heart Rhythm Society (HRS) definition of NVAF can be summarized by the presence of AF in the absence of rheumatic mitral valve stenosis, a mechanical or bioprosthetic heart valve, or a mitral valve repair.[4] In contrast, the 2016 consensus of the European Society of Cardiology (ECS), European Heart Rhythm Association, and European Stroke Organisation removed the term "nonvalvular" AF, but rather references the specific underlying contributory clinical conditions.[5] Such scenarios may include AF secondary to structural heart disease, mitral stenosis, or prosthetic heart valves, suggesting the need for being more specific when selecting an anticoagulant or estimating stroke risk. For the purposes of this chapter, we refer to the ACC/AHA/HRS definition of NVAF.

The United States Food and Drug Administration (US FDA) has approved traditional and modern anticoagulants for the prevention of stroke and systemic embolism in patients with NVAF, thromboprophylaxis postoperatively in orthopedic and other procedures, as well as in treatment and in risk reduction of recurrent venous thromboembolism, such as deep vein thrombosis and pulmonary embolism. The scope of this chapter is a focus on the use of anticoagulants for AF with an emphasis on NVAF. The goal is to provide a decision analysis of anticoagulant drug selection and use based on clinical pharmacology, evidence, and patient characteristics.

ESTABLISH STROKE AND BLEEDING RISK

CHA2DS2-VASc SCORE

In addition to the shared decision making between clinician and patient, selecting the appropriate antithrombotic therapy for NVAF is often based on assessing the risk of thromboembolic stroke and bleeding.[4] The CHA_2DS_2-VASc stroke risk stratification score (**Table 31.1**), recommended for use by the 2014 AHA/ACC/HRS Guideline for the Management of Atrial Fibrillation, is an expansion of the $CHADS_2$ score with three additional risk factors including female sex, age of 65 to 74 years, and history of vascular disease, such as prior

myocardial infarction, peripheral arterial disease, and aortic plaque.[4] Therefore, the CHA_2DS_2-VASc score is said to be a more accurate predictor of stroke risk in patients with a $CHADS_2$ score of 0 or 1 and thus improving guidance on the need for anticoagulant therapy.

TABLE 31.1 CHA_2DS_2-VASc and HAS-BLED Risk Stratification Tools

CHA2DS2-VASc		HAS-BLED	
CONDITION	**POINTS**	**CONDITION**	**POINTS**
Chronic heart failure	1	Hypertension (ie, uncontrolled)	1
Hypertension	1	Abnormal renal/liver function	1 or 2
Age ≥ 75 y	2	Stroke	1
Diabetes mellitus	1	Bleeding tendency or predisposition	1
Stroke/TIA or thromboembolism, prior	2	Labile INR	1
Vascular disease (MI, PAD, or aortic plaque)	1	Age (eg, >65 y)	1
Age 65–74 y	1	Drugs (eg, concomitant aspirin or NSAIDs) or alcohol	1 or 2
Sex category (female)	1		
Total possible score	9	Total possible score	9

INR, international normalized ratio; MI, myocardial infarction; NSAIDs, non-steroidal anti-inflammatory drugs; PAD, peripheral arterial disease; TIA, transient ischemic attack.

The total score of the CHA_2DS_2-VASc is up to 9 points. On the basis of a strong level of evidence, the recommendation is to provide anticoagulation therapy for CHA_2DS_2-VASc scores of 2 or higher that indicate high risk for a thrombotic event. A CHA_2DS_2-VASc score of 1 indicates an intermediate risk of an event and thus the clinician may consider offering antithrombotic therapy with either aspirin, an anticoagulant, or no therapy with continued monitoring. Assessing bleeding risk may assist with the decision process.

When the decision is to initiate anticoagulation therapy, several considerations need to be evaluated. Warfarin remains the gold-standard anticoagulant method

for AF due to a mechanical or bioprosthetic heart valve.[4] The intensity of warfarin anticoagulation to a target international normalized ratio (INR) of 2.5 (range 2 to 3) is recommended for mechanical aortic valves without risks for thromboembolism (eg, CHA_2DS_2-VASc = 0), bioprosthetic aortic or mitral valves, and mitral valve stenosis or regurgitation. On the other hand, a target INR of 3 (range 2.5 to 3.5) is recommended for mechanical aortic valves with risks for thromboembolism (eg, CHA_2DS_2-VASc ≥ 2) and mechanical mitral valves.[6] When introducing warfarin, a parenteral anticoagulant with complete anticoagulant activity using either unfractionated heparin (UFH) as a continuous infusion with a steady-state target-activated partial thromboplastin time (aPTT) 1.5 to 2 times the upper limit of the "normal" range or a low-molecular-weight heparin (LMWH), such as enoxaparin, is recommended concomitantly with warfarin until the INR is at target on two separate samples 24 hours apart after at least 5 days of overlap.[3] The timing in which therapeutic INR is achieved is dependent on the half-lives of vitamin-K–dependent clotting factors II, VII, IX, and X. On average, a therapeutic INR is achieved by day 5, which is based on complete depletion of factor II, which has the longest half-life of approximately 48 to 64 hours.[7]

For NVAF with a CHA_2DS_2-VASc score of 2 or greater, oral anticoagulation therapy with either warfarin to a target INR 2 to 3 or a novel oral anticoagulant (NOAC) is recommended.[4] The NOAC agents include dabigatran, which elicits its anticoagulant effect by directly inhibiting thrombin activity, similar to argatroban; and apixaban, edoxaban, and rivaroxaban that inhibit factor Xa (FXa) activity similar to that of LMWHs.[8–11]

HAS-BLED

Several tools are available to assess the risk of bleeding from anticoagulation for AF. The HAS-BLED score (**Table 31.1**) has been validated to predict clinically significant bleeding and has been demonstrated to outperform the HEMORR(2)HAGES and ATRIA (***A***n***T***icoagulation and ***R***isk factors ***I***n ***A***trial fibrillation) assessment tools that are more complicated to complete.[12, 13] The components of the HAS-BLED tool include modifiable and nonmodifiable risk factors such as hypertension, abnormal renal and/or liver function, stroke, bleeding tendencies, labile INR, age (eg, older than 65 years), and drug (eg, aspirin, $P2Y_{12}$ antiplatelet agents, nonsteroidal anti-inflammatory drugs

[NSAIDs]) or alcohol use that increases the risk of bleeding. The highest possible HAS-BLED score is 9, whereby a score of 0 suggests a low risk of bleeding, 1 to 2 an intermediate risk of bleeding, and 3 or higher indicating a high risk of bleeding. In patients with a high risk of bleeding, improvements of modifiable risk factors, such as blood pressure control and avoidance of alcohol, may assist in determining anticoagulation selection during follow-up.

Although the clinical utility of these scoring systems requires additional evidence,[4] their results are useful in identifying those at a high risk of bleeding and may aid in the decision-making process between the clinician and patient. To illustrate a thought process for clinically evaluating stroke and bleeding risks, **Figure 31.1** illustrates a decision pathway that incorporates the CHA_2DS_2-VASc in the context of the HAS-BLED score. For example, an intermediate risk of stroke (eg, CHA_2DS_2-VASc score of 1) may result in one of three therapeutic options including no antithrombotic therapy, aspirin, or oral anticoagulation therapy. To help guide the clinician and patient in this scenario, using the HAS-BLED scoring system may lead to a more conservative approach from the standpoint of bleeding risk, such as selecting no antithrombotic therapy or aspirin. On the other hand, a high risk of stroke (eg, CHA_2DS_2-VASc score of 2 or greater) and a high risk of bleeding (eg, HAS-BLED score greater of 3 or equal) is a therapeutic challenge often encountered that requires careful consideration of the risks and benefits. One approach may be to address modifiable bleeding risk factors during routine follow-up while selecting an anticoagulant with complete reversibility.

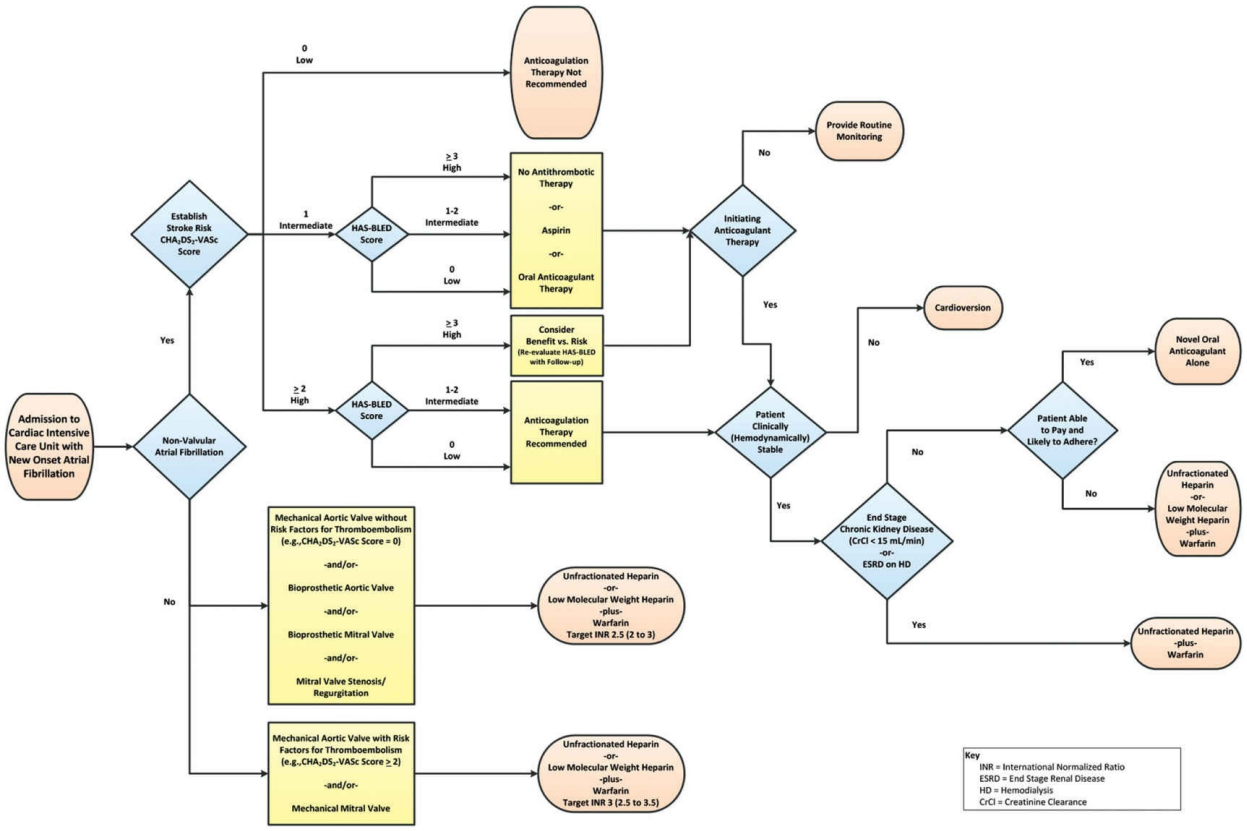

FIGURE 31.1 Anticoagulation pathway for atrial fibrillation in the cardiac intensive care unit.

Once the decision has been confirmed to initiate anticoagulation therapy in the cardiac intensive care unit, patient characteristics need to be considered for selecting an agent(s).

ANTICOAGULANT DECISION BASED ON PATIENT CHARACTERISTICS

>HEMODYNAMICALLY UNSTABLE REQUIRING CARDIOVERSION

Details surrounding patient selection criteria for and procedures involved with synchronized direct current electrical cardioversion are not discussed in this section because the technique extends beyond the scope of this chapter. For the hemodynamically unstable patient, it is important to first rule out AF as, indeed, the primary problem and not a compensatory response of another underlying condition, such as sepsis or hemorrhage.

Synchronized direct current electrical cardioversion is preferred for hemodynamically unstable patients presenting with new-onset AF greater than

48 hours for restoration of normal sinus rhythm, but does carry a risk for cardioembolic events, particularly during the first 72 hours after the procedure.[4] Anticoagulation should be initiated immediately following the procedure and continued for at least 4 weeks with life-long anticoagulation dependent upon the CHA_2DS_2-VASc score.[4, 5] Following cardioversion in hemodynamically unstable patients with AF or atrial flutter less than 48 hours, the decision to provide anticoagulation is dependent upon the patient's CHA_2DS_2-VASc score.

Warfarin has traditionally been the preferred agent for anticoagulation in combination with either UFH or an LMWH until a therapeutic INR is achieved in this setting; however, growing evidence supports the use of NOACs in this population.[4, 5] Selecting the specific anticoagulant therapy is discussed in further detail based on specific patient characteristics.

HEMODYNAMICALLY STABLE WITH ELECTIVE CARDIOVERSION

In a nonurgent setting for those who are hemodynamically stable with AF greater than 48 hours or unknown duration, transesophageal echocardiography (TEE) should be performed to exclude the left atrial thrombus for elective cardioversion.[4, 5] When a thrombus is present, anticoagulation should be initiated for 3 weeks and a repeat TEE should be completed to verify resolution to proceed with cardioversion.[4, 5] In the absence of a thrombus, the patient should proceed with immediate anticoagulation with UFH, starting with a weight-based bolus, followed by continuous infusion to attain target-aPTT, or weight-based LMWH, or a NOAC. The results of a recent trial utilizing data from the Finnish CardioVersion (FinCV) study demonstrated that peri-procedural anticoagulation reduced the risk for thromboembolic complications (TEC) by 82% and the CHA_2DS_2-VASc score provided a strong predictor for TEC post cardioversion in those without anticoagulation.[14] Following cardioversion, anticoagulation should be continued for a period of 4 weeks and life-long therapy is guided by the CHA_2DS_2-VASc score. Both warfarin and NOACs have been used for anticoagulation in this population of patients. To further consider anticoagulant selection, patient-specific factors including renal function needs to be considered.

CHRONIC KIDNEY DISEASE OR END-STAGE RENAL DISEASE ON HEMODIALYSIS

In the setting of stage 5 chronic kidney disease (CKD), defined as a creatinine clearance (CrCl) less than 15 mL/min or end-stage renal disease (ESRD) requiring hemodialysis, the NOACs have minimal data to support the use in NVAF. This is because all of these agents are, to some extent, renally excreted and thus pose an increased risk for accumulation and bleeding.[15] CKD itself poses an increased risk for bleeding as well as thromboembolism.[5] In addition, with a moderate reduction in renal function, when the CrCl calculated by the Cockcroft–Gault equation is less than 50 mL/min, NOACs have been demonstrated to differ from one another in their relative risk for major bleeding.[15] **Table 31.2** compares the differences in dosing with renal impairment for anticoagulants. LMWH as an alternative to NOAC is also not preferred in this patient population because the use is relatively contraindicated in CrCl less than 15 mL/min**.**

TABLE 31.2 Clinical Pharmacology Overview of Anticoagulants for Nonvalvular Atrial Fibrillation

anti-Fxa, antifactor Xa activity; aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; ECT, ecarin clotting time; INR, international normalized ratio; kg, kilograms; P-gp, P-glycoprotein (transport); PO, per oral; PT, prothrombin time; SubQ, subcutaneously.

Warfarin therefore remains the oral anticoagulant option for patients with CKD stage 5 (CrCl < 15 mL/min) or ESRD requiring hemodialysis or renal replacement therapy. To achieve therapeutic INR, warfarin must be initiated with an infusion of UFH until therapeutic INR is achieved, as previously described.

HEMODYNAMICALLY STABLE WITH ADEQUATE RENAL FUNCTION

All anticoagulants are potential options for the hemodynamically stable patient with adequate renal function (defined as those with up to CKD stage 3 with CrCl > 30 mL/min). Therefore, the decision to select an anticoagulant is multifactorial. Factors to consider for anticoagulant selection are baseline risk assessment for bleeding and thromboembolic events, potential for drug interactions, patient medication adherence, compliance with provider follow-up, cost, and drug tolerability. **Table 31.2** provides an overview of the anticoagulant options for NVAF. UFH or an LMWH transitioning to warfarin has traditionally been the gold-standard anticoagulation regimen. The time in therapeutic range for target INR is an important consideration for those on warfarin because there

is a direct correlation with the annual risk for stroke or systemic embolism when frequently above or below the target range.

The NOACs include the direct thrombin inhibitor, dabigatran, and FXa inhibitors apixaban, edoxaban, and rivaroxaban. Their primary difference from that of warfarin is the rapid onset of action, which eliminates the need for bridging with UFH or an LMWH and the elimination of required laboratory monitoring for therapeutic efficacy. However, there are notable differences between each of the NOACs, which should be taken into consideration when selecting the optimal agent.

NOAC DOSING COMPARISON

Dabigatran etexilate is a prodrug that is rapidly converted into its active form dabigatran independently of the cytochrome P-450 (CYP) pathway. The lack of direct involvement with the CYP pathway is attractive to patients who may be on multiple medications, because this minimizes the risk for drug interactions, which are extensively hepatically metabolized by this means. The adverse effect of dyspepsia (5% to 10%) seen in the RE-LY (***R***andomized ***E***valuation of ***L***ong-Term Anticoagulation Therap***Y***) trial is attributed to its formulation with tartaric acid,[8] thereby making it a pH-dependent environment for absorption within the gastrointestinal tract. Thus, the medication should not be crushed or chewed and the contents of the capsule cannot be opened for administration down feeding tubes because this will increase the risk of bleeding. Taking dabigatran with food delays the onset of action up to 2 hours. It is suggested that patients requiring acid-suppressive therapy for peptic ulcer disease and individuals with total or subtotal gastrectomy as well as gastric bypass surgery should avoid this anticoagulant or use it with caution.[16]

Despite its twice-daily dosing being an issue for medication compliance, apixaban has demonstrated superiority to warfarin in NVAF. In ARISTOTLE, patients with a CHA_2DS_2-VASc score greater than 1, apixaban is associated with a lower annual incidence of stroke or systemic embolism (1.27% vs 1.60%) while having a decreased rate of lower major bleeding (2.13% vs 3.09%) than warfarin.[9] Apixaban tablets may be chewed or crushed for ease of administration down feeding tubes and are administered without regard to meals.

Edoxaban is not yet incorporated into the ACC/AHA/HRS guidelines for AF because the publication of its utility versus warfarin in NVAF in ENGAGE AF-TIMI 48 was published after the cutoff for inclusion into the most recent

guidelines.[4] However, a class I, level A recommendation in the ESC guidelines for AF yields preference to edoxaban along with the other NOACs over vitamin K antagonists (VKAs) such as warfarin.[5] Edoxaban may be administered independent of meals, but may have some benefit when administered with food, because bioavailability has been shown to increase from 6% to 22%.[16] Presently, there is no existing data on the effects of bioavailability if this medication is chewed or crushed to administer down a feeding tube.

Rivaroxaban must be administered with food because bioavailability is significantly increased from 66% to greater than 80%.[16] As with apixaban, rivaroxaban may be chewed or crushed for ease of administration down feeding tubes. The pharmacokinetic profile of this medication along with dabigatran is not affected by extremes in body weight.

Medication adherence may be a concern with both dabigatran and apixaban because they are both administered twice daily. Edoxaban and rivaroxaban may be more suitable for patients who are at risk for issues with adherence because they are administered once daily. All NOACs have shorter half-lives than their counterpart warfarin. Thus, the importance of not missing doses should be strongly emphasized during patient education because of the increased risk for embolic events.

HEPATIC AND RENAL IMPAIRMENT AND OTHER DOSAGE CONSIDERATIONS

Unlike rivaroxaban and dabigatran, apixaban is minimally excreted by the kidneys and predominantly through multiple nonrenal mechanisms including fecal and hepatic. This provides an advantage of apixaban over dabigatran, edoxaban, and rivaroxaban, with the potential for its use with moderate hepatic dysfunction. All NOACs require renal dose adjustments and should not be used in patients with an estimated CrCl < 15 mL/min depending on the individual agent.

In the ENGAGE AF-TIMI 48 study, NVAF patients with CrCl > 95 mL/min had an increased rate of ischemic stroke with edoxaban 60 mg once daily compared with patients treated with warfarin.[10] Although uncommon for the majority of patients with NVAF, this anticoagulant is recommended for use only for those with a CrCl less than 95 mL/min. Apixaban and dabigatran should be used with caution in patients at and older than 80 years of age. With respect to lower extremes of weight, apixaban and edoxaban require dosage adjustment in

patients less than 60 kg.

DRUG INTERACTIONS

There are two primary considerations for drug interactions with the NOACs: CYP450 isoenzyme metabolism, specifically CYP3A4, and P-glycoprotein (P-gp) transport. Each of these mechanisms may take the form of either inhibiting or inducing drug metabolism. Inhibition may increase NOAC exposure leading to toxicities, such as major or minor bleeding events. Induction may decrease NOAC exposure leading to insufficient NOAC exposure, resulting in thrombotic events.

The CYP3A4 isoenzyme is involved in the metabolism of all NOACs, with the exception of dabigatran. Despite this advantage, many medications commonly metabolized by CYP3A4 are also involved with P-gp transport for elimination, which must be considered with concomitant use of dabigatran. Common CYP3A4 and P-gp inhibitors include erythromycin, clarithromycin, grapefruits and grapefruit juice, and protease inhibitors. Common inducers include barbiturates, phenytoin, rifampin, and carbamazepine. Additional monitoring is recommended when these agents are concomitantly administered.

CONVERTING FROM ONE ANTICOAGULATION REGIMEN TO ANOTHER

Throughout the course of an inpatient hospitalization, it may be necessary to convert between different anticoagulation regimens for NVAF. This may be particularly relevant for the patient admitted to the intensive care unit, where there may be acute changes in hemodynamics and organ function. **Table 31.3** outlines the specific details on transitioning between anticoagulation regimens.

TABLE 31.3 Converting Novel Oral and Other Anticoagulants

	APIXABAN (ELIQUIS) FACTOR Xa INHIBITOR	EDOXABAN (SAVAYSA) FACTOR Xa INHIBITOR	RIVAROXABAN (XARELTO) FACTOR Xa INHIBITOR	DABIGATRAN (PRADAXA) DIRECT THROMBIN INHIBITOR
Warfarin to NOAC	Discontinue warfarin, initiate when INR < 2	Discontinue warfarin, initiate when INR ≤ 2.5	Discontinue warfarin, initiate when INR < 3	Discontinue warfarin, initiate when INR < 2
				CrCl > 50

NOAC to warfarin	Start parenteral anticoagulant plus warfarin at next time of apixaban dose Discontinue parenteral anticoagulant when INR is within therapeutic range	(Oral option): reduce edoxaban dose in half and begin warfarin concomitantly. Measure INR at least weekly and just before edoxaban dose. Once INR stable ≥ 2, discontinue edoxaban (Parenteral option): Start parenteral anticoagulant and warfarin at time of next dose	Initiate warfarin and a parenteral anticoagulant 24 h after discontinuation of rivaroxaban	mL/min: Initiate warfarin 3 d before discontinuation of dabigatran CrCl 31–50 mL/min: initiate warfarin 2 d before discontinuation of dabigatran CrCl 15–30 mL/min: initiate warfarin 1 d before discontinuation of dabigatran
NOAC to non-warfarin oral anticoagulants	Discontinue apixaban, start new agent at time of next scheduled apixaban dose	Discontinue edoxaban, start new agent at time of next scheduled edoxaban dose	Initiate the new agent 24 h after discontinuing rivaroxaban	Discontinue dabigatran, start new agent at time of next scheduled edoxaban dose
Non-warfarin oral anticoagulants to NOAC	Discontinue current agent, start apixaban at time of next scheduled dose	Discontinue current agent, start edoxaban at time of next scheduled dose	Discontinue current agent, initiate rivaroxaban within 2 h of the next scheduled dose	Discontinue current agent, initiate dabigatran within 2 h of the next scheduled dose
LMWH to NOAC	Discontinue LMWH, start apixaban at time of next scheduled dose	Discontinue LMWH, start edoxaban at time of next scheduled dose	Discontinue the LMWH, initiate rivaroxaban within 2 h of next dose	Discontinue the LMWH, initiate dabigatran within 2 h of next dose
NOAC to LMWH	Discontinue apixaban, start LMWH at time of next dose	Discontinue edoxaban, start LMWH at time of next dose	Discontinue rivaroxaban, start LMWH at time of next dose	Discontinue dabigatran, start LMWH at time of next dose

CrCl, creatinine clearance; INR, international normalized ratio; LMWH, low-molecular-weight heparin; NOAC, novel oral anticoagulant.

NOAC MONITORING

Routine laboratory monitoring is not required for the novel oral anticoagulants.

The aPTT test provides an approximation of dabigatran's anticoagulant effect.

Anti-FXa activity with apixaban and rivaroxaban can be used to determine the degree of anticoagulation. Signs and symptoms of bleeding should be part of a

daily routine and managed accordingly if bleeding should occur.

ACTIVE BLEEDING AND REVERSING ANTICOAGULANTS

In the emergent need for surgery or urgent need for a procedure that might result in clinically significant bleeding, there may be a requirement for reversing the anticoagulant effects. In addition, bleeding is a heterogeneous phenomenon with management that requires individualized treatment approaches.[17] **Figure 31.2** illustrates a decision pathway for addressing bleeding while on anticoagulants, and **Tables 31.4 to 31.6** provide information on reversal strategies for anticoagulants used when treating AF. The use of a reversal agent is probably not warranted in most cases when active bleeding is responding to supportive care, attempting to accelerate the time to an elective procedure, a response to high drug serum concentrations, or elevated laboratory parameters.[4]

Prothrombin complex concentrate, 4-factor use is off-label for reversing apixaban, edoxaban, rivaroxaban, and enoxaparin.
[a]Andexanet alfa is not yet approved by the United States Food and Drug Administration, doses adapted from the ANNEXA-4 interim analysis study.
[b]Evidence does not support complete reversal of the anticoagulant effect. Use clinical judgment and consider other treatment options.

TABLE 31.5 Reversal of Warfarin for Elevated INR and/or Bleeding

INR < 5 without significant bleeding	Lower or hold next dose, then resume at lower dose when INR is therapeutic
INR between 5 and 9 without significant bleeding	Hold warfarin until INR is in therapeutic range, then resume at a lower dose May consider PO vitamin K 2.5 mg
INR > 9 without significant bleeding	Hold warfarin and give PO vitamin K 2.5–5 mg, expect INR reversal in 24–48 h
Significant bleeding with any INR	Hold warfarin Administer prothrombin complex concentrate (PCC) 25–50 units/kg-or-FFP 15 mL/kg (1 unit = 200–250 mL) plus vitamin K IV[a] 10 mg over 30 min depending on clinical situation Note: Expect INR reversal with vitamin K within 12–48 h, FFP within 1–4 h, and PCC within

15 min PCC preferred option in patients with TBI and/or ICH

[a]Evidence does not support complete reversal of the anticoagulant effect. Use clinical judgment and consider other treatment options.
FFP, fresh frozen plasma; ICH, intracranial hemorrhage; INR, international normalized ratio; IV, intravenously; PCC, prothrombin complex concentrate; PO, per oral; TBI, traumatic brain injury.

TABLE 31.6 Protamine Sulfate Dosing for Low-Molecular-Weight and Unfractionated Heparins

TIME SINCE LAST LMWH DOSE	PROTAMINE DOSE FOR EACH: DALTEPARIN 100 UNITS OR ENOXAPARIN 1 MG
<8 h	1 mg (or 50 mg fixed dose)
8–12 h	0.5 mg (or 25 mg fixed dose)
>12 h	Not likely useful (consider 25 mg fixed dose)
TIME SINCE LAST HEPARIN DOSE	**PROTAMINE DOSE FOR EACH 100 UNITS OF HEPARIN**
Immediate	1 mg (or 25 mg fixed dose)
30 min	0.5 mg (or 10 mg fixed dose)
>2 h	0.25 mg (or 10 mg fixed dose)
Consider a second protamine dose (50% of first dose) if prolonged aPTT continues	

aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin.

The source of bleeding has to be appropriately identified, managed, and treated such that rapid reversal of anticoagulation will not necessarily solve the underlying bleeding.[4] Thus, once bleeding is identified, the first priority is to locate the source and discontinue the anticoagulant agent. The clinical stability of the patient should serve as a guide for the next steps. For example, significant blood loss causing hypovolemic shock from a gastrointestinal bleed may require volume administered with blood transfusions. In addition, directly reversing the anticoagulant effect may also aid in restoring the bleeding diathesis. On the other hand, an intracranial hemorrhage generally requires less volume, but directly reversing the anticoagulant effect may be preferred. Volume restoration during hemorrhage, for example, with crystalloids, colloids, and/or blood transfusion protocols is beyond the scope of this chapter, but an overview of anticoagulant reversal agents is provided.

Reversal agents and strategies discussed include idarucizumab for dabigatran,

andexanet alfa (andexanet) for anti-FXa NOACs and LMWHs, prothrombin complex concentrates (PCCs) with vitamin K for warfarin, and protamine sulfate for UFH. Andexanet is currently in later phases of premarketing clinical trials. An additional agent, ciraparantag, is in very early stages of development with a broader spectrum of anticoagulants potentially reversed by this agent.

IDARUCIZUMAB FOR DABIGATRAN REVERSAL

Idarucizumab is a monoclonal antibody fragment that binds dabigatran with a 350-fold or so higher affinity to that of thrombin.[18] As a result, idarucizumab adheres to thrombin-bound dabigatran and neutralizes its activity. Currently, idarucizumab is approved by the US FDA for the reversal of the anticoagulant effects of dabigatran, needed for emergency surgery/urgent procedures or in life-threatening or uncontrollable bleeding.

The RE-VERSE AD trial examined the safety and reversal capacity of idarucizumab on dabigatran in patients who had a serious bleeding event or required reversal for an urgent procedure.[18] Serious bleeding was defined as overt, uncontrollable, or life-threatening bleeding that was judged by the treating clinician to require a reversal agent, and an urgent procedure was defined as requiring surgery or other invasive procedures that could not be delayed for at least 8 hours and for which normal hemostasis was required.[18] Idarucizumab was administered as a 5-g dose divided into two separate bolus infusions of 2.5 g in 50 mL within 15 minutes of one another. The results demonstrated rapid and complete reversal effects of dabigatran in 88% to 98% of patients.[18]

Idarucizumab is not without potential side effects that may include direct effects of the agent such as anaphylaxis, other hypersensitivity reactions, and serious reactions with hereditary fructose intolerance because sorbitol is a component of the preparation. A prothrombotic effect of dabigatran reversal by idarucizumab leading to thrombosis may also occur once the anticoagulant effects have been reversed, for example, in those with a high CHA_2DS_2-VASc score. In some patients, a delayed increase in dabigatran serum concentrations, such as 12 to 24 hours after idarucizumab administration, may reflect an increase in clotting time markers possibly due to intravascular redistribution of dabatran.[18] It is unknown whether additional doses of idarucizumab would be effective and safe in such scenarios.[18]

Because the cost of each dose of idarucizumab is currently in the several thousands of US dollars, it may be fiscally prudent for hospitals and health

systems to create multidisciplinary policies, procedures, and standardized protocols. Components of such consensus documents may include selecting appropriate clinical scenarios for use, monitoring parameters and frequencies, procurement quantities, and location of refrigerator storage within the institution to avoid waste.

ANDEXANET ALFA FOR FACTOR XA INHIBITOR REVERSAL

Not yet approved by the US FDA, andexanet alfa (andexanet) is a recombinant modified human FXa decoy protein that reverses the inhibitory effects of anti-FXa agents.[19] These counteractive effects of FXa inhibition by NOACs and LMWHs restore FXa activity and therefore the potential for clot formation.

The ANNEXA-4 trial is actively evaluating the activity of andexanet in patients with acute major bleeding within 18 hours of the administration of an FXa inhibitor, including apixaban, edoxaban, rivaroxaban, and enoxaparin.[19] Andexanet was administered by an initial bolus infusion over 15 to 30 minutes followed by a 2-hour infusion to maintain activity against the anti-FXa agent. Doses were relatively lower for patients who had taken apixaban or rivaroxaban more than 7 hours before the administration of andexanet and higher for patients who had taken enoxaparin, edoxaban, or rivaroxaban 7 hours or less before the administration of the bolus dose or at an unknown time. Clinical monitoring parameters for efficacy endpoints included changes in anti-FXa activity and hemostasis within a 12-hour period.[19] The most updated preliminary analysis of this ongoing trial demonstrated 79% of patients with relatively effective hemostasis after receiving the bolus and 2-hour infusion of andexanet. There were no reported serious side effects attributed directly to andexanet; however, thrombotic events occurred in 18% of patients.[19]

Additional data from the ongoing ANNEXA-4 trials, as well as from controlled trials, are needed to determine the safety of thrombotic event frequency compared with what is expected.[19] Further research is necessary to understand how this antidote will be used in clinical practice.

PROTHROMBIN COMPLEX CONCENTRATES WITH VITAMIN K FOR WARFARIN REVERSAL

The traditional approach to treat bleeding associated with warfarin is to administer fresh frozen plasma (FFP). However, there are significant drawbacks with using FFP. All clotting factors are included in FFP, derived from human

plasma, which often contains numerous antibodies. This increases the risk of infusion-related reactions, with the most severe consequence being transfusion-related acute lung injury. In addition, an extensive volume (15 mL/kg per unit) is required for reversal, which may be a limiting factor for volume-restricted patients with poor cardiovascular status. FFP also possesses its own intrinsic INR ranging from 1.5 to 1.7, owing to the presence of all clotting factors.

PCC is a concentrated form of factors II, VII, IX, and X and proteins C and S, which specifically targets all mechanisms involved with warfarin and includes those involved with NOACs. This product requires a higher degree of purity for processing compared with FFP, which dramatically lessens the likelihood of transfusion-related complications. The major advantages of PCC is that reversal requires much smaller volumes (1 to 2 mL/kg per unit), which can be infused over a shorter period of time.

Vitamin K may be administered as an individual agent in the setting of INR elevations with warfarin without significant bleeding. When administered as a single agent as intravenous or po, it is extremely slow to reverse the effects of INR, which will not be evident until approximately 24 to 48 hours after administration.

Over time, concentrated vitamin-K–dependent clotting factors have been used until recently with the introduction of 4-factor (4F)-PCC with vitamin K. In a multicenter, open-label, randomized, plasma-controlled noninferiority clinical trial using FFP versus 4F-PCC in patients with acute bleeding associated with VKA therapy for the achievement of effective hemostasis within 24 hours was evaluated. Superiority was also examined through reduction of INR to ≤1.3 within 30 minutes of the completed infusion.[20] Effective hemostasis was defined as cessation of bleeding within 4 hours of the end of the infusion and no additional coagulation intervention required within 24 hours. Within 24 hours, hemostasis was achieved in 72.4% of those receiving 4F-PCC versus 65.4% receiving FFP, demonstrating noninferiority.[20] There was no statistically significant difference detected for mortality or length of stay between 4F-PCC and FFP. Serious adverse events associated with reversal of VKAs with 4F-PCC were reported in 31% of patients, of which only 10 were deemed directly related to treatment.[20] When compared with FFP, rates of serious adverse events appeared similar; however, no clinical trial has been powered to specifically evaluate differences in safety.

Tables 31.4 and 31.5 outline the specific information regarding the dosing for FFP, PCC, and vitamin K for anticoagulation reversal.

PROTAMINE FOR REVERSAL OF HEPARINS

Particularly relevant to those patients requiring bridging with UFH when initiating therapy with warfarin, protamine will provide an effective means for stopping acute bleeding. There is no role for the use of protamine for reversal of NOACs. Protamine provides complete reversal of anticoagulant effects from UFH and partial reversal with LMWH, enoxaparin and dalteparin. See **Table 31.6** for dosing recommendations for protamine, which is based on administration times for each anticoagulant. Protamine should be administered slowly, with a maximum dose of 50 mg over 10 minutes to minimize the adverse effect of hypotension. If outcomes are promising from the future reversal agent in the pipeline, ciraparantag may end up replacing protamine for these agents, noting its broad effect upon reversal of anticoagulants.

REINITIATING ANTICOAGULATION POST BLEEDING

When bleeding occurs, especially from the gastrointestinal or urinary tracts, the presence of an underlying occult lesion should always be considered.[3] Once hemostasis is achieved, the decision whether and when to reinitiate anticoagulation therapy after reversing the anticoagulant effects for a severe bleeding episode may be necessary and should be considered on an individualized basis.[4] The ongoing use of the $CHADS_2$-DS_2-VASc and HAS-BLED systems together may provide guidance in this particular decision-making process. In patients for whom anticoagulation therapy is needed after hospitalization for a gastrointestinal bleed, reinitiating anticoagulation within 90 days of the event demonstrated positive outcomes on thrombotic events and death.[21, 22]

PERIOPERATIVE BRIDGING FOR SURGERY AND PROCEDURES

When chronic anticoagulation therapy is required, such as in AF, adequate anticoagulation before and after surgery or an invasive procedure may be needed, particularly when the risk of thromboembolism is high. The concept of anticoagulant “bridging” is essentially administering a short-acting anticoagulant (eg, UFH or LMWH) during the time when a long-acting warfarin is being withheld before the surgery, then continued after the surgery or procedure until

the long-acting anticoagulant is again within the target therapeutic range.[23] Because the NOACs have a faster offset of action compared with warfarin and a rapid onset of action, bridging with UFH or an LMWH may not be necessary, unless the patient is not able to take oral therapy such as with gastric resection or postoperative ileus.[23]

Not all procedures require anticoagulants to be held, for example, minor dental and skin procedures, cataract extraction, and selected cardiac device implantation.[23] The NOACs need to generally be held for 1 to 4 days before the procedure, with the interruption interval depending on the specific agent, patient's renal function, and type of bleeding risk of the procedure.[24] **Table 31.7** provides recommendations by the manufacturers and from clinical trials for the timing of discontinuing anticoagulants before surgery or procedures. Postoperative resumption of NOACs should take into account their rapid onset of action (1 to 3 hours postingestion), and can be restarted approximately 24 hours after low-bleed risk and 48 to 72 hours after high-bleed risk procedures.[24] With urgent surgery, there is no evidence suggesting higher bleeding rates with NOACs as compared with patients treated with warfarin.[24]

TABLE 31.7 Periprocedural Bridging: Anticoagulation Interruption for Surgery and Procedures

	APIXABAN FACTOR XA INHIBITOR	EDOXABAN FACTOR XA INHIBITOR	RIVAROXABAN FACTOR XA INHIBITOR	ENOXAPARIN FACTOR XA INHIBITOR	DABIGATRAN DIRECT THROMBIN INHIBITOR	WARFARIN VITAMIN K ANTAGONIST	UNFRACTIONATED HEPARIN
Procedures to not withhold anticoagulation	Not all procedures require anticoagulation to be held. Examples include minor dental procedures (such as cleaning, scaling, extraction), minor skin procedures, cataract extraction, selected cardiac device implantation, and routine endoscopy. Design a plan with the clinician performing the procedure and the patient.						
Elective low risk surgery and procedures	Discontinue apixaban at least 24 h before elective procedure	Discontinue edoxaban at least 24 h before invasive or surgical procedures. Risk of bleeding should be considered against the urgency of intervention if surgery cannot be delayed	Discontinue rivaroxaban at least 24 h before the procedure	Discontinue 12–18 h before the procedure	CrCl ≥ 50 mL/min Discontinue dabigatran 1–2 d before elective procedure CrCl < 50 mL/min Discontinue dabigatran 3–5 d before elective procedure	Discontinue until desired INR is reached (usual target < 1.5, acheived over 4–5 d)	Discontinue 6–12 h before procedure
Elective moderate to high-risk surgery and procedures	Discontinue apixaban at least 48 h before elective procedure	Discontinue edoxaban at least 24 h before invasive or surgical procedures. Risk of bleeding should be considered against the urgency of intervention if surgery cannot be delayed	Consider longer times based on clinical judgment	Discontinue 12–18 h before the procedure	Consider longer times for major surgery, spinal puncture, or spinal or epidural catheter or port placement	Discontinue until desired INR is reached (usual target < 1.5, acheived over 4–5 d)	Discontinue 6–12 h before procedure

CrCl, creatinine clearance; INR, international normalized ratio.

The BRIDGE investigators conducted a randomized, double-blind, placebo-controlled trial to determine whether foregoing anticoagulant bridge therapy in patients with AF treated with warfarin is noninferior to bridging with the LMWH dalteparin and superior with respect to major bleeding.[25] The mean $CHADS_2$ score was 2.3 (CHA_2DS_2-VASc score was not used for risk stratification at the time of the trial) with only about one-third with a score of 3 or higher, suggesting a relatively lower risk of thrombosis. It is important to point out that patients at high risk for thrombosis, such as those with CHA_2DS_2-VASc scores 2 or greater, and/or those requiring higher intensity warfarin, for example, with mechanical mitral valves may still require perioperative bridge therapy because these scenarios were excluded in the study.[25] In addition, surgical procedures associated with high risks of thrombosis, such as carotid endarterectomy, major cancer surgery, cardiac surgery, or neurosurgery were excluded from the trial. The results of this trial, demonstrated in patients with

AF on warfarin therapy, that LMWH perioperative bridge therapy did not prevent thromboembolic events, but did increase the risk of major bleeding.

It therefore may be reasonable to forego bridging warfarin with UFH or an LMWH in patients at relatively low thromboembolic risk and undergoing procedures to avoid clinically significant bleeding. Using this approach, the patient would therefore discontinue warfarin usually until the INR decreases to below 1.5 (approximately 5 days) before the procedure without being additionally anticoagulated. The perioperative treatment plan should therefore be designed in collaboration with the operating clinician and the patient.

ANTIPLATELET THERAPIES WITH ATRIAL FIBRILLATION

The Stroke Prevention in Atrial Fibrillation-1 (SPAF-1) trial from the early 1990s is the only trial among eight or so evaluated in a meta-analysis to show the benefit of aspirin alone in preventing stroke among patients with AF.[4] The dose seemingly effective was aspirin 325 mg once daily. Aspirin was not effective in those older than 75 years of age, did not prevent severe stroke, and has not been studied in low-risk populations.[4]

Clopidogrel 75 mg once daily plus aspirin 75 to 100 mg once daily was evaluated for stroke prevention in the ***A***trial Fibrillation ***C***lopidogrel ***T***rial With ***I***rbesartan for Prevention of ***V***ascular ***E***vents (ACTIVE-W) trial and terminated early because in patients with a mean $CHADS_2$ score of 2, the combination of antiplatelet agents was inferior to warfarin (target INR 2 to 3).[4] The ACTIVE-A trial compared clopidogrel plus aspirin versus aspirin alone and demonstrated superiority in stroke prevention of the combination antiplatelet therapy to aspirin alone; however, the benefits were diminished by the increases in severe bleeding rates.

The AVERROES study was a direct comparison between aspirin and the FXa inhibitor apixaban.[4, 26] This double-blind study of 5,599 patients deemed unsuitable for warfarin therapy were randomized to apixaban 5 mg twice daily (2.5 mg twice daily for those who had two of the following three: age ≥ 80 years, weight ≤ 60 kg, serum creatinine ≥ 1.5 mg/dL) or to aspirin 81 or 325 mg once daily. The trial was prematurely terminated owing to the observed superiority of apixaban over aspirin for the occurrence of any stroke or systemic embolism.

Major bleeding rates were similar between apixaban and aspirin.

With respect to triple antithrombotic therapy with concomitant dual antiplatelet agents and NOACs, there is a paucity of literature for evaluation. Several landmark trials that studied NOACs for stroke prophylaxis with NVAF excluded the combination of aspirin with a $P2Y_{12}$ inhibitor (eg, clopidogrel, prasugrel, ticagrelor).[8–11,26] Therefore, an important remaining unanswered question is in patients with AF requiring anticoagulation and at the same time dual antiplatelet therapy with aspirin and a $P2Y_{12}$ inhibitor for coronary intervention such as stenting.

The SAFE-A study that compares 1-month versus 6-month $P2Y_{12}$ inhibitor therapy in combination with aspirin and apixaban, in patients with AF who undergo drug-eluding stent implantation, is currently under way.[27] The primary outcome will be the incidence of all bleeding complications occurring within 12 months. Ultimately, this study will provide data that may guide the optimal management of triple antithrombotic therapy.

Additional medications that have antiplatelet properties should be used with caution when taken concomitantly with NOACs. Such agents include NSAIDs, such as naproxen, ibuprofen, celecoxib, diclofenac, and meloxicam. In addition, selective serotonin reuptake inhibitors (SSRIs) commonly used as antidepressants, such as paroxetine, fluoxetine, sertraline, citalopram, and escitalopram, and serotonin norepinephrine reuptake inhibitors (SNRIs) commonly used as antidepressants and neurogenic pain analgesics, such as duloxetine and venlafaxine, should be used with caution.

ABILITY TO PAY AND LIKELY TO ADHERE TO THERAPY

Perhaps the greatest risk factor for thrombotic events with AF is the inability to take the prescribed anticoagulant on a daily basis.[4] This is particularly important with NOACs because the duration of action is shorter than that of warfarin, so missing even one dose of a NOAC increases the risk of thrombosis.

The reasons for nonadherence to a drug therapy regimen are multifaceted and highly individualized. Barriers that cause patients not to take their medication as prescribed may include the health literacy of the patient and/or caregiver, emotional state and acceptance of the need for chronic daily medications, side effects and intolerances, and the inability to obtain the drug because of cost or

other reasons. Discontinuing a NOAC should not occur without proper anticoagulant coverage, such as with warfarin and/or LMWH for patients who will still require treatment.[4] During the transitions of care when patients are admitted to and discharged from the hospital and/or patient care units, it is critical to accurately reconcile the medication regimen, including anticoagulant therapy to avoid thromboembolic events from omission errors. Prescribers are encouraged to discuss outpatient prescription drug coverage and the patient's intentions and ability to continue the oral anticoagulant therapy upon hospital discharge.

Patient and Family Information for: MODERN ANTICOAGULATION THERAPY

ATRIAL FIBRILLATION

AF is an irregular heart beat that increases the risk of forming a blood clot in the heart. If the blood clot travels from the heart, it can cause a stroke. Anticoagulants are medications that lower the chances of having a stroke by thinning the blood and therefore helping to prevent clots from forming.

A patient who stops taking the prescribed anticoagulant may have an increased risk of forming a clot in the heart and bloodstream. Do not stop taking the prescribed anticoagulant without talking to the doctor who prescribed it. Missing even one dose may increase the chances of forming a blood clot. In case the anticoagulant medicine has to be stopped, be sure to tell the doctor.

TAKING ANTICOAGULANT MEDICATIONS

Take medication exactly as prescribed by the doctor. If the instructions are not clear, ask the doctor or pharmacist to explain.

- Do not change the dose or stop taking the anticoagulant unless the doctor says so.
- The doctor will tell how much medicine to take and when to take it.
- The doctor may change the dose if needed.

SIDE EFFECTS

All medications have the potential to cause side effects, and anticoagulants are no exception. There is a difference between an allergic reaction and a side effect. Allergic reactions are types of side effects, for example, a rash, which usually means the patient never takes the medicine again. Side effects, for example, bleeding or an upset stomach, due to an anticoagulant are usually dealt with simply by stopping the medication or changing to another similar alternative. It is important to report any side effects the patient may think he or she is having and to get medical help right away if the patient thinks he or she is bleeding. It is important to learn the signs or symptoms of bleeding.

Anticoagulants can cause bleeding in the brain that can be serious and can cause internal bleeding, which on rare occasions lead to death. This is because anticoagulants are blood thinner medications that reduce blood clotting. While on anticoagulants, the patient is likely to bruise more easily and it may take longer for the bleeding to stop. Do not stop taking the anticoagulant without notifying the doctor on noticing bruising.

SIGNS AND SYMPTOMS OF BLEEDING

Examples of unexpected bleeding or bleeding that lasts a long time may include the following:

- Unusual bleeding from the gums
- Nose bleeds that happen often
- Menstrual bleeding that is heavier than normal or vaginal bleeding
- Bleeding that is severe or cannot be controlled
- Red, pink, or brown urine
- Bright red or black tarry stools
- Coughing up blood or blood clots
- Vomiting blood or the vomit looks like “coffee grounds”
- Headaches and feeling dizzy or weak
- Pain, swelling, or new drainage at wound sites

DRUG INTERACTIONS

There is a chance that while on anticoagulants the patient may have a higher likelihood of bleeding if he or she takes other medicines that cause bleeding. These medications may include aspirin or aspirin-containing products, clopidogrel (Plavix), prasugrel (Effient), ticagrelor (Brilinta), NSAIDs, SSRIs, SNRIs, or any other medicines to prevent or treat blood clots. Inform the doctor about taking any of these medicines and ask the doctor or pharmacist if unsure whether the medicine is one among those listed earlier. Also ask the doctor or pharmacist before taking any new medications, over-the-counter medications, vitamins, or herbal supplements.

SPINAL OR EPIDURAL BLOOD CLOTS

People who take a blood thinner medicine and have an injection into their spinal and epidural area or have a spinal puncture have a risk of forming a blood clot that can cause long-term or permanent loss of the ability to move.

It is important to recognize the signs and symptoms of spinal or epidural blood clots if receiving spinal anesthesia or a spinal puncture. Tell the doctor immediately in case of back pain, tingling, numbness, muscle weakness (especially in the legs and feet), and loss of control of the bowels or bladder (incontinence).

Do not take an anticoagulant, without first talking to the doctor, under the following conditions:

- If the patient has certain types of abnormal bleeding
- If the patient is allergic to the prescribed medication or any of the ingredients; a pharmacist can help identify these ingredients

What to tell the doctor before taking an anticoagulant medication: Inform the doctor about the following:

- Bleeding problems
- Liver or kidney problems
- Any other medical condition
- Being pregnant or planning to become pregnant
- Breastfeeding or plan to breastfeed

Tell the doctor about all the medicines the patient takes, including prescription and nonprescription medicines, vitamins, and herbal supplements.

Also inform all the doctors and dentists about taking an anticoagulant medication.

They should talk to the doctor who prescribed the anticoagulant before the patient has any surgery and medical or dental procedure.

How to take anticoagulant medications:

- Take the medication exactly as prescribed by the doctor.
- Do not change the dose or stop taking the anticoagulant unless the doctor says so.
- The doctor will tell how much anticoagulant to take and when to take it.
- The doctor may change the dose if needed.

How to store anticoagulant medication:

- Anticoagulant medications should be stored at room temperature between 68°F to 77°F (20°C to 25°C).
- Be sure to keep all medicines out of the reach of children.

VI

RISK FACTORS: FROM THE ACUTE SETTING TO CHRONIC MANAGEMENT

Acute Aortic Syndrome

INTRODUCTION

Acute aortic syndrome (AAS) represents a spectrum of life-threatening conditions with similar clinical presentation and the need for urgent management. It includes classic acute aortic dissection (CAAD), intramural hematoma (IMH), and penetrating aortic ulcer (PAU). Although not included in the original definition of AAS, traumatic aortic rupture (TAR) and aortic aneurysm rupture have also been considered to be part of the AAS spectrum.

AAS is characterized by disruption of the media layer of the aorta and typically presents with acute chest pain. The term “acute aortic syndrome” was first coined in 2001 by the Spanish cardiologists Vilacosta and San Román, who described AAS as a spectrum of interlinked lesions[1] with the intent to increase awareness and to speed up diagnosis and appropriate treatment (**Figure 32.1**).

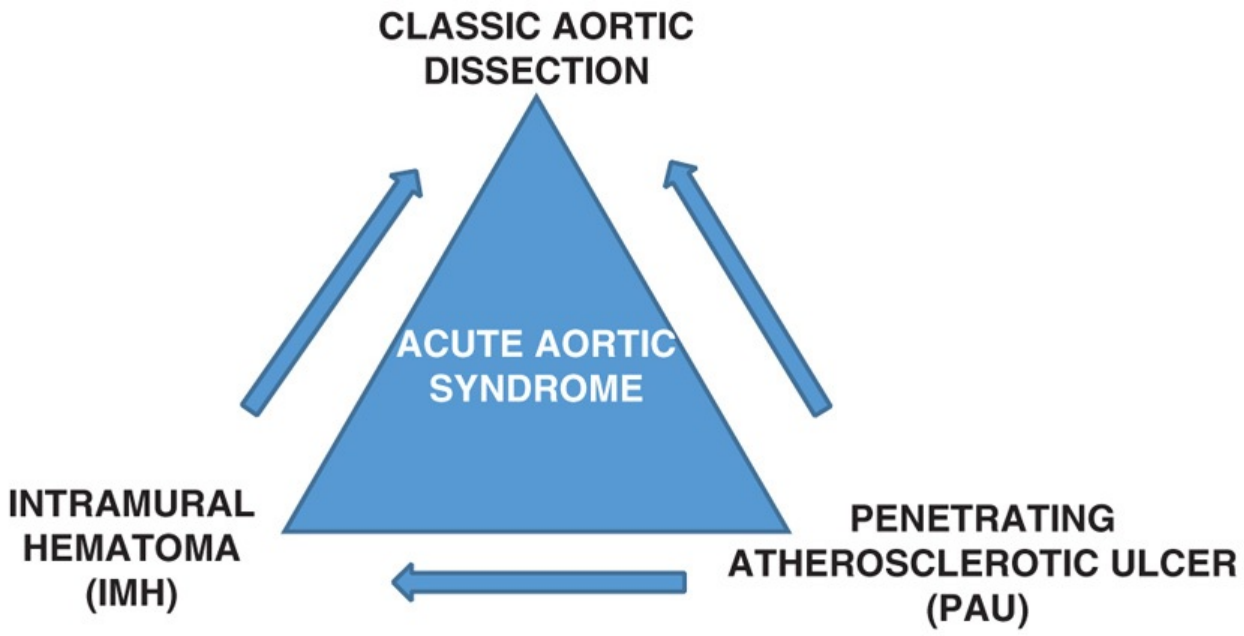

FIGURE 32.1 Acute aortic syndrome. The acute aortic syndrome triad first described by Vilacosta and San Román. Arrows signify possible progression of aortic lesions (penetrating aortic ulcer to IMH, penetrating aortic ulcer to classic dissection, IMH to classic dissection). IMH, intramural hematoma.

Although the incidence of AAS is lower than that of acute coronary syndrome (ACS), AAS carries a higher mortality, and is therefore a critical component of the differential diagnosis of chest pain in the Cardiac Care Unit (CCU). Overall incidence of AASs is 2 to 4 cases per 100,000 individuals. Because AAS is rare, the International Registry of Acute Aortic Dissection (IRAD) was created in 1996 as a way to combine data acquired from multiple top institutions in Europe, North America, and Asia.[2] The 2010 intersocietal guidelines for the diagnosis and management of patients with thoracic aortic disease proposed a standard approach to the diagnosis and treatment of AAS.[3]

Although clinical history and physical examination are important, imaging is essential in the diagnosis of AAS. Transesophageal echocardiography (TEE), computed tomography (CT), and magnetic resonance imaging (MRI) are the preferred imaging modalities and angiography is rarely needed.

CLASSIFICATION OF ACUTE AORTIC SYNDROMES

Historically, CAAD was the first recognized form of AAS. The classification schemes used for the classic aortic dissection were subsequently extended to

include IMH and PAU.

AASs are classified on the basis of the location and extent of involvement of the aorta. Two systems have been proposed, the DeBakey and the Stanford systems (**Figure 32.2**). The DeBakey system, which was proposed in 1965 by the Lebanese-American surgeon Michael Ellis DeBakey, divided aortic dissection into three types based on the anatomic location. Type I originates in the ascending aorta and propagates beyond the aortic arch, type II is limited to the ascending aorta only, and type III is limited to the descending aorta.[4]

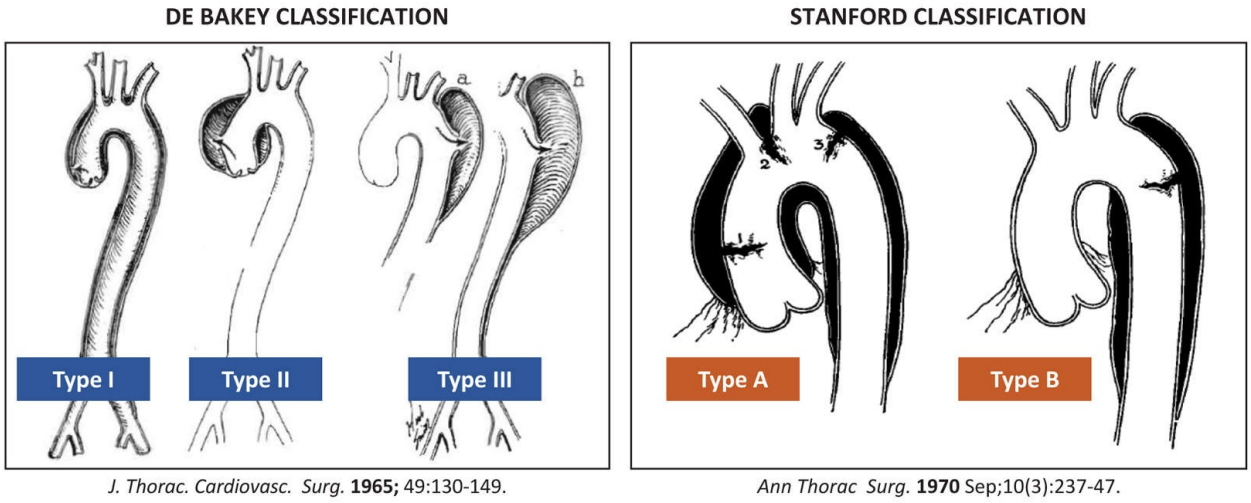

FIGURE 32.2 DeBakey and Stanford classifications. Left: DeBakey classification of aortic dissection. Type I includes the ascending and descending aorta, type II includes the ascending aorta only, and type III includes the descending thoracic aorta only. (DeBakey ME, Henly WS, Cooley DA, et al. Surgical management of dissecting aneurysms of the aorta. *J Thorac Cardiovasc Surg.* 1965;49:130-149.) Right: Stanford classification. Type A aortic dissection involves the ascending thoracic aorta, and type B involves the descending thoracic aorta only. All three AAS conditions; CAAD, IMH, and PAU use the Stanford classification. CAAD, classic acute aortic dissection; IMH, intramural hematoma; PAU, penetrating aortic ulcer. (Daily PO, Trueblood HW, Stinson EB, et al. Management of acute aortic dissections. *Ann Thorac Surg*. 1970;10[3]:237-247.)

The Stanford system, which was created by researchers at Stanford University in 1970, divides aortic dissections into two types. Type A includes any dissection that involves the ascending aorta, whereas type B dissections are limited to the descending thoracic aorta.[5] The Stanford classification appears to have wider acceptance and is now used for all three AAS types: CAAD, IMH, and PAU.

INTRAMURAL HEMATOMA

IMH is defined by crescentic or circumferential thickening of the media layer of

the aortic wall. IMH is likely due to a ruptured vasa vasorum resulting in intramural bleeding but without a detectable intimal tear. It was first described in 1920 by the German pathologist Ernst Kruckenberg, who is also well known for his description of the so-called Kruckenberg tumors (transperitoneal ovarian metastases from stomach and colon cancers). On TEE, CT, or MRI, IMH is typically visualized as a crescentic or concentric thickening of the aortic wall > 5 mm (**Figure 32.3**). The natural history of IMH often includes progression to CAAD, which accounts for its high morbidity and mortality.

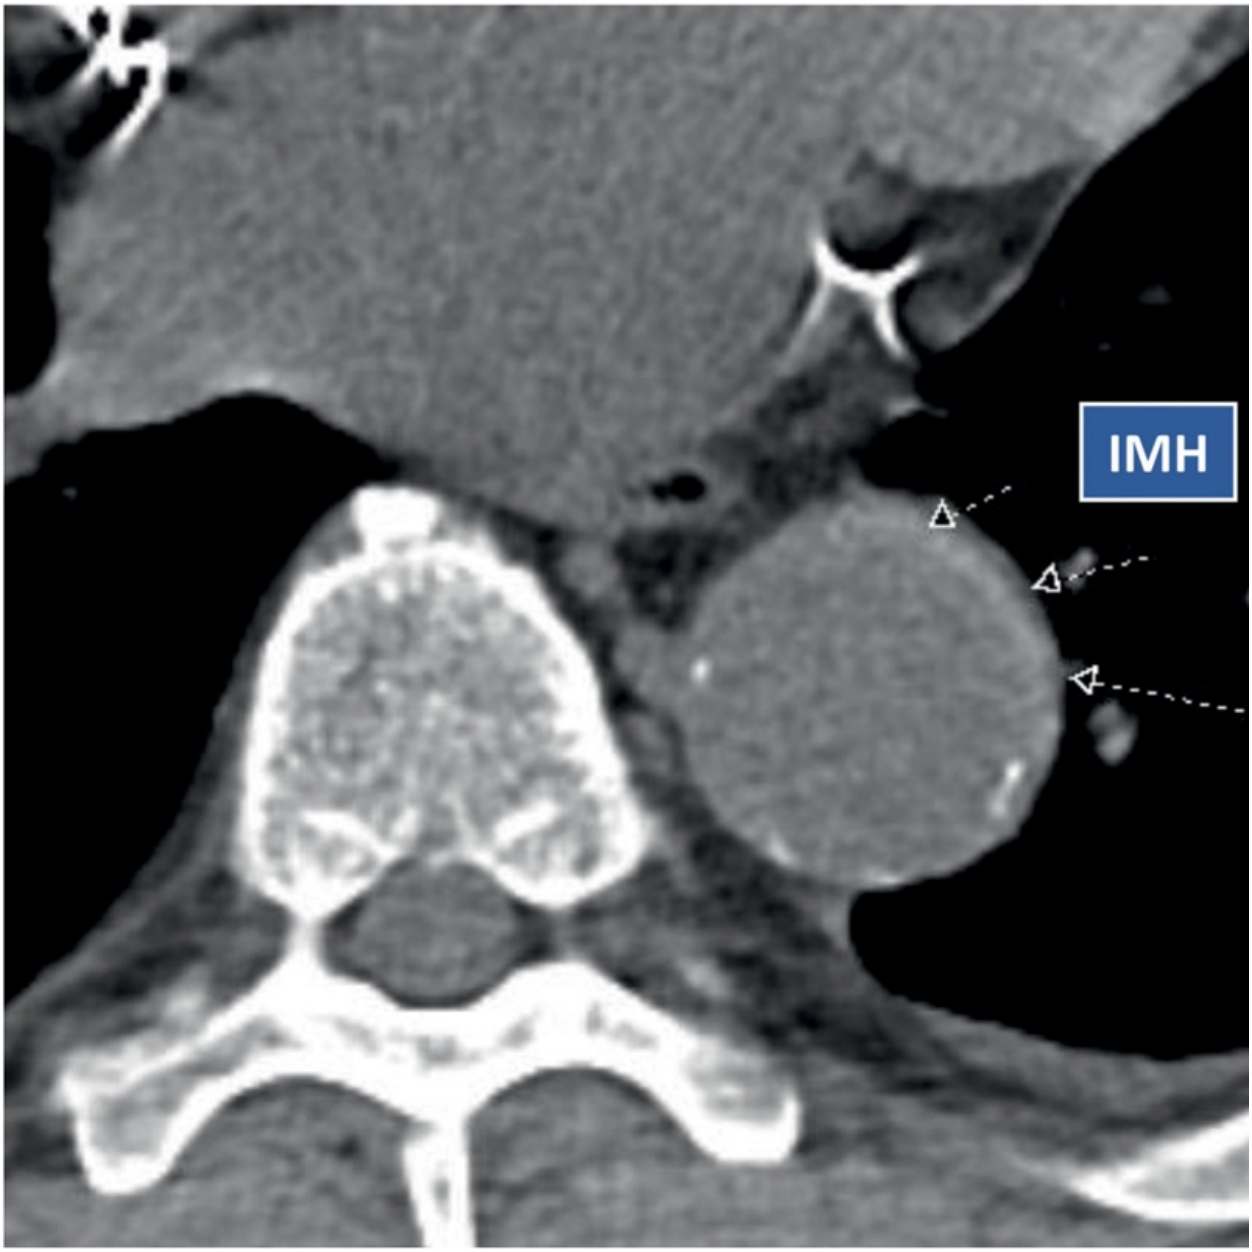

FIGURE 32.3 Intramural hematoma: CT. CT of the chest shows the descending thoracic aorta. The crescentic-shaped lesion on the patient's left signifies an IMH (dashed arrows). CT, computed tomography; IMH, intramural hematoma.

Etiology and Pathophysiology

IMH may account for up to 6% to 30% of all AAS, with a higher reported prevalence among the Korean and Japanese populations as compared with Western subjects.[6] It is unclear whether this is a true discrepancy in prevalence versus a reflection of differing classification, evaluation, or treatment practices. Often, IMH is diagnosed as such even though very small intimal tears indicative of limited aortic dissection may be present but missed by modern imaging modalities. This may overestimate the true prevalence of IMH as opposed to CAAD.

The characteristic feature of IMH is its location in the portion of the media closer to the adventitia, as opposed to CAAD which is typically located in the media closer to the intima. Although the most cited hypothesis of the pathophysiologic mechanism of IMH is rupture of the vasa vasorum, there is very little corroborating clinical or experimental evidence. Owing to the low incidence of IMH and the close association with CAAD, a definitive etiology still remains unclear.[7]

Clinical Manifestations

According to the IRAD experience, IMH typically presents with the symptoms of severe chest and back pain, similar to CAAD. However, IMH is less likely to present with manifestations of severe aortic regurgitation and pulse deficits.[6] IMH is rarely stable. It may either progress to CAAD or regress spontaneously, and therefore serial imaging is crucial. Stanford type B lesions in the descending aorta are more common than type A lesions in the ascending aorta (60% vs 35% of all IMH, respectively). Cardiogenic shock may be present in 14% of patients, more typically with type A IMH.[8] Pericardial effusion and tamponade may also be present, which are also more common in type A IMH. When compared with CAAD, type A IMH has a significantly higher risk of rupture (26% vs 8%, respectively).[9] A widened mediastinum may be present on chest X-ray; however, this is neither sensitive nor specific to IMH.

Diagnosis

As with all types of AAS, rapid diagnosis is paramount in IMH. TEE, CT, and MRI are the preferred diagnostic tools. CT is often chosen because of widespread availability, rapid acquisition, and its ability to diagnose other causes of acute chest pain such as trauma and pulmonary embolism.

Classically, absence of an intimal flap or tear differentiates IMH from CAAD. Often, IMH can be identified even on non–contrast-enhanced CT. On contrast CT scans, a crescentic or circular area of high attenuation that does not enhance with contrast is present. Similar findings are seen on MRI, which has the advantage of not requiring iodinated contrast.

On TEE, IMH is diagnosed if there is regional thickening of the aortic wall > 5 mm in a crescentic or circumferential pattern without an intimal flap or tear (**Figure 32.4A, B**). Limitations of TEE in diagnosing IMH arise from the TEE's inability to visualize all portions of the aorta including the area around the origin of the brachiocephalic artery and all but the most proximal portions of the abdominal aorta. TEE is very useful in diagnosing complications of IMH, such as pericardial effusion or aortic regurgitation.

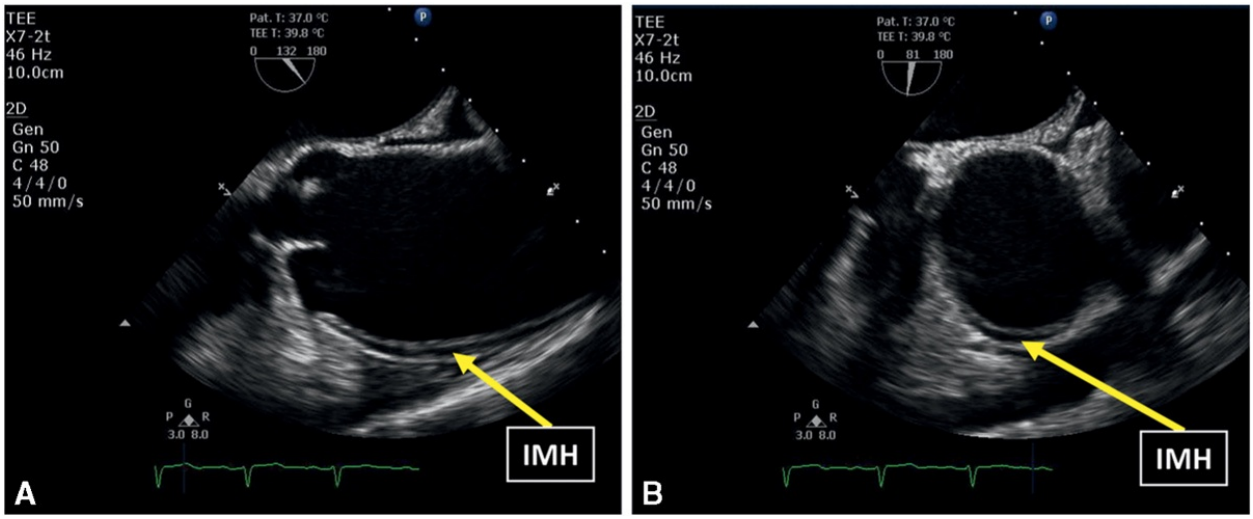

FIGURE 32.4 Intramural hematoma: TEE. Two-dimensional (2D) TEE of the ascending thoracic aorta in the long-axis (A) and short-axis (B) views. Yellow arrows point to a crescentic thickening of the anterior portion of the ascending thoracic aortic wall, consistent with a type A IMH. IMH, intramural hematoma; TEE, transesophageal echocardiography.

Small intimal tears may be missed by any modern imaging technique, challenging the diagnosis of classic IMH.

Management and Prognosis

The prognosis of IMH is somewhat better than that of CAAD. As in all AAS, the main determinant of prognosis is its aortic location. According to the IRAD registry, the mortality of type A IMH is approximately 27%, compared with 4% in type B IMH. Invasively managed patients with type A IMH typically fare better than medically managed patients. Invasive options include open surgical repair and percutaneous thoracic endovascular aortic repair. Medical management typically consists of heart rate (HR), blood pressure, and pain control. Surgical mortality for IMH is similar to that for other forms of AAS.

Type B IMH is often managed medically. Approximately 50% of type B patients may improve with medical management alone, 15% will remain stable, and 35% may progress to aneurysm formation, CAAD, or focal aortic rupture (pseudoaneurysm).[10]

Intramural Hematoma in Pregnancy

Although there are no specific guidelines in pregnancy for patients with IMH, pregnancy is considered a risk factor for the development of aortic pathology, especially in Marfan syndrome. As with other forms of AAS, expedited delivery via caesarian section is considered reasonable for pregnant patients with acute IMH, if possible.

CLASSIC ACUTE AORTIC DISSECTION

CAAD is the most common form of AAS.[2] It occurs in approximately 66% to 75% of all AAS. The overall incidence of CAAD is low, estimated at 0.5 to 4.0 cases per 100,000 per year, and is thought to affect men more than women in a 2:1 ratio.

Risk factors for CAAD include connective tissue disorders such as Marfan (fibrillin gene), Loeys–Dietz (transforming growth factor β receptor 1 and 2 genes), Ehlers–Danlos type 4 (collagen gene), and Turner syndrome (X monosomy), as well as the aortopathy associated with bicuspid aortic valve (*NOTCH1* gene). In addition, hypertension is a significant risk factor and is more prevalent among older patients. Last, aortic instrumentation or surgery, as well as cardiac catheterization, are rare but reported causes of aortic dissection.

CAAD was first described in 1555 by Andreas Vesalius (1514–1564) who reported traumatic abdominal aortic aneurysm in a man who fell off a horse.[11] Intimal tear, the hallmark of CAAD, was first described by Daniel Sennert (1572–1637), a German anatomist and published in 1650 posthumously.[12] A

very famous description of CAAD was by the British royal physician Frank Nichols (1699–1778) who provided the first unmistakable account of CAAD (deemed a “Transverse fissure of the aortic trunk”) in his autopsy of King George II, who died in 1760 while straining in the lavatory. Successful surgical repair of descending aortic dissection was not reported until 1955, by Michael Debakey (1908–2008) and his colleagues, and ascending dissection until 1962 by Frank Spencer and Hu Blake.[13,14]

Etiology and Pathophysiology

CAAD is characterized by an intimal tear, which leads to abnormal blood flow from the aortic lumen into the media (**Figure 32.5**). Consequently, there is a longitudinal separation of the media layers by the blood flow, which tears an intimomedial flap from the remainder of the aortic wall (**Figure 32.6A–C**). This flap separates the abnormal false lumen from the true aortic lumen. Intimal tears typically occur at the locations within the aorta with the highest shear stress. These are at the right side of the ascending aorta immediately distal to the ostium of the right coronary artery (type A dissections) and immediately distal to the ostium of the subclavian artery adjacent to the insertion of the ligamentum arteriosus (type B dissections).

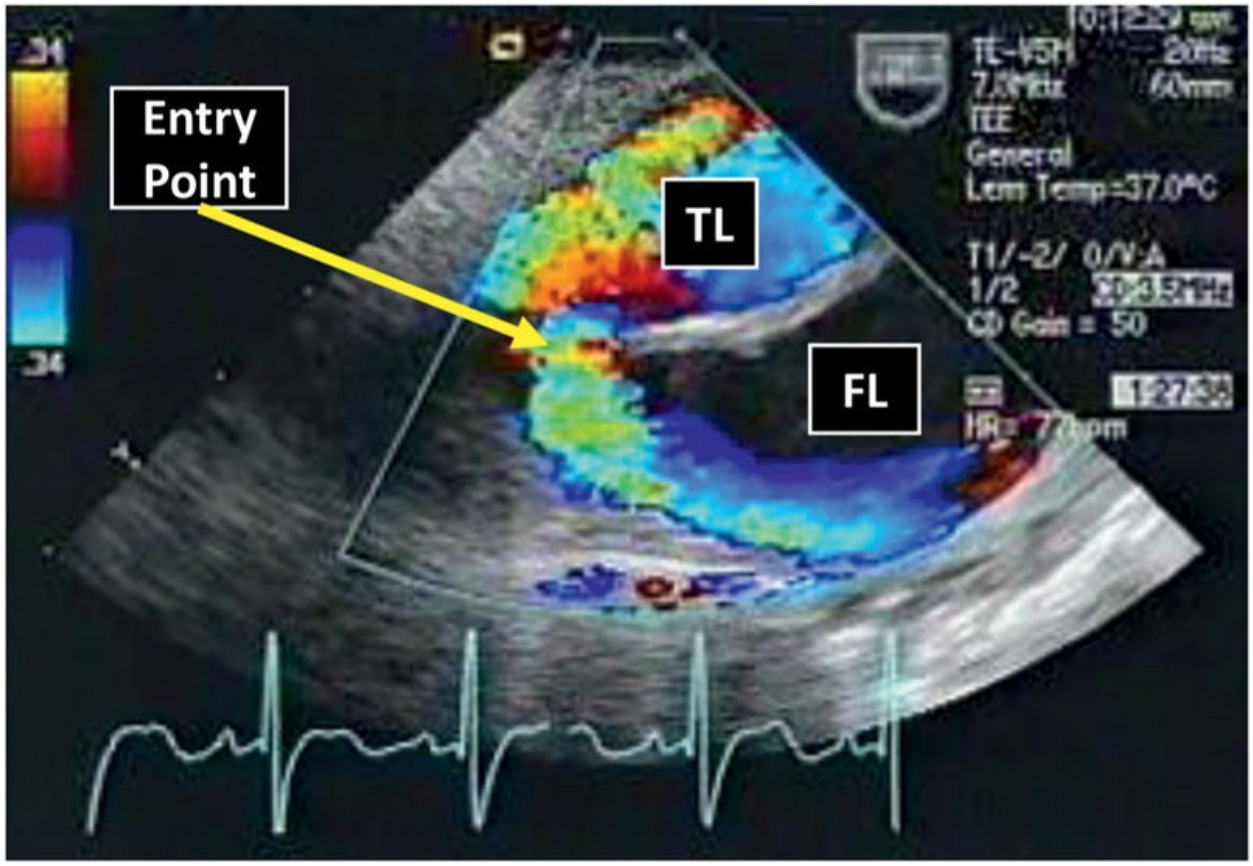

FIGURE 32.5 Classic acute aortic dissection: entry point on TEE. Two-dimensional (2D) TEE with color Doppler of the aortic arch in the upper esophageal view. Yellow arrow points to the entry point of flow from the true lumen to the false lumen, characteristic of CAAD. CAAD, classic acute aortic dissection; FL, false lumen; TEE, transesophageal echocardiography; TL, true lumen.

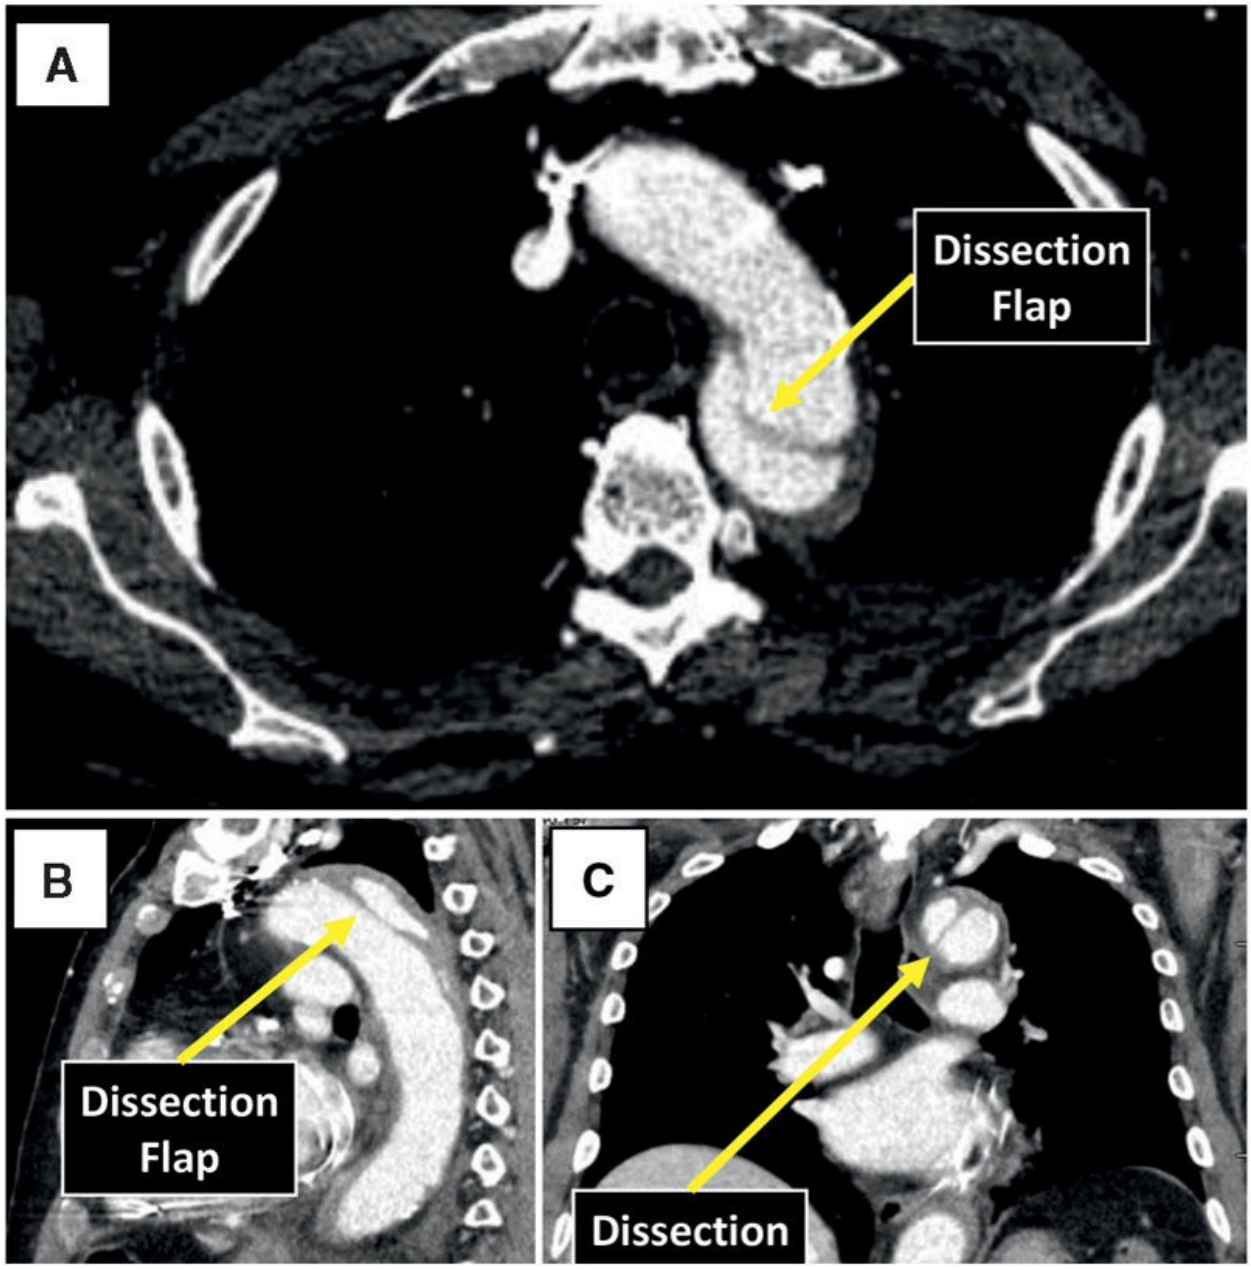

FIGURE 32.6 Classic acute aortic dissection: CT. Multidetector row CT with intravenous iodinated contrast in the axial view (A), sagittal view (B), and the coronal view (C). Yellow arrows point to dissection flap at the junction of the aortic arch and descending thoracic aorta, consistent with CAAD. CAAD, classic acute aortic dissection; CT, computed tomography.

Complications such as aortic regurgitation and pericardial tamponade can occur; and, over time, chronic changes such as false lumen thrombosis and aneurysm are common.

Clinical Manifestations

The typical symptom of acute aortic dissection is “aortic pain” similar to other forms of AAS. Acute, severe, tearing chest pain is the hallmark symptom of CAAD. Pain limited to the chest is typical of type A CAAD, and pain in the back is more often the symptom of type B CAAD. One study found older patients are less likely to abrupt onset of pain as compared with younger patients.[15]

Pulse deficit, present in up to 33% of patients according to the IRAD study, reflects impaired or absent blood flow to peripheral vessels. This is manifested by weak carotid, brachial, or femoral pulses on physical examination.

Other physical examination findings of CAAD include diastolic murmur or aortic regurgitation, hypotension related to either tamponade or aortic rupture, focal neurologic deficits reflecting propagation of the dissection toward involvement of carotid or cerebral arteries, and syncope.

Electrocardiogram (ECG) may be useful in distinguishing the chest pain of AAS from ACSs; unlike ACS, uncomplicated CAAD does not present with ischemic ECG changes. However, if the aortic dissection leads to coronary ischemia through involvement of coronary ostia (type A), the ECG will be less helpful with differentiation of symptoms.

Chest X-ray (CXR) imaging occasionally shows widening of the mediastinum, a nonspecific finding seen with other syndromes such as mediastinal hematoma. Other CXR findings are double aortic knob (40% of patients), tracheal displacement to the right, and enlargement of the cardiac silhouette.

Serum biomarkers such as D-dimer are often elevated in CAAD, but this is a nonspecific finding. In contrast, a normal D-dimer level may help exclude the diagnosis of CAAD. Investigational biomarkers such as elastin degradation products, calponin, fibrinogen, fibrillin, and smooth muscle myosin heavy chain are currently being evaluated.

Diagnosis

As with other forms of AAS, the 2010 intersocietal guidelines for the diagnosis and management of patients with thoracic aortic disease provide a useful decision tool to help guide diagnostic and management strategies for CAAD with a special emphasis on a combination of clinical risk assessment and rapid imaging.

CT with intravenous iodinated contrast is often the diagnostic modality of choice for CAAD because of its superb spatial resolution, rapid acquisition times, widespread availability, and its ability to diagnose other causes of acute

chest pain such as trauma and pulmonary embolism. The reported sensitivity of CT for CAAD is 87% to 94% and specificity is 92% to 100%. CT features of CAAD are intimal tear, dissection flap with a true and false lumen, dilatation of the aorta, and pericardial effusion.

TEE is especially useful in the diagnosis of CAAD when a CT with contrast cannot be performed, such as in hemodynamically unstable patients or in patients in whom the risk of iodinated intravenous contrast is high such as renal insufficiency or severe allergy. The reported sensitivity of TEE is 98% and specificity is 63% to 93%. Findings on TEE are a dissection flap separating the true and false lumen, site of intimal tear represented by flow from the true lumen into the false lumen on color Doppler (**Figure 32.7**). Spectral Doppler may help corroborate the diagnosis by demonstrating "to and fro" flow into and out of the false lumen.

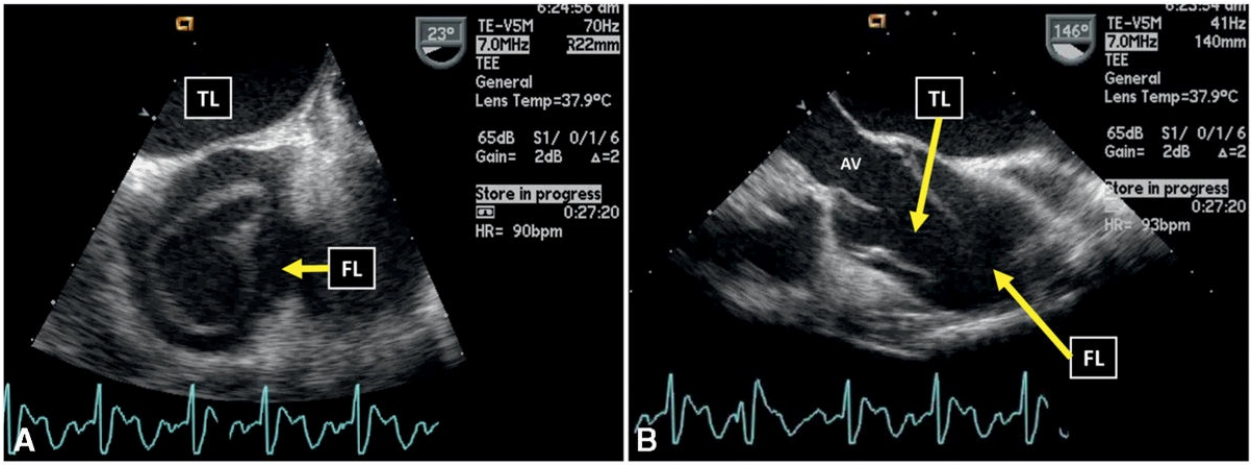

FIGURE 32.7 Classic acute aortic dissection: dissection flap on TEE. Two-dimensional (2D) TEE of the ascending thoracic aorta in short axis (A) and long axis (B) demonstrating CAAD. In this case, the dissection flap is circumferential with a 360° separation of the true and false lumens. CAAD, classic acute aortic dissection; FL, false lumen; TEE, transesophageal echocardiography; TL, true lumen.

The true lumen is identified by its expansion with systole and contraction in diastole. The true lumen is often smaller than the false lumen. In early stages, the false lumen may be echo free or may contain spontaneous echo contrast (also known as "smoke") due to stasis of blood flow. In later, more chronic stages, the false lumen may be partly or completely obliterated by thrombus formation.

Complications of CAAD may be seen on echocardiography such as aortic regurgitation, pericardial effusion/tamponade, and wall motion abnormalities indicative of ischemia if there is coronary ostial involvement.

It is important not to confuse the intimomedial flap of CAAD with either artifacts or surrounding vascular structures. Linear reverberation artifacts in the ascending aorta should not be mistaken for type A aortic dissection. Typically, reverberation artifacts are located twice as deep as the anterior aortic wall. In addition, a dilated azygos vein adjacent to the descending thoracic aorta may give an illusion of a type B dissection. Color or spectral Doppler imaging in both instances may help distinguish true aortic dissection from its masqueraders (**Figure 32.8**).

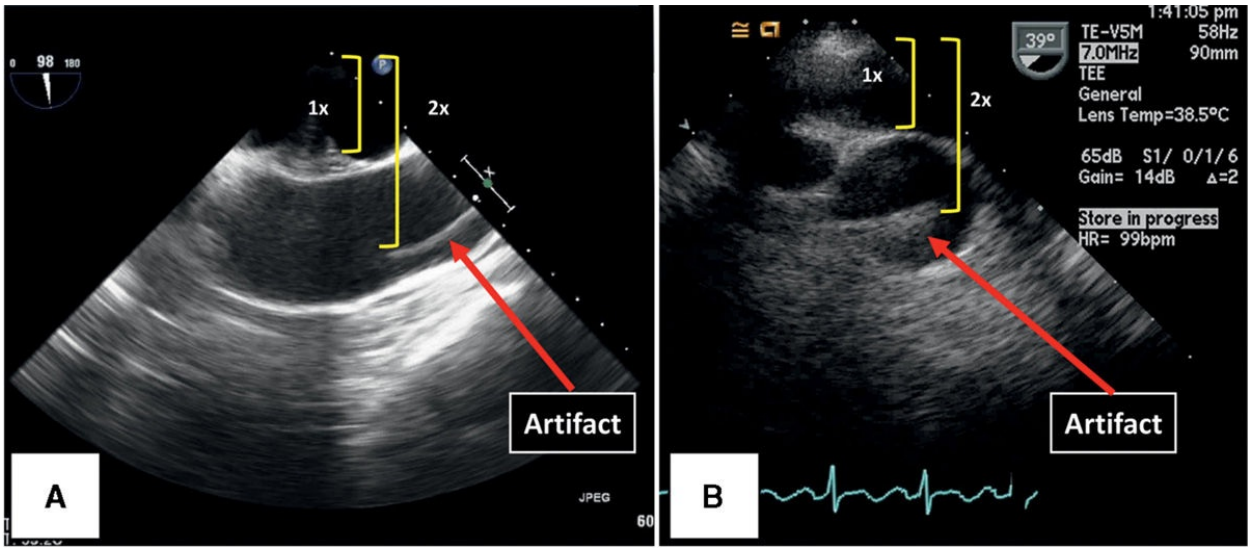

FIGURE 32.8 Reverberation artifact masquerading as type A dissection on TEE. Two-dimensional (2D) TEE of the ascending thoracic aorta in a long-axis view (A) and a short-axis view (B). Red arrows point to linear reverberation artifact. Note that the reverberation artifact is located twice as deep (2×) as the anterior aortic wall, characteristic of reverberation artifacts. TEE, transesophageal echocardiography.

Although on transthoracic echocardiography (TTE) aortic dissection can occasionally be seen, TTE should only be used as a screening tool owing to lack of sufficient sensitivity and specificity.

MRI and aortography also may reveal aortic dissection; however, they are reserved for specific situations. MRI may be used when the patient cannot receive iodinated contrast for CT nor undergo TEE. Aortography is of limited use and is typically performed during invasive endovascular therapeutic procedures.

Management and Prognosis

Type A CAAD is a true medical emergency, requiring immediate surgical repair

because the mortality increases by the hour. Approximately 90% of medically managed patients with type A CAAD die within 3 months of presentation. On the other hand, the prognosis is more favorable for patients with type B CAAD in whom medical management is often preferred over surgical repair because surgically managed patients have been shown to have higher mortality compared with those on medical therapy alone. Medical therapy generally consists of tight blood pressure control and β-blockade. Surgical management of type A CAAD typically consists of excision of the intimal tear if possible and obliteration of entry into the false lumen, as well as implantation of a graft to replace the ascending aorta.[16] Surgical therapy for type B is more complicated because of the presence of many spinal artery branches, and therefore has a risk of paraplegia. Nevertheless, surgical therapy of type B dissection is often necessary when there is aortic branch ischemia and end-organ damage. Endovascular graft therapy to treat type B CAAD has shown promise (**Figure 32.9**).[17]

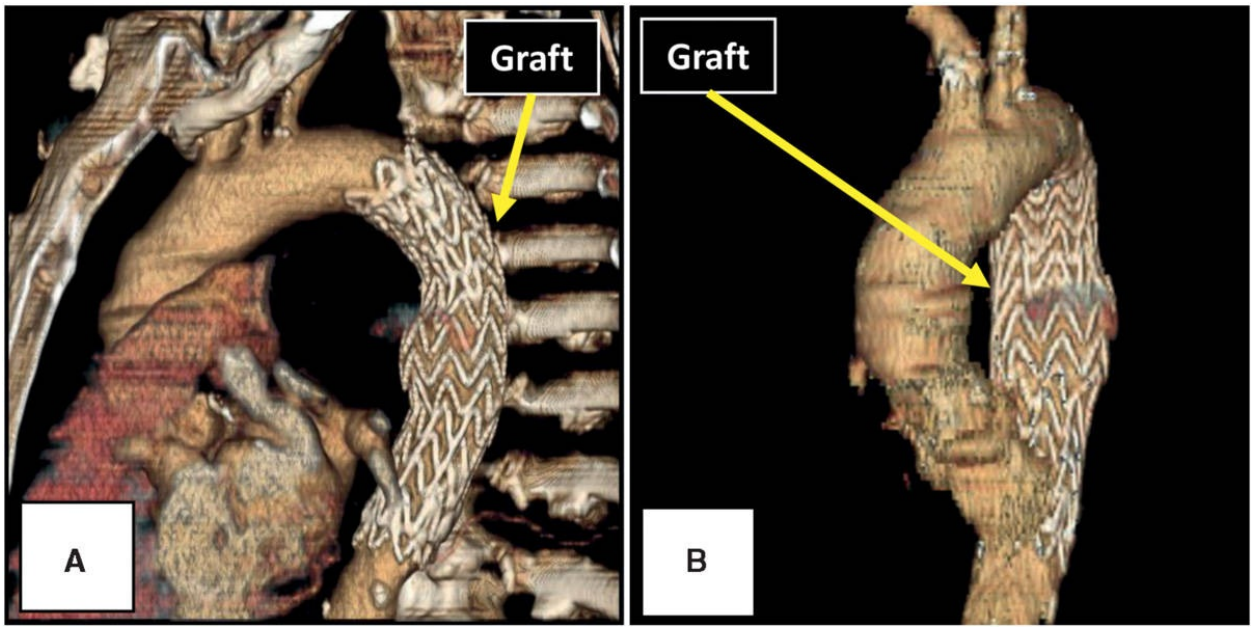

FIGURE 32.9 Endovascular graft repair: 3D CT. Three-dimensional (3D) reconstruction of contrast-enhanced chest CT in a sagittal view (A) and coronal view with surrounding structures removed (B) demonstrating an endovascular stent graft located between the junction of the aortic arch and descending thoracic aorta, extending to the distal descending thoracic aorta. CT, computed tomography.

It is important to identify risk factors for higher mortality in type A CAAD such as advanced age, prior cardiac surgery, hypotension or shock, pulse deficit, cardiac tamponade, and ischemic ECG changes.

Classic Acute Aortic Dissection in Pregnancy

The 2010 intersocietal guidelines for the diagnosis and management of patients with thoracic aortic disease recommends expedited fetal delivery via caesarian section for patients with CAAD during pregnancy given the high mortality of the disease (class IIa recommendation). The diagnostic imaging modality of choice is MRI without gadolinium to avoid exposing the mother and fetus to ionizing radiation.[18] TEE is an option and is considered safe in pregnancy; however, caution must be used when providing procedural sedation because the medications typically administered (midazolam and fentanyl) may be teratogenic, especially in the first trimester. In these cases, topical anesthesia with viscous lidocaine is crucial. There have been reports recommending monitoring fetal HR and uterine tone during TEE.[19]

PENETRATING AORTIC ULCER

PAU represents the process by which an atherosclerotic plaque erodes and penetrates through the elastic lamina into the media layer of the aorta, causing ulceration (**Figure 32.10**). PAU may further erode through the adventitia leading to either focal (pseudoaneurysm) or complete aortic rupture (**Figure 32.11**). Thrombus occasionally forms within PAU. In addition, PAU may lead to either IMH or aortic dissection, which is why PAU is characterized as an AAS.

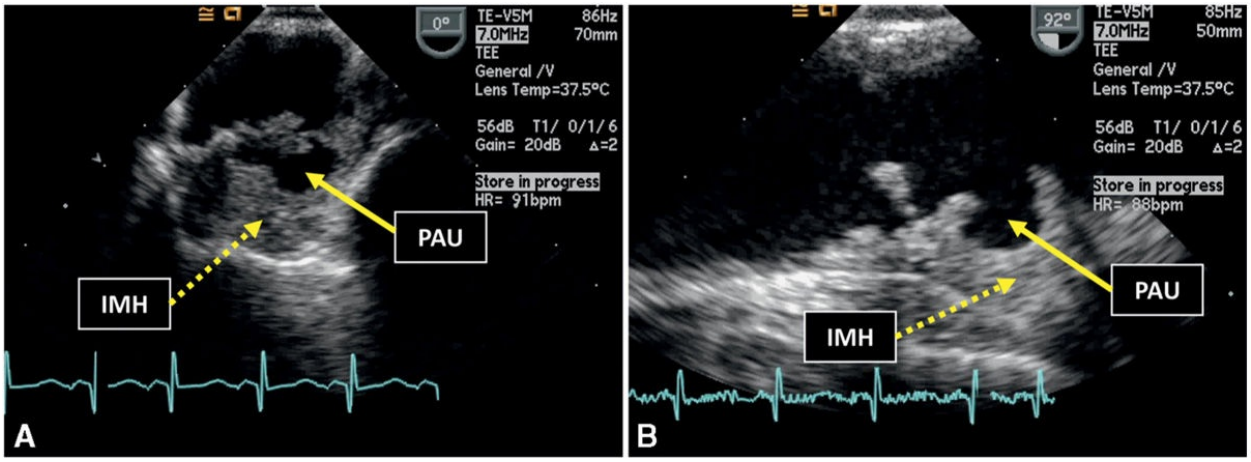

FIGURE 32.10 Penetrating aortic ulcer: TEE. Two-dimensional (2D) TEE of the descending thoracic aorta in the midesophageal short-axis view (A) and long-axis view (B). Yellow arrows point to demonstrating severe atherosclerotic plaque and PAU; yellow dashed arrows point to an area with developing IMH. IMH, intramural hematoma; PAU, penetrating aortic ulcer; TEE, transesophageal echocardiography.

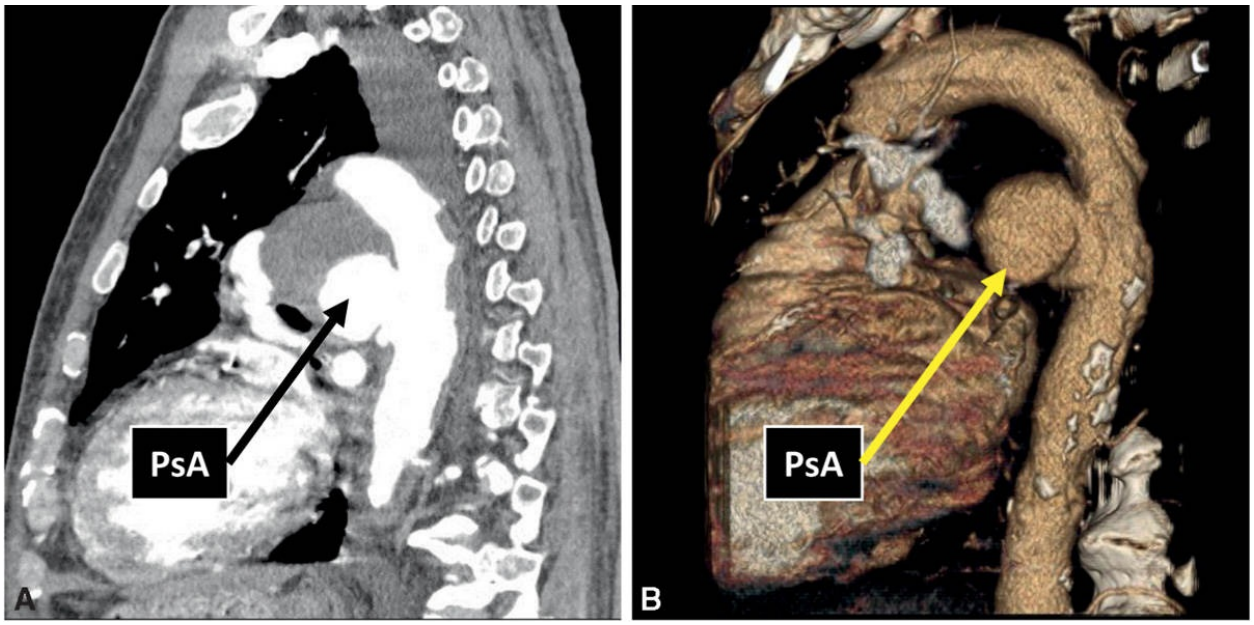

FIGURE 32.11 Penetrating aortic ulcer with rupture/pseudoaneurysm visualized by contrast-enchanced 2D (A) and 3D CT (B). Arrows point to PAU with aortic rupture and pseudoaneurysm of anterior portion of the proximal descending thoracic aorta. CT, computed tomography; PsA, pseudoaneurysm.

Etiology and Pathophysiology

PAU accounts for 2% to 11% of all AASs.[20,21] It was first described in 1986 by Anthony Stanson and colleagues.[22] Patients with PAU typically are older (>70 years old) and have risk factors for atherosclerosis including hypertension, smoking, and hyperlipidemia.

The natural history of PAU is not well described. PAU may cause remodeling of the aortic wall and aneurysm formation, contained rupture through the aortic wall and attendant pseudoaneurysm formation, complete aortic rupture with mediastinal or pleural hemorrhage, or progression to IMH and CAAD.

Clinical Manifestations

Symptoms of PAU are similar to that of other AASs. The pain associated with PAU is variable, and dependent on the location of the ulceration. Type A PAU typically presents with chest pain and type B PAU is more likely to present with back pain. Unlike IMH or CAAD, there have been reports of PAU as an incidental finding in asymptomatic patients.

Diagnosis

The diagnosis of PAU is primarily made by CT, TEE, and MRI. Aortography is

not typically used for PAU because of lack of direct visualization of the aortic wall. All three techniques are able to image atherosclerotic changes, ulceration, and complications such as pseudoaneurysm, rupture, and mediastinal and pleural hemorrhage. Identification of an ulcer crater distinguishes PAU from IMH. PAU lesions are typically focal as opposed to those of CAAD and IMH, which are more extensive.

Management and Prognosis

The natural history of PAU is poorly understood. On one hand, PAU is considered to be a surgical emergency with risk similar to or worse than other forms of AAS. On the other, reports have described the progression of PAU as slow, with a low prevalence of life-threatening complications.[23] There is therefore equipoise regarding the optimal medical versus surgical treatment strategies. Nevertheless, surgical management of PAU with aortic grafting is considered appropriate in the presence of aortic rupture, persistent or recurrent pain, hemodynamic instability, or rapidly expanding aortic diameter.

Penetrating Aortic Ulcer in Pregnancy

Because PAU is a disease that primarily affects older people (>70 years of age), it is highly unlikely that it will occur during pregnancy. There is therefore no available guideline to direct optimal management.

TRAUMATIC AORTIC RUPTURE

Although TAR is not considered to be a part of the original AAS triad, it is a life-threatening aortic emergency with only a 15% to 20% survival.[24] TAR is typically caused by deceleration injuries sustained in motor vehicle accidents (MVAs) and falls greater than 3 m.[25] It is the second leading cause of death after blunt trauma, occurring in approximately 1.5% to 1.9% cases.[26]

Etiology and Pathophysiology

The most common site of injury in TAR is at the aortic isthmus, immediately distal to the left subclavian artery at the site of the ductus arteriosus. This location is considered to be the most vulnerable to torsional and shear forces because it is thought to be a transition zone between the semi-mobile aortic arch and the fixed descending thoracic aorta. Other possible sites of injury are the transverse arch, ascending aorta, and descending aorta proximal to the

diaphragm.[27] Typically, the intima and medial layers rupture first, followed by rupture of the adventitia after an unpredictable interval of time.[28] Multiple tears may occur.

Clinical Manifestations

There is no specific symptom associated with TAR. Chest pain in the patient with trauma should, however, raise suspicion, especially in the presence of the "seat belt sign" (seat belt imprint on the surface of the skin). Pulse deficit and murmur of aortic regurgitation may be present. CXR may show a widened mediastinum, obscured aortic knob, and left hemothorax.

Diagnosis

TAR is best diagnosed using either contrast-enhanced CT or TEE because both modalities have high diagnostic sensitivity and specificity (**Figure 32.12**). Findings seen on CT include intimal flap, periaortic hematoma, luminal filling defects, pseudoaneurysm, or active extravasation of contrast from the aorta. It is important to distinguish TAR from a ductus arteriosus diverticulum, which is helped by the improved special and temporal resolution of modern multidetector row CT scanners. However, TEE may be more specific in differentiating ductus arteriosus diverticula from TAR. Another very useful advantage of TEE is its portability, with the ability to be performed at the bedside of hemodynamically unstable patients, a common scenario in TAR. The main limitation of TEE is an apparent "blind spot" at the distal ascending aorta and proximal aortic arch caused by bronchial shadowing. Aortography, the former gold standard, may be performed; however, it is invasive and can result in worsening of the aortic rupture in as many as 10% of patients and is therefore not the preferred diagnostic modality.

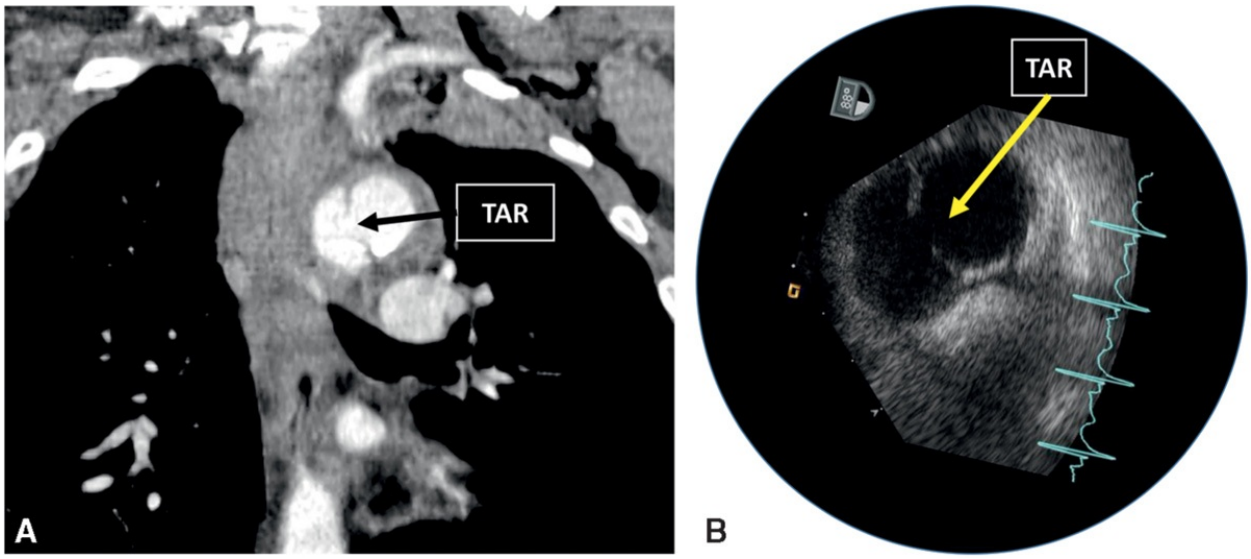

FIGURE 32.12 Traumatic aortic rupture. CT of the chest with iodinated contrast, coronal view (A), and TEE upper esophageal view (B) of the aortic arch. Arrows point to traumatic aortic rupture. Note that the TEE image was rotated to align with the CT image. CT, computed tomography; TAR, traumatic aortic rupture; TEE, transesophageal echocardiography.

Management and Prognosis

Emergent surgical therapy is the standard of care for TAR. As with AAS, medical therapy consists of very close blood pressure and HR control. Hemodynamically unstable patients should be operated on immediately. Surgical options comprise open repair with prosthetic grafts, and endovascularly delivered fabric-covered stents. Endovascular repair has been shown to have decreased overall mortality compared with surgical repair and is recommended when possible. The overall survival of TAR is approximately 10% to 18%. Survival to emergency room care greatly improves the odds of long-term survival, and survival to surgical therapy improves the odds even more, to approximately 70% to 90%.[29]

Traumatic Aortic Rupture in Pregnancy

Although there are no specific guidelines for the management of TAR in pregnancy, expedited delivery via caesarian section with emergent aortic surgery is a reasonable therapeutic approach given the high mortality both to the mother and fetus.

Patient and Family Information for:
ACUTE AORTIC SYNDROME

GENERAL CONCEPTS OF ACUTE AORTIC SYNDROME

WHAT IS THE ILLNESS?

AAS refers to four related diseases of the large vessel that leaves the heart, called the aorta. These are CAAD, IMH, PAU, and TAR. These conditions involve damage to the wall of the aorta and require prompt care because they are associated with a high chance of dying unless treated rapidly.

HOW WILL THE PATIENT BE TREATED?

Once the diagnosis of AAS is established by CT, TEE, or MRI, the disease is typically treated with mediations that lower blood pressure and HR. The doctor will determine the type of AAS (type A or type B) based on the location of involvement in the aorta. A cardiothoracic surgeon may be consulted, who will assess the need for surgery. Surgery is often needed as soon as possible.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

Given the high mortality of AAS and the frequent need for emergency cardiac surgery, the doctor may recommend expedited delivery. If at risk of AAS because of genetic conditions that may affect the aorta, the patient should consult the doctor to assess the risk if she is thinking about becoming pregnant.

INTRAMURAL HEMATOMA

WHAT IS THE ILLNESS?

IMH is described as bleeding into the wall of the aorta due to breakage of the internal blood vessels of the aorta. Symptoms of IMH are sudden severe chest or back pain. IMH is best diagnosed by imaging the aorta using CT, TEE, or MRI. On experiencing symptoms suggestive of IMH, the patient or a family member should seek medical care immediately because the risk of dying from this condition increases by the hour.

HOW WILL THE PATIENT BE TREATED?

Once the diagnosis of IMH is established, medications will be given to reduce the blood pressure and HR. A cardiothoracic surgeon may be consulted, who will assess the need for surgery. Surgery will often involve either replacement of the diseased portions of the aorta or placement of special type of stent within the aorta that will help contain the bleeding and prevent the aorta from bursting.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

IMH carries a high risk of mortality, and often requires emergency surgery. The doctor will tailor the medications for IMH to include only those with minimal risk to the baby. If the pregnant patient or family member requires emergency surgery, expedited delivery is prudent. Rapid consultation with an obstetrician is crucial. If the person has a condition that puts her at risk for IMH such as Marfan syndrome or other genetic disorders of the aorta, consult the doctor to assess the risk if thinking about becoming pregnant.

CLASSIC ACUTE AORTIC DISSECTION

WHAT IS THE ILLNESS?

CAAD is the most common type of AAS. It is caused by a tear of the inner layer of the aorta, called the intima. This tear can then propagate, leading to separation of the layers of the aorta. There are hereditary disorders such as Marfan syndrome and bicuspid aortic valve that may put the person or a family member at risk of CAAD because of weakening of the aortic wall.

Symptoms typically experienced are severe “tearing” chest or back pain that occurs at rest. If the person or a family member experiences such symptoms,

seek medical care immediately.

CAAD will be diagnosed using CT, TEE, or MRI, which are widely available and can be performed and interpreted rapidly.

HOW WILL THE PATIENT BE TREATED?

As with other types of AAS, the doctor will prescribe medications that lower blood pressure and HR. A cardiothoracic surgeon may be consulted immediately, who will assess the need for surgery. The location of the dissection is a crucial component in deciding what the best treatment is. Surgical options are open heart surgery or placement of a tube called stent. The cardiothoracic surgeon will assess which procedure is the most appropriate.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

As with other types of AAS, CAAD is often a surgical emergency. As such, consultation with an obstetrician and expedited delivery may be recommended. If the patient or a family member has a disorder that involves the aorta, consult the obstetrician before deciding to conceive.

PENATRATING AORTIC ULCER

WHAT IS THE ILLNESS?

Atherosclerosis or hardening of the arteries is a disease in which cholesterol and fat build up within the walls of the blood vessels called arteries. PAU is caused when a very severe plaque breaks through the aorta, causing a hole, or ulceration. Risk factors for PAU include advanced age, high blood pressure, high cholesterol, and smoking. Symptoms include chest and back pain, although some patients may have no symptoms.

Along with other forms of AAS, PAU is diagnosed by CT, TEE, or MRI.

HOW WILL THE PATIENT BE TREATED?

The doctor may recommend close monitoring with imaging studies, medications, or surgery.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF

BECOMING PREGNANT?

PAU is typically a disease that affects older people (more than 70 years of age). It is highly unlikely that it will occur during pregnancy.

TRAUMATIC AORTIC RUPTURE

WHAT IS THE ILLNESS?

TAR describes tearing of the aorta after a chest injury. It most commonly occurs after MVAs and bad falls.

TAR is a very dangerous condition and requires prompt medical attention. A mark across the skin of the chest due to a seat belt often is present when TAR is caused by an MVA. TAR is diagnosed using CT and TEE.

HOW WILL THE PATIENT BE TREATED?

Emergency surgery is the standard of care for TAR. The doctor may prescribe medications to lower HR and blood pressure if necessary; however, a cardiothoracic surgeon may be consulted as soon as possible. Treatment typically requires open heart surgery.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

Because TAR is a surgical emergency, consultation with an obstetrician for early delivery is crucial.

The surgeon may recommend delivery by cesarean section at the time of surgery to repair the broken aorta.

Pericardial Effusion and Tamponade

INTRODUCTION

Pericardial effusion is a relatively common finding in high-risk patients evaluated in the acute setting.[1] It should be considered in differential diagnosis for a variety of clinical presentations including chest pain, shortness of breath, and hypotension.[1] Pericardial effusion can be directly causal for patients' complaints (like in patients with pericardial tamponade) or be an incidental finding still carrying a prognostic significance (like in patients with pulmonary hypertension). The general approach to pericardial effusion once it is recognized includes establishing the cause of pericardial disease and assessing its hemodynamic significance.

RECOGNIZING THE PRESENCE OF PERICARDIAL EFFUSION

Pericardial effusion can be recognized on the basis of clinical suspicion or it can be an incidental finding on chest or cardiac imaging.[2] The following clinical settings may indicate the need to specifically evaluate for the presence of pericardial effusion[3]:

1. Cardiac arrest with pulseless electrical activity or asystole
2. Chest discomfort and/or any signs of hemodynamic instability in chest trauma, recent cardiac surgery, or percutaneous cardiac intervention
3. Any of the following when otherwise unexplained: chest pain, fever, dyspnea, and elevated cardiac biomarkers
4. Physical and electrocardiographic findings attributable to pericardial disease; the latter includes tachycardia, low voltage, and electrical alternans (**Figure 33.1**)
5. Enlarged cardiac silhouette or pleural effusions on chest X-ray
6. Any patient with ascending aortic dissection, severe pulmonary hypertension, renal failure, use of some medications, rheumatic diseases, malignancy, or other systemic conditions when pericardial effusion is thought to contribute to presentation or have prognostic significance[3]

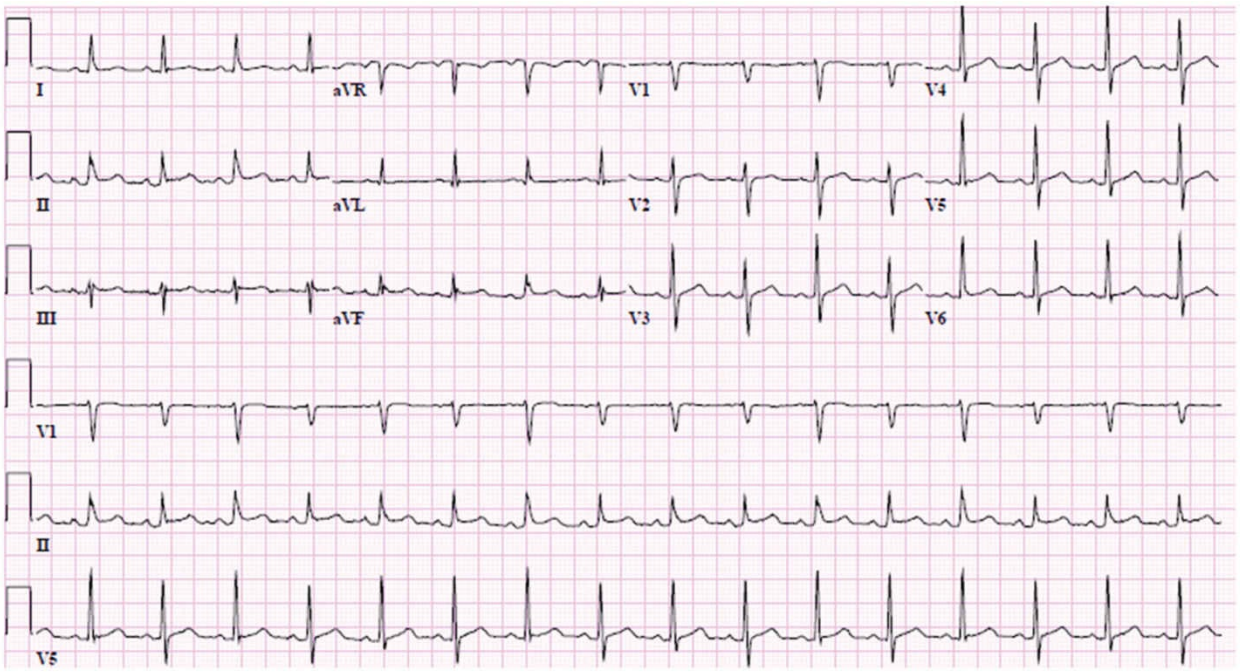

FIGURE 33.1 Electrocardiogram in a patient with large pericardial effusion. Electrical alternans is evident in multiple leads including V1and V5. ECG, electrocardiogram.

Echocardiography is the most commonly used modality to diagnose pericardial effusion: owing to its accuracy and portably, it can be easily used in any health care setting including bedside in an acutely ill patient. Other modalities (such as computed tomography [CT] scan or cardiac magnetic resonance) can be occasionally used to diagnose pericardial effusion, especially

when echocardiographic examination is limited or nondiagnostic.[4]

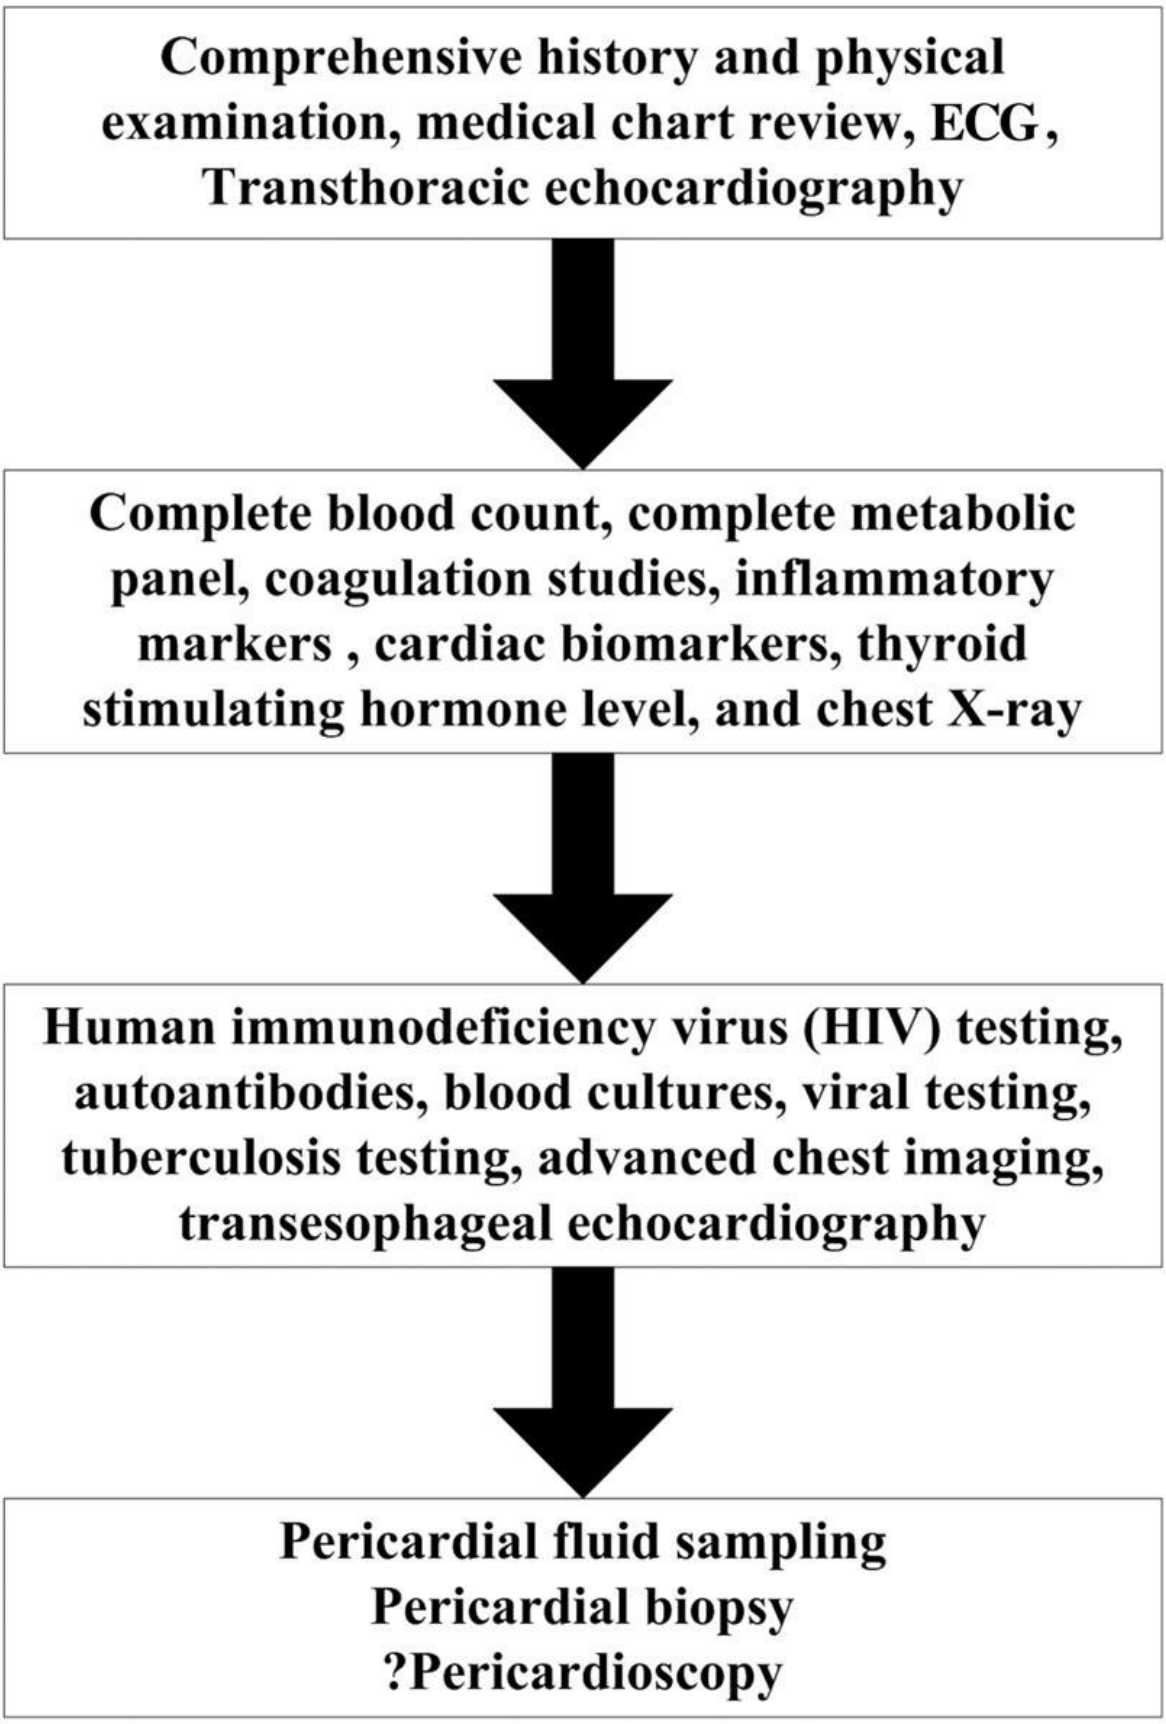
ESTABLISHING THE CAUSE OF PERICARDIAL EFFUSION

There is a long list of possible causes for pericardial effusion (**Table 33.1**), but a limited number of etiologies account for the majority of diagnoses.[5] A structured approach helps establish the cause of pericardial effusion in most cases.[6] A very aggressive approach, as is used in some studies, has a high diagnostic yield but low clinical relevance, especially for small effusions.[7,8] Routine sampling of pericardial fluid for diagnostic purposes is unnecessary.[3] History and physical examination often provide clues to the etiology of pericardial effusion. For example, the pericardium can be involved in patients with active systemic malignancy, and malignant effusion should be strongly considered in these patients. Active or recent infection, radiation therapy, rheumatic disease, and recent acute coronary syndrome, cardiac surgery, or percutaneous cardiac procedure, all provide relevant clues to etiology. A typical clinical presentation, physical findings, and electrocardiographic changes commonly confirm the diagnosis of acute idiopathic pericarditis.[9] In one study, the presence of "inflammatory" signs (characteristic chest pain, pericardial friction rub, fever, and/or diffuse ST-segment elevation) in patients with pericardial effusion was strongly associated with acute idiopathic pericarditis.[10]

TABLE 33.1	Causes of Pericardial Effusion
Aortic dissection	
Endocrine (hypothyroidism)	
Idiopathic	
Infectious (including viral, tuberculous, and purulent pericarditis)	
Medications	
Neoplastic (typically secondary)	
Perimyocardial infarction and postcardiotomy syndrome	
Pulmonary hypertension and right-sided heart failure	

Radiation
Renal failure
Rheumatic/autoimmune diseases
Traumatic (chest injury, procedure, surgery)

We use a parsimonious stepwise approach to laboratory testing and imaging in patients with pericardial effusion at our institution (**Figure 33.2**).[6] Transthoracic echocardiography is the standard test in establishing the presence of pericardial effusion, quantifying the size of the effusion and assessing its hemodynamic impact. The initial tier of testing includes complete blood count, complete metabolic panel, coagulation studies, inflammatory markers (erythrocyte sedimentation rate, C-reactive protein), cardiac biomarkers, thyroid stimulating hormone level, and chest X-ray. In appropriate clinical settings, human immunodeficiency virus (HIV) testing, autoantibodies, and blood cultures are obtained. Advanced chest imaging (CT scan, positron emission tomography, and magnetic resonance imaging) can be helpful in certain clinical situations, especially when malignancy is suspected. Besides, CT scan and cardiac magnetic resonance can be used as adjunct imaging modalities for assessing pericardial effusion in some patients.[4] They offer precise effusion localization, quantification, and tissue characterization, which are especially important for loculated and complex effusions. Tuberculosis testing should also be considered in the right epidemiologic and clinical settings. Viral cultures have little clinical significance and should not be routinely obtained, but they may be useful in some patients (eg, cytomegalovirus infection in transplant patients).[3] Transesophageal echocardiography can diagnose loculated effusion when transthoracic echocardiography is limited (eg, postoperative patients) and regional tamponade is considered. Our structured approach has yielded diagnosis by noninvasive targeted testing in 68% of patients, based on a retrospective review.[6]



Comprehensive history and physical examination, medical chart review, ECG, Transthoracic echocardiography
Complete blood count, complete metabolic panel, coagulation studies, inflammatory markers , cardiac biomarkers, thyroid stimulating hormone level, and chest X-ray
Human immunodeficiency virus (HIV) testing, autoantibodies, blood cultures, viral testing, tuberculosis testing, advanced chest imaging, transesophageal echocardiography
Pericardial fluid sampling
Pericardial biopsy
?Pericardioscopy

FIGURE 33.2 Parsimonious stepwise approach to laboratory testing and imaging in patients with pericardial effusion. This systematic approach allows establishing diagnosis noninvasively in the majority of patients with moderate-to-large pericardial effusion. Question mark indicates optional and controversial.

Simple clinical assessment has also been shown to assist in establishing the diagnosis: large effusion without "inflammatory" signs or clinical signs of tamponade (jugular venous distension, hypotension, and/or pulsus paradoxus) commonly signifies chronic idiopathic pericardial effusion (likelihood ratio = 20, $P < .001$), whereas large effusions with clinical signs of tamponade and without "inflammatory" signs should raise the suspicion for malignancy (likelihood ratio = 2.9, $P < .001$).[10]

Pericardial effusion sampling for diagnostic purposes and occasionally for pericardial biopsy should be considered in the following settings:

1. Concern for purulent and tuberculous pericarditis
2. Clinical suspicion of neoplastic pericardial effusion
3. Moderate-to-large pericardial effusion in patients with advanced HIV and/or immune suppression
4. Moderate-to-large or progressive pericardial effusion in patients who are not responding to initial therapy or when the tiered workup is inconclusive

Pericardial fluid analysis can include Gram and acid-fast bacilli stains and cultures, polymerase chain reaction, tuberculosis-specific testing (eg, adenosine deaminase, lysozyme, and gamma-interferon), tumor markers, and cytology.[3] Contrary to common practice and unlike pleural effusion workup, cell count, lactate dehydrogenase, and protein and glucose levels have not been shown to be particularly useful in differential diagnosis and management of patients with pericardial effusion.[11] Pericardioscopy allows a targeted pericardial biopsy and it can potentially increase the diagnostic accuracy of sampling (eg, neoplastic pericardial effusion).

ASSESSING HEMODYNAMIC SIGNIFICANCE OF PERICARDIAL EFFUSION

When evaluating the hemodynamic impact of pericardial effusion one should take into account the acuity of presentation. Acute accumulation of fluid (within

minutes to hours) rapidly exceeds the pericardial stretch limit and commonly presents as cardiogenic shock.[12] This dramatic presentation is called acute or surgical tamponade and it requires immediate intervention. Chamber perforation during a percutaneous procedure is a good example of acute tamponade. Blunt chest trauma and ascending aortic dissection resulting in blood accumulation within the pericardium require prompt surgical intervention, and percutaneous pericardial effusion drainage is relatively contraindicated. When pericardial fluid accumulates slowly (within days to weeks), a large amount of fluid can be present without dramatic lowering of the cardiac output.[12] This can lead to subacute or medical tamponade, which requires careful assessment of both clinical and imaging data to establish the need for pericardial effusion drainage.[13] The following discussion elaborates the assessment for subacute (medical) tamponade.

HISTORY AND PHYSICAL EXAMINATION

Although many refer to pericardial tamponade as a "clinical diagnosis," the existing evidence suggests that subacute tamponade is a difficult diagnosis to make on mere clinical grounds.[13] Dyspnea is the cardinal symptom of subacute pericardial tamponade, but it is nonspecific. Other symptoms such as fever, cough, and chest pain can occur and typically reflect the underlying cause (ie, pericarditis) rather than pericardial fluid accumulation. Clinical findings of pericardial tamponade include tachycardia, jugular venous distension, pulsus paradoxus, and diminished heart sounds; and all lack both sensitivity and specificity.[14] Tachycardia is common in hospitalized patients for many reasons and it could be blunted by medications such as β-blockers. In a systematic review, the jugular venous distension had a pooled sensitivity of 76% for pericardial tamponade.[14] Assessment of jugular venous distension is limited by the experience of the observer; it can be difficult in some patients, even for experienced clinicians. Besides, jugular venous distension is associated with other conditions causing shortness of breath such as pulmonary hypertension and congestive heart failure. Although patients with acute (surgical) tamponade rapidly progress to cardiogenic shock, hypotension is rather uncommon in patients with subacute tamponade who accumulate pericardial effusion within days to weeks. On the contrary, many patients are hypertensive because of the high levels of circulating catecholamines in response to hemodynamic stress. In

studies of pericardial tamponade, the mean systolic blood pressure ranged from 127 to 144 mm Hg.[15] According to a recent review, hypertensive tamponade is seen in 27% to 43% of patients.[15] Systolic blood pressure commonly decreases in these patients after pericardial effusion drainage, and treating the hypertensive response without draining the effusion can be dangerous.

PULSUS PARADOXUS

Pulsus paradoxus is considered the cornerstone of the clinical diagnosis of pericardial tamponade.[12] Under normal conditions, the decrease in blood pressure is <10 mm Hg, and it is explained by phasic variation in the filling of the right- and left-sided cardiac chambers related to intrathoracic pressure changes with respiration. With tamponade, the accumulating pericardial effusion restricts cardiac filling and makes the respiratory variation in the right and left ventricular filling more pronounced and interdependent.[12] Pulsus paradoxus is measured by manual sphygmomanometer as the difference between intermittent and persistent Korotkoff sounds during normal respiration, not with deep breathing (**Figure 33.3**).[14] A wide variation in the incidence of pulsus paradoxus has been reported in patients with pericardial tamponade, ranging from 12% to 75%.[16] In patients with “low-pressure” tamponade, the incidence of pulsus paradoxus was reported as only 7%.[17] Besides limited sensitivity for pericardial tamponade, pulsus paradoxus is not very specific. A myriad of conditions have been reported to be associated with pulsus paradoxus; a short list includes asthma, right ventricular infarction, severe hypovolemia, constrictive pericarditis, restrictive cardiomyopathy, pneumothorax, chronic obstructive lung disease, and pulmonary embolism.[13] Some of these conditions can also cause jugular venous distension and tachycardia, common associated findings of pericardial tamponade.

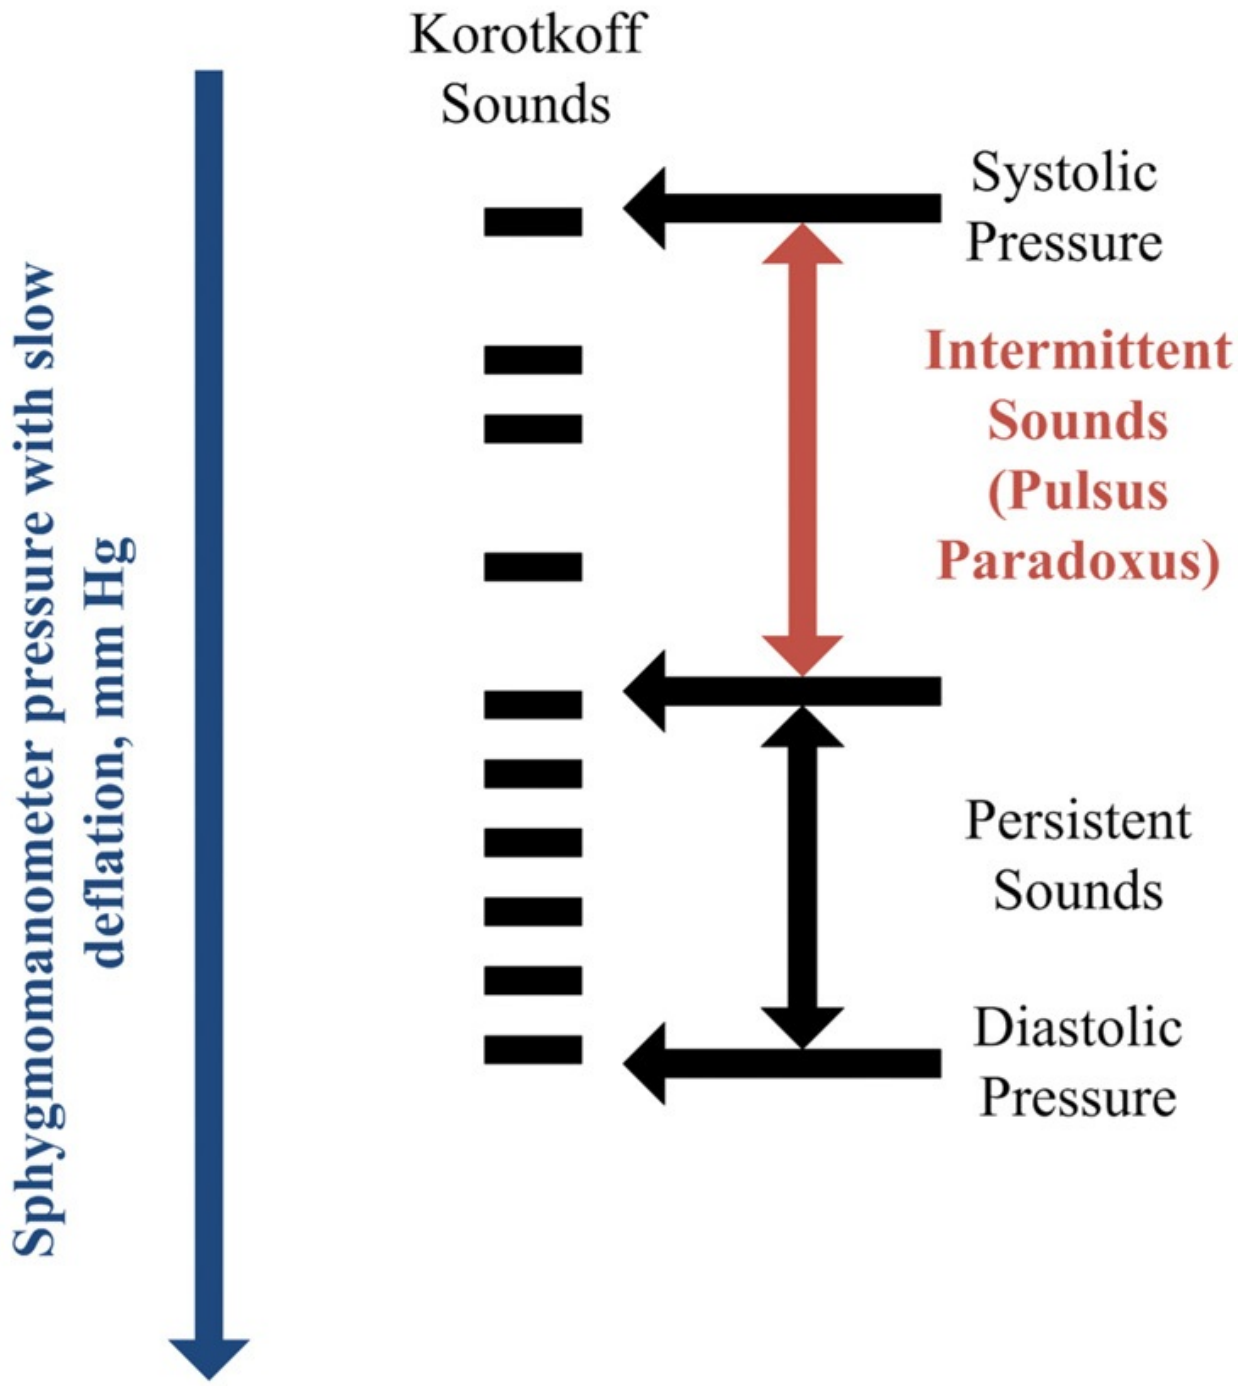


FIGURE 33.3 Assessing for pulsus paradoxus. Pulsus paradoxus is measured by manual sphygmomanometer as the difference between intermittent and persistent Korotkoff sounds during normal respiration.

INVASIVE AND IMAGING DATA

Before the widespread use of echocardiography, invasive data using cardiac

catheterization were commonly obtained to confirm the diagnosis of tamponade. Cardiac catheterization in tamponade demonstrates equilibration of diastolic intracardiac pressures and respiratory variation in right- and left-sided cardiac pressures corresponding to pulsus paradoxus.

Echocardiography is currently the cornerstone of hemodynamic evaluation of pericardial effusion.[4] Pericardial effusion is easily recognized during ultrasound examination as an echo-free space around the heart (**Figure 33.4**). Normally, intrapericardial pressure is lower than the central venous pressure. As pericardial fluid accumulates, the intrapericardial pressure equilibrates first with the right-sided filling pressures and then left-sided filling pressures.[14] During tamponade, intrapericardial pressure temporarily exceeds intracavitary pressure in various chambers during the cardiac cycle and results in chamber collapse (**Figure 33.5**).[4] Certain pitfalls should be kept in mind when interpreting echocardiographic findings. Transient buckling of the right atrium is commonly seen in patients with pericardial effusion and it is not specific. A more sustained collapse of the right atrium lasting at least one-third of the cardiac cycle appears to be more specific for pericardial tamponade.[18] Right ventricular early diastolic collapse is a less sensitive finding but has a high specificity. Left-sided chamber collapse is much less sensitive but highly specific for tamponade. Importantly, a study by Merce et al showed that 34% of patients with pericardial effusion but without clinical features of pericardial tamponade had at least one chamber collapse on echocardiography.[19] Therefore, in patients with pericardial effusion who have chamber collapse, one should carefully document respiratory flow variation across valves as a sign of ventricular interdependence (**Figure 33.6**) and interrogate the inferior vena cava size and collapsibility as a sign of elevated right-sided filling pressures.[20] The presence of respiratory variation in the inflow velocities is defined by consensus as >30% across the mitral valve and >60% for the tricuspid valve.[4] These echocardiographic signs, when present, increase the specificity of diagnosis. Finally, the size of the pericardial effusion seems to be an important but frequently underappreciated part of the echocardiographic assessment. In one study of hospitalized patients with pericardial effusion, the size of the effusion was the only independent predictor of adverse in-hospital outcomes in a multivariate model, but not chamber collapse or inferior vena cava plethora.[21]

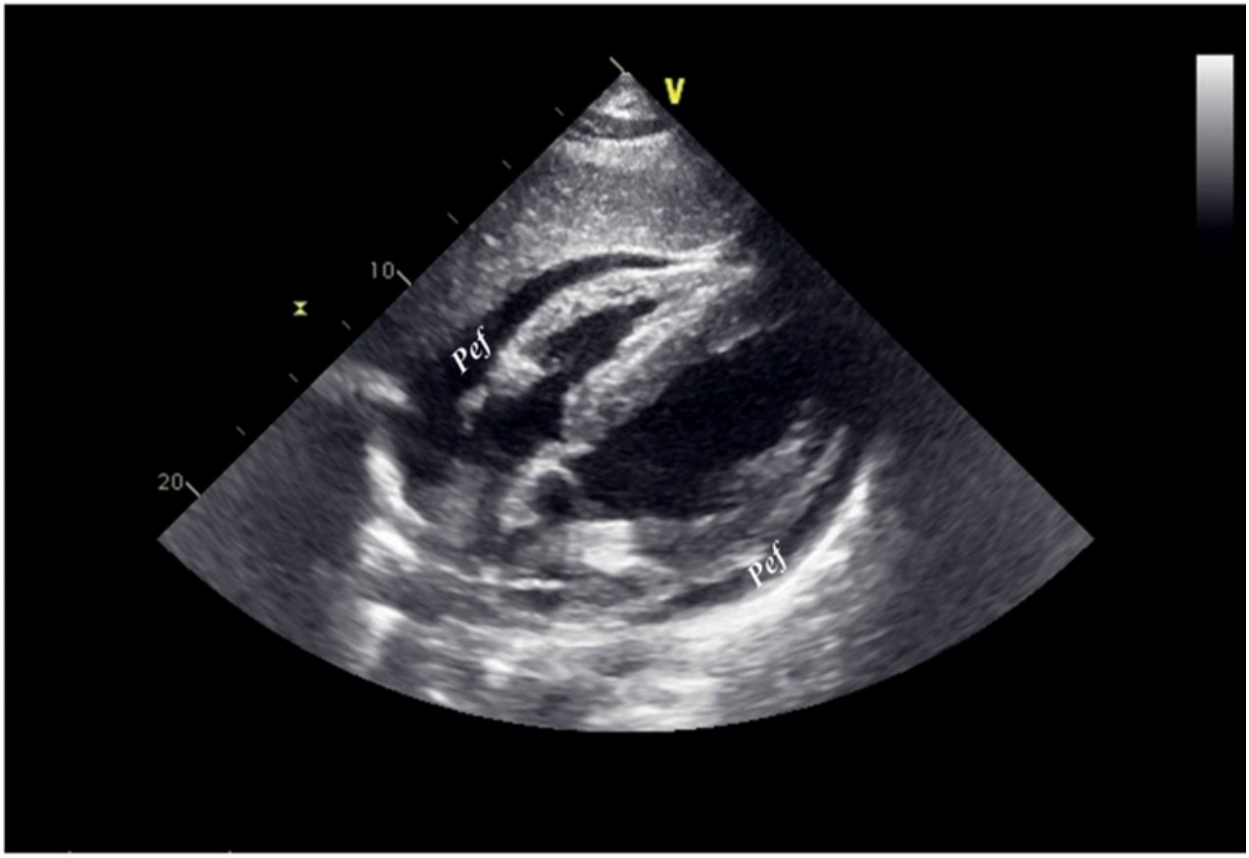

FIGURE 33.4 Pericardial effusion as seen with the ultrasound examination. Pericardial effusion (*Pef*) is easily recognized during ultrasound examination as an echo-free space around the heart.

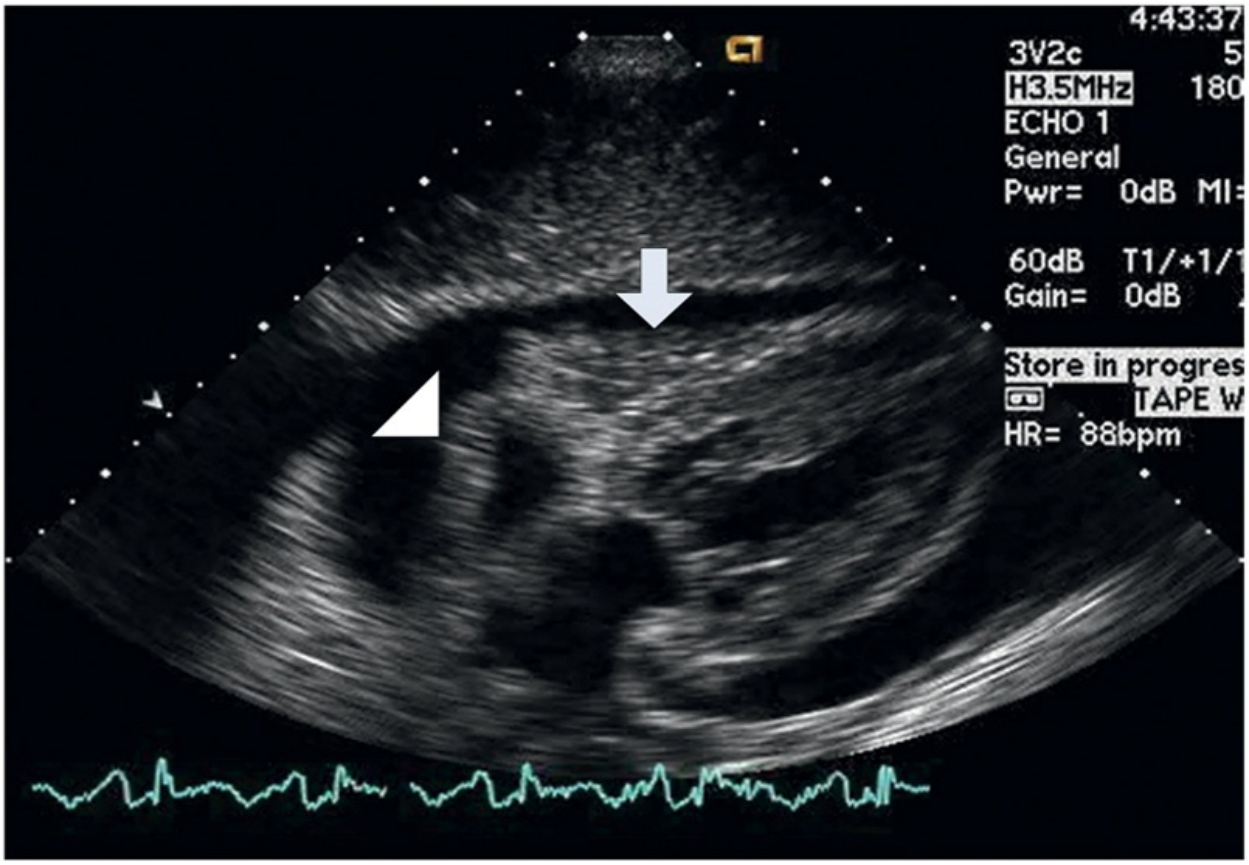

FIGURE 33.5 Chamber collapse with pericardial tamponade as seen with the ultrasound examination. There is evidence of right atrial collapse (arrowhead) as well as right ventricular compression by pericardial fluid (arrow).

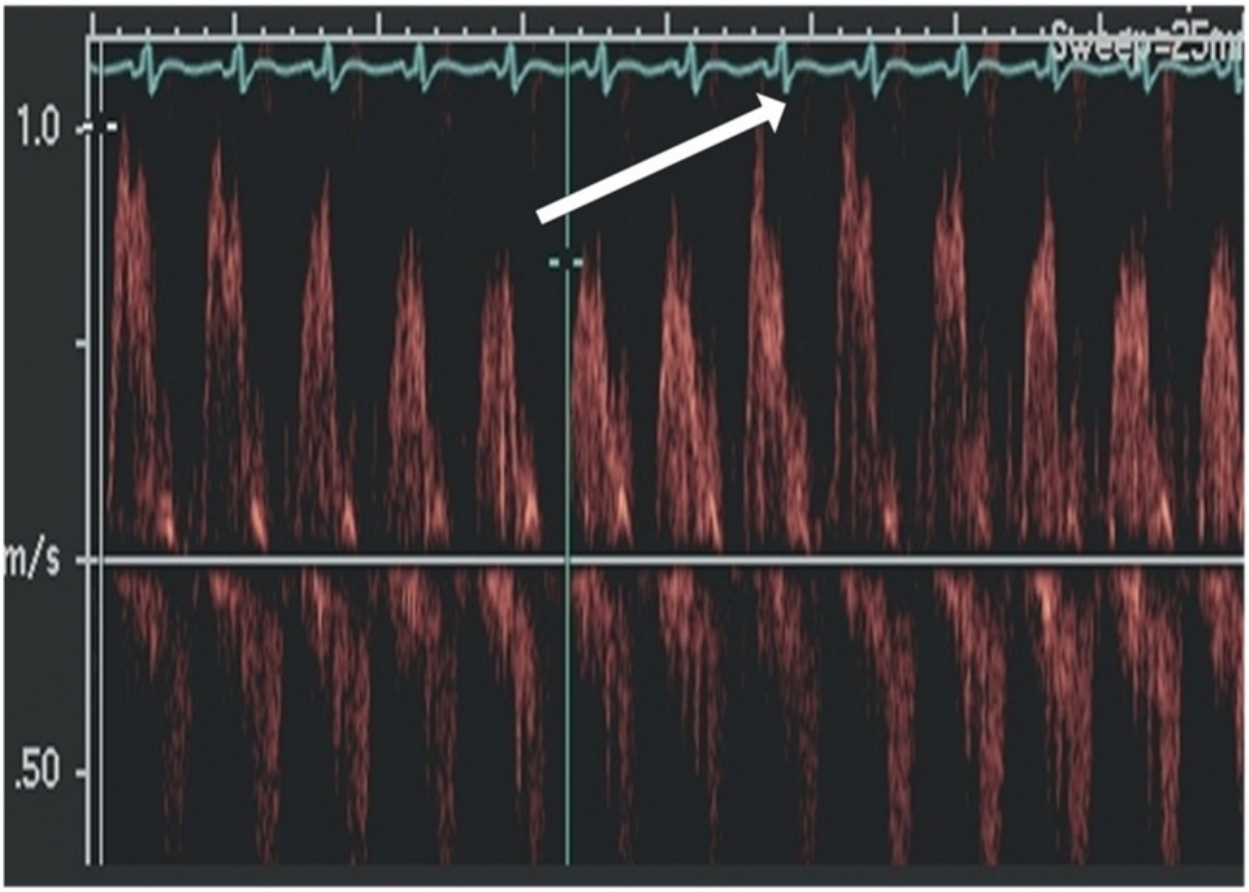

FIGURE 33.6 Doppler echocardiography in pericardial tamponade. Respiratory variation in the mitral inflow velocities (arrow) is seen.

The diagnosis of pericardial tamponade may be particularly difficult in patients with pulmonary hypertension and right ventricular failure because they commonly accumulate pericardial effusion. Pericardial effusion in these patients is a marker of adverse outcomes. Common clinical findings of pericardial tamponade such as tachycardia and jugular venous distension may not be helpful in differential diagnosis for shortness of breath and progressive right-sided heart failure. Collapse of the left-sided cardiac chambers has been described as an important echocardiographic clue to the presence of pericardial tamponade in these settings.[22] Conversely, more common findings of tamponade such as right atrial and ventricular collapse can be masked by elevated right-sided filling pressures. Poor outcomes have been reported with routine draining of pericardial effusion in these patients.

INTEGRATIVE APPROACH TO PERICARDIAL DRAINAGE

The diagnosis of subacute pericardial tamponade can be challenging because most patients are not hypotensive and can actually be hypertensive. An integrative approach that includes careful consideration of both clinical and imaging data helps clinicians assess the hemodynamic impact of pericardial effusion and the need for drainage.[13] The decision making should include the following factors:

1. Presence and timeline for symptoms (commonly dyspnea)
2. Supportive physical findings (jugular venous distension, tachycardia, and pulsus paradoxus)
3. Etiology of pericardial effusion and response to initial treatment
4. Size of pericardial effusion
5. Evidence of chamber collapse on echocardiography
6. Supporting signs for pericardial tamponade on echocardiography (respiratory variation in velocities and flows, engorgement of the inferior vena cava)

Percutaneous pericardiocentesis guided by echocardiography is the intervention of choice in many cases when pericardial drainage is desired. Emergency pericardiocentesis in acute (surgical) tamponade can be lifesaving. A study summarizing the 21-year experience from Mayo Clinic showed that echo-guided approach is rapid, safe, and effective with a major complication rate of 1.2%.[23] Extended catheter drainage has been used in certain scenarios, including neoplastic pericardial effusion when intrapericardial treatment is also occasionally employed. Stepwise drainage of pericardial effusion is reasonable in very large effusions and patients with pulmonary hypertension to avoid acute right ventricular dilation ("decompression syndrome").[3] Surgical drainage is generally preferred in traumatic pericardial effusion, aortic dissection, small effusions, recurrent effusions, and purulent pericarditis. In loculated (typically postsurgical) effusions, surgical approach or video-assisted thoracoscopic pericardiectomy can be used. Pericardial biopsy, when necessary, can be done using surgical procedure or pericardioscopy. Postdrainage echocardiography is important in assessing the efficacy of the procedure, possible complications and fluid reaccumulation, and diagnosing constriction physiology.[3]

SUPPORTIVE CARE

Promptly instituted treatment for presumed etiology of pericardial effusion (ie, anti-inflammatory therapy in acute pericarditis) can result in improvement and

defer the need for pericardial drainage. The response should be monitored by serial echocardiographic examinations. Endotracheal intubation with positive pressure ventilation requires great caution because it can markedly reduce cardiac preload and result in rapid hemodynamic deterioration.[24] Fluid resuscitation should also be used cautiously. In a hemodynamic study by Sagrista-Sauleda et al, 49 patients with pericardial tamponade were given 500 mL of intravenous normal saline before pericardiocentesis.[25] Increase in cardiac index > 10% from baseline was observed in 47% of patients. The improvement in cardiac index was modest, and only patients with systolic blood pressure < 100 mm Hg got the benefit. Actually, 31% of patients experienced a decrease in the cardiac output as the result of volume expansion. Intravenous saline infusion also consistently caused a significant increase in intrapericardial pressure, right atrial pressure, and left ventricular end-diastolic pressure.[25]

CONCLUSIONS

Pericardial disease is relatively common in acute settings and it requires prompt diagnosis. A structured approach to differential diagnosis of pericardial effusion and hemodynamic assessment is necessary in managing patients with pericardial effusion and suspected pericardial tamponade.

Patient and Family Information for: PERICARDIAL EFFUSION AND TAMPONADE

Pericardial effusion refers to fluid accumulation in the double-membrane pericardial sack which surrounds the heart. Normally, there is a little amount of fluid that allows the heart to expand and receive blood. Abnormal fluid or blood accumulation in the pericardial sack can occasionally compress the heart and impair normal filling of heart chambers and therefore normal heart functioning. This is referred to as “tamponade,” a potentially life-threatening condition. Pericardial effusion can develop suddenly, for example, during a cardiac procedure when even a small amount of accumulated blood around the heart can cause compression; immediate intervention is necessary in that case to relieve the compression. Sometimes pericardial fluid accumulates slowly, over days and weeks as a result of infection, cancer spread, renal failure, or some other causes. In those cases, the symptoms are less dramatic but commonly include shortness of breath. Other symptoms may include tiredness, chest pain, and fever. Certain findings on physical examination and changes on electrocardiogram and chest X-ray can be suggestive of pericardial effusion. Ultrasound of the heart (also called echocardiogram) is the most commonly used diagnostic test to establish the presence of pericardial effusion and to assess the degree of heart compression. To establish the cause of pericardial effusion, the physician will typically order certain diagnostic tests which may include blood tests and occasionally advanced imaging tests (such as CT scan). Draining the pericardial fluid can be considered in some patients for two reasons: (1) establishing the diagnosis if the other tests are inconclusive and (2) relieving compression of the heart. It is performed either by a needle or surgery. During the former, a needle is introduced into the pericardial sack commonly under the guidance of ultrasound

or X-ray. The physician may decide to leave a tube (called a “drain”) in the pericardial sack for several days to avoid re-accumulation. The tube can be pulled out easily once the amount of drainage from the pericardial sack decreases significantly.

Pathway for the Management of Pericardial Disease

Pericardial disease is a broad term that describes a wide range of pathologies. The clinical aspects of pericardial disease encompass acute pericarditis, pericardial tamponade, pericardial effusion, constrictive pericarditis, and effusive–constrictive pericarditis. These disorders differ not only in clinical presentation but also in the timeline of disease development; for example, pericardial tamponade is commonly an acute, life-threatening event, whereas constrictive pericarditis is a chronic process developing over months to years. Therefore, pericardial disease management is challenging for most clinicians. The evidence base in the field is relatively scarce compared with other disease entities in cardiology. The European Society of Cardiology released in 2015 its updated guidelines for the diagnosis and management of pericardial diseases.[1] Currently, there are no guidelines from American cardiology societies to help clinicians in managing pericardial disease. In this chapter we outline a unified, stepwise, pathway-based approach for the management of pericardial disease (**Figure 34.1**).[2]

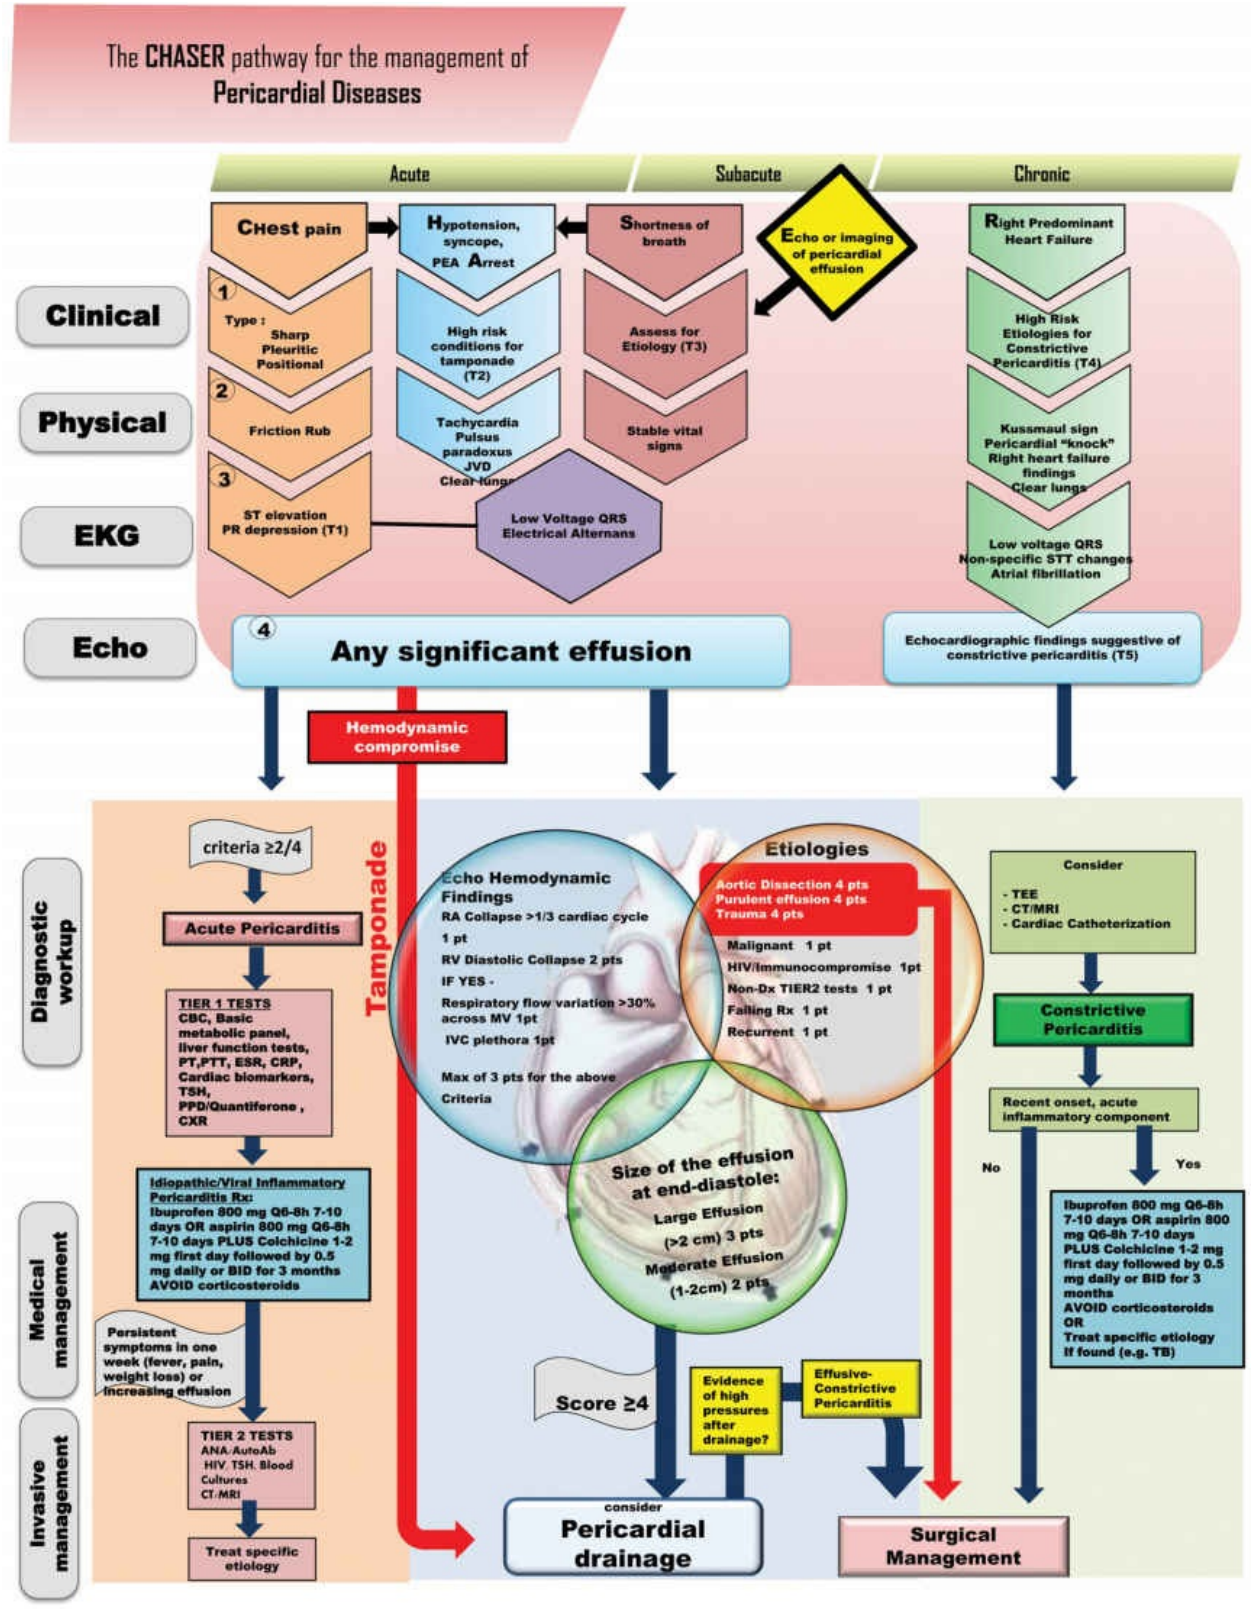

FIGURE 34.1 Novel "CHASER" pathway for the management of pericardial disease. The figure outlines a unified, stepwise pathway-based approach to pericardial disease management. ANA, antinuclear antibody;

CBC, complete blood count; CRP, C-reactive protein; CT, computed tomography; CXR, chest X-ray; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; IVC, inferior vena cava; JVD, jugular vein distension; MRI, magnetic resonance imaging; MV, mitral valve; PEA, pulseless electrical activity; PPD, purified protein derivative; PT, prothrombin time; PTT, partial thromboplastin time; RA, right atrium; RV, right ventricule; TB, tuberculosis; TEE, transesophageal echocardiography; TSH, thyroid-stimulating hormone. T1: Table 34.1, T2: Table 34.2, T3: Table 34.3, T4: Table 34.4, T5: Table 34.5

THE ADVANCED CARDIAC ADMISSION PROGRAM

The "Advanced Cardiac Admission Program (ACAP)" was launched in New York, in 2004. It consists of a series of projects that have been developed to bridge the gap between published guidelines and implementation during "real-world" patient care. The pericardial disease management pathway is the ninth project of the ACAP program.[2]

HOW TO USE THE PATHWAY

ENTERING THE PATHWAY

Despite the broad range of pericardial pathologies, there are a limited number of clinical presentations that would make a clinician suspect pericardial disease (**Figure 34.2**). We assigned each clinical presentation a certain pathway, which starts with patients' complaints and continues along the lines of further workup, diagnosis, and management. Typical clinical presentations in patients with pericardial disease include chest pain, hypotension/arrest, dyspnea, and right-predominant heart failure. Incidental finding of pericardial effusion during imaging study is also a common clinical scenario. **Figure 34.2** outlines the entry points into the pericardial disease management pathway. The timeline of symptom development is a continuum ranging from acute, immediate presentation to subacute and chronic symptoms. The recent European guideline[1] classified inflammatory pericardial syndromes as follows:

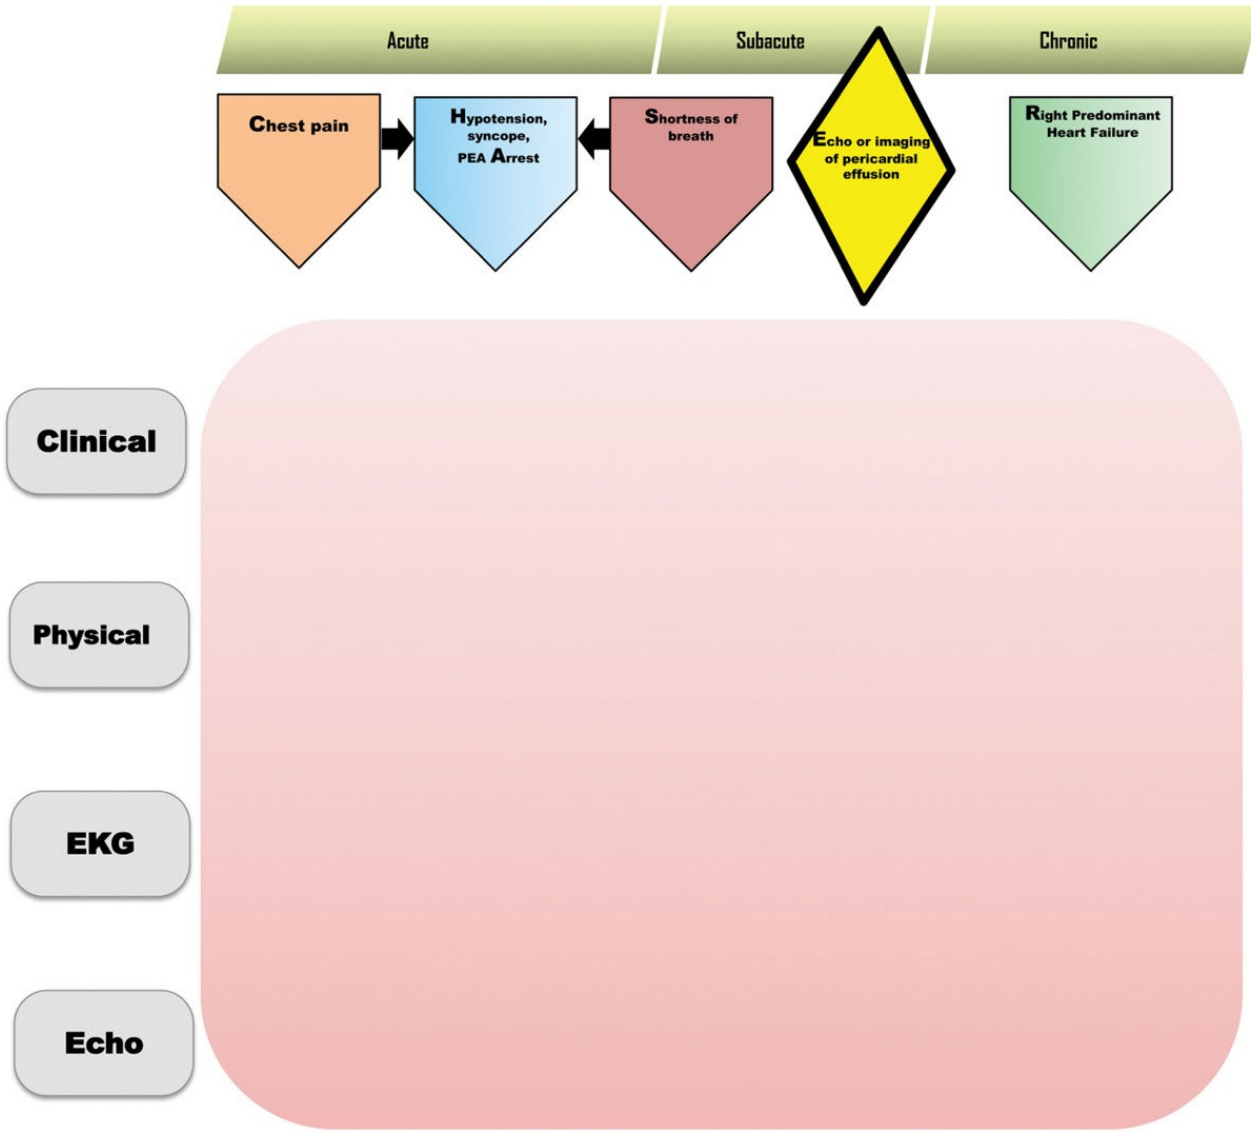

FIGURE 34.2 Entry points into the pericardial disease pathway. The entry points based on the initial clinical presentation form the "CHASER" acronym.

A. Acute pericarditis: new-onset pericarditis
B. Recurrent pericarditis: recurrence of symptoms after being symptom-free for 4 to 6 weeks
C. Incessant pericarditis: symptoms over 4 to 6 weeks
D. Chronic pericarditis: symptoms over 3 months

A systematic approach to patients with suspected pericardial disease starts with the chief presenting complaint and is followed by a history taking, physical examination, electrocardiogram (ECG), and echocardiography. Further

diagnostic testing is tailored to the initial findings.

The following are the five entry points:

1. Chest Pain

Acute pericarditis should be considered in the differential diagnosis of any patient presenting with chest pain along with other etiologies. The chest pain algorithm of the pathway is outlined in **Figure 34.3**. The diagnosis of acute pericarditis relies on the following four cardinal features: characteristic chest pain which is pleuritic and positional, friction rub on physical examination, characteristic evolving ECG changes (**Table 34.1**), and pericardial effusion demonstrated by echocardiography.[3–5] Presence of at least two of these features is usually diagnostic of acute pericarditis. Most cases of acute pericarditis in the Western world are idiopathic or viral, but other causes should also be considered.[6] Initial testing in all patients with acute pericarditis should include tier 1 testing (**Figure 34.3**).[7] Positive cardiac biomarkers indicate myocardial involvement and carry a worse prognosis. Inflammatory markers such as C-reactive protein can be followed sequentially to monitor disease progression and response to treatment. Typical treatment includes nonsteroidal anti-inflammatory agents at full doses for 7 to 10 days.[1] We recommend the following doses: ibuprofen 600 to 800 mg every 6 to 8 hours for 7 to 10 days or aspirin 800 mg every 6 to 8 hours for 7 to 10 days. In post–myocardial infarction pericarditis, aspirin is preferred. In patients without contraindications, colchicines at a dose of 1 to 2 mg first day followed by 0.5 mg daily or twice daily for 3 months should be given because it reduces the rate of recurrence substantially.[5,8]

Corticosteroids increase the likelihood of relapse and should be avoided unless specifically indicated (eg, in patients with connective tissue disease).[5,9] Patients with idiopathic or viral pericarditis usually respond promptly to treatment. Patients with persistent symptoms or with atypical clinical features are more likely to have other causes of pericarditis such as connective tissue disease and should undergo tier 2 testing, as seen in **Figure 34.3**.[10] Those tests include imaging studies such as computed tomography scan of the chest or magnetic resonance imaging.[1] Corticosteroids can be used as a last resort for those patients if no specific cause is found.[1]

2. Hypotension, Syncope, or Pulseless Electrical Activity Arrest

Patients with tamponade can have an acute, dramatic presentation as do patients with acute ascending aortic dissection involving the pericardial sac, or these patients can present with subacute symptoms of chest pain, dyspnea, and syncope as do patients with neoplastic pericarditis. Cardiac tamponade should be suspected in any patient with hypotension, collapse, and pulseless electrical activity arrest (**Figure 34.4**), and high-risk conditions commonly associated with tamponade should be specifically thought of (**Table 34.2**).[11] These include blunt chest trauma, recent procedure/intervention (eg, electrophysiology procedures and coronary interventions), chest surgery, and aortic dissection. Neoplastic pericardial effusion, tuberculous pericarditis, and, uncommonly, idiopathic pericarditis can progress to tamponade. Physical examination findings should focus on pulsus paradoxus, jugular vein pressure, and lung auscultation. ECG findings may include low-voltage QRS complex size and finding of pulsus alternans. Echocardiography is essential in diagnosing pericardial effusion and confirming tamponade by the echocardiographic signs of hemodynamic compromise (**Figure 34.5**). Echocardiography is also commonly used for guiding the intervention. Pericardiocentesis can be lifesaving in these patients.

3. Dyspnea

Patients with significant pericardial effusion often present with dyspnea, poor exercise tolerance, chest discomfort, and fatigue. Although the differential

diagnosis of dyspnea is broad, it should include pericardial effusion (**Figure 34.6**). The pericardium can be the primary focus for the disease, as in most cases of acute pericarditis, or it can be involved in a systemic process such as malignancy, endocrine diseases, or rheumatic diseases. In every patient with suspected pericardial disease, a systematic approach and consideration of possible etiologies are important parts of clinical reasoning (**Table 34.3**). These patients are hemodynamically stable and have no clinical signs of tamponade. ECG characteristics commonly include low-voltage QRS complex size. Pulsus alternans is occasionally seen with large effusions without tamponade.[11] Echocardiography is an effective and inexpensive tool in diagnosing pericardial effusion.

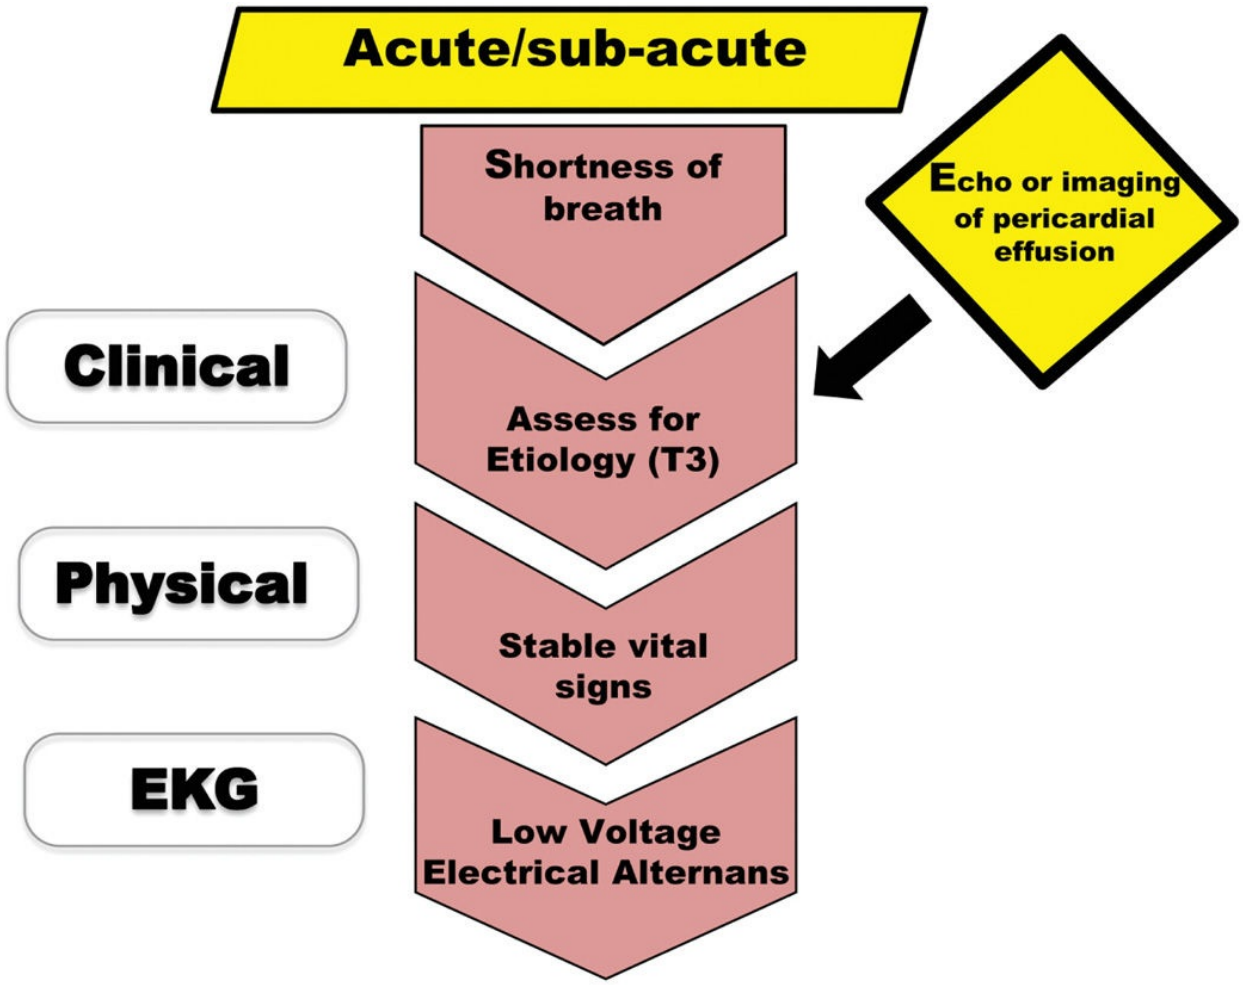

FIGURE 34.6 Approach to a patient with dyspnea and possible pericardial effusion. Initial clinical evaluation of patients suspected to have pericardial effusion is outlined in the figure. 4. Incidental Finding of Pericardial Effusion

Sometimes, pericardial effusion is found as an incidental finding in patients worked up for other causes. Although it is important to search systematically for possible etiologies of pericardial disease in each individual patient (**Table 34.3**), a substantial number of these cases remain unexplained.[12,13] In patients with moderate-to-large effusion, tier 1 and tier 2 testing seem reasonable.[12] If a specific cause is found, it should be addressed. In patients with no obvious clue to the cause of the effusion and no evidence of hemodynamic compromise, elevated inflammatory markers suggest acute idiopathic pericarditis and trial of nonsteroidal anti-inflammatory agents is justified. If inflammatory markers are within normal limits and there is no evidence of hemodynamic compromise, idiopathic pericardial effusion is high on the list of differential diagnoses.[12] Some patients with pericardial effusion have elevated right-sided pressures after pericardial drainage and they might have effusive–constrictive pericarditis.[14]

5. Right-Sided Heart Failure

Patients with constrictive pericarditis typically present with right-predominant heart failure (**Figure 34.7**). Careful review of medical history for high-risk conditions associated with constrictive pericarditis is necessary (**Table 34.4**).[15] Peripheral edema, hepatomegaly, jugular venous distension, and ascites are prominent findings on physical examination. The lungs are typically clear, although pleural effusion may be present. ECG findings, especially repolarization abnormalities, are nonspecific. Atrial fibrillation is present in over one-fifth of patients.[16] Echocardiography is essential in patients suspected to have constriction; these patients typically have normal left ventricular ejection fraction. Other echocardiographic findings include biatrial enlargement and

restrictive filling pattern on the mitral inflow Doppler recording (**Table 34.5**).[14] Further studies to confirm the diagnosis and differentiate it from restrictive cardiomyopathy include imaging studies (such as magnetic resonance imaging) and cardiac catheterization. Pericardial thickness as measured by transesophageal echocardiography may be helpful in making the diagnosis.[17] Early stages of pericardial constriction due to idiopathic pericarditis may have an inflammatory component and may respond to anti-inflammatory therapy.[18] Surgical therapy is otherwise the standard of care.

PERICARDIAL EFFUSION SCORE

Acute cardiac tamponade necessitates immediate pericardiocentesis. The decision to drain the pericardium in patients with slowly accumulating and subacute tamponade is often challenging. We proposed a score approach to decision making in clinically stable patients with pericardial effusion, as outlined in **Figure 34.8**. The score is composed of the following three major parameters: the etiology of the effusion, the size of the effusion, and the echocardiographic assessment of hemodynamic parameters. Etiologic factors favoring drainage of the effusion include traumatic effusion, aortic dissection, and purulent effusion. These effusions typically require surgical drainage as opposed to pericardiocentesis.[1] In malignant effusions, drainage should be considered to relieve symptoms and confirm neoplastic involvement of the pericardium.[19] Pericardial effusion in patients with advanced human immunodeficiency virus and immunosuppression, as well as unexplained and progressive effusion should

also be considered for drainage because some of the neoplastic and infectious causes in these patients are treatable.[20,21] The size of the pericardial effusion as assessed by echocardiography at the end of a diastole is a very important variable.[22] It should be viewed in the context of disease progression (the rate of fluid accumulation).

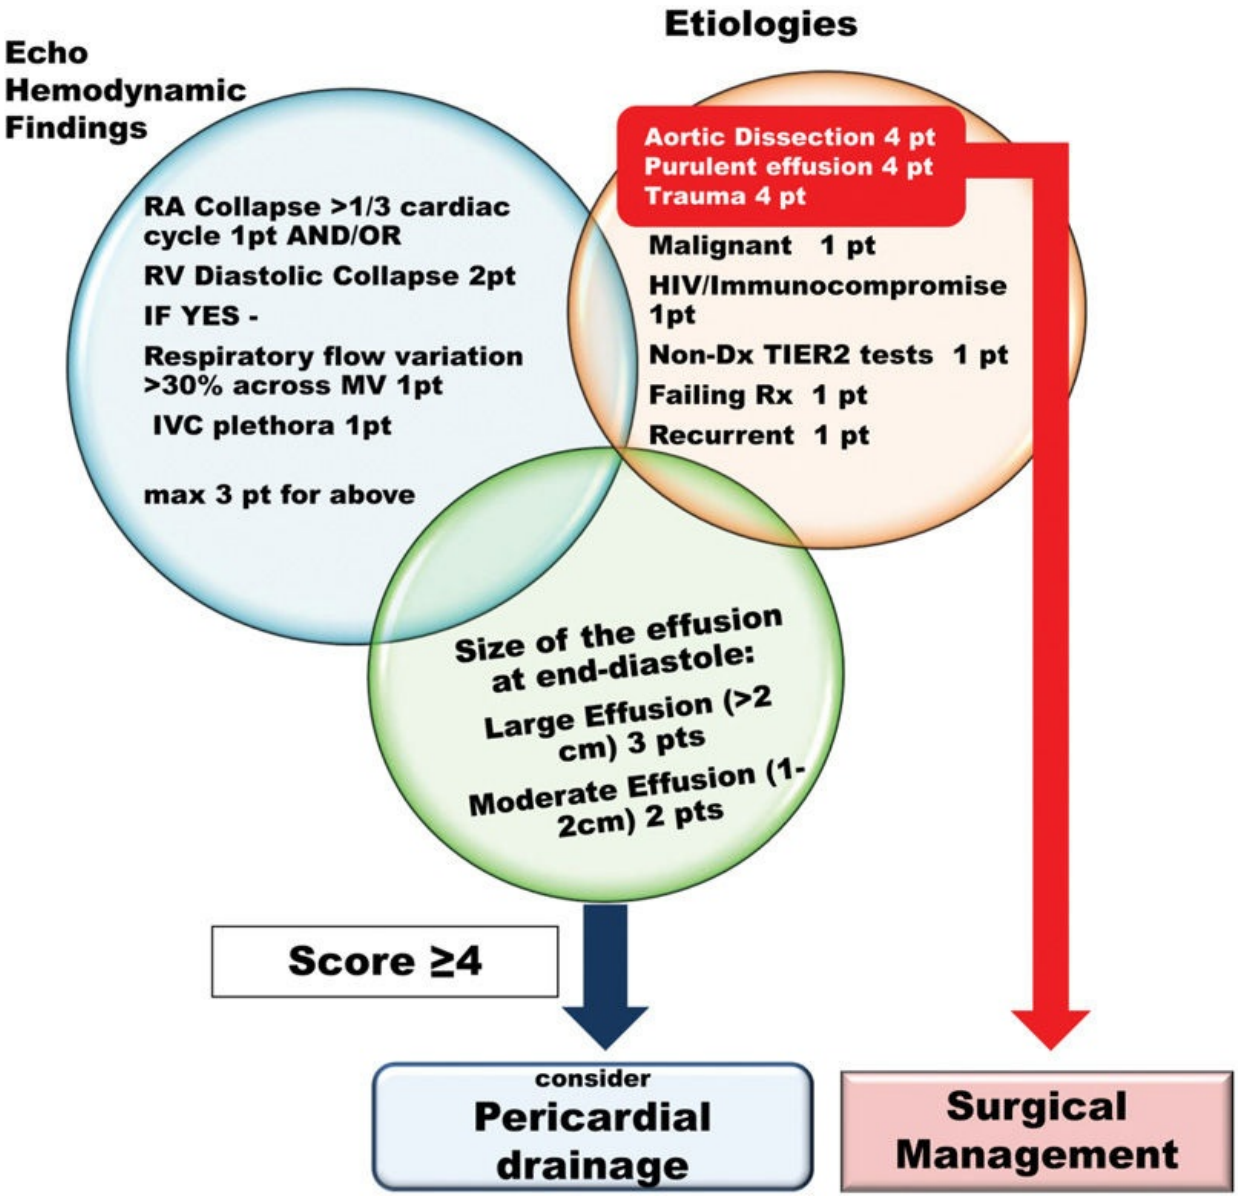

FIGURE 34.8 Pericardial effusion score. The pericardial effusion score, which has three components (etiology of the effusion, effusion size, and echocardiographic evidence of hemodynamic compromise), helps guide clinical decision making in clinically stable patients with pericardial effusion. HIV, human immunodeficiency virus; IVC, inferior vena cava; MV, mitral valve; RA, right atrial; RV, right ventricular.

Chronic large effusions present for more than 3 months are less likely to cause hemodynamic compromise as opposed to recent effusion (<1 month).[14] Echocardiographic signs of hemodynamic compromise provide important evidence in favor of drainage because they may indicate early or impending tamponade. Of note, right atrial collapse is the earliest sign of hemodynamic compromise but has a low specificity if only buckling is present. Right atrial collapse lasting more than one-third of the cardiac cycle seems to be both specific and sensitive.[23] Right ventricular diastolic collapse is a specific sign of hemodynamic compromise but is less sensitive than right atrial collapse.[24] In patients with significant pulmonary hypertension and right ventricular hypertrophy, the sensitivity of this finding is even lower. Left-sided chamber collapse is a late finding in tamponade, and therefore lacks sensitivity.[25] Confirmatory findings should be specifically looked for once a chamber collapse is present. These include respiratory variation in flow velocity across the atrioventricular valves (the mitral and the tricuspid valves), implying ventricular interdependence and engorgement of the inferior vena cava with reduced respiratory collapse. Any chamber collapse combined with a confirmatory finding has a very high sensitivity and specificity for tamponade.[26] In general, a score of 4 or more provides strong evidence in favor of draining the effusion. It should not be viewed as an absolute indication for drainage but rather as a qualitative measure to support decision making. Importantly, the score may change over time as the variables change. Patients with a borderline score may need frequent reassessment in terms of effusion size progression and echocardiographic evidence of hemodynamic compromise.

We conducted a case–control study in consecutive hospitalized patients with moderate-to-large pericardial effusion who had no evidence of hemodynamic compromise upon admission. Patients with pericardial effusion drained for diagnostic and/or therapeutic purpose served as cases, and patients who were not drained served as controls. Our conclusion was that the pericardial effusion scoring index obtained at the initial presentation in patients without immediate hemodynamic compromise showed a high accuracy in identifying patients who required pericardial effusion drainage downstream.[27]

PERICARDIAL DRAINAGE

In patients who need pericardial drainage, echocardiographically guided pericardiocentesis appears to be safe.[28] Depending on the pericardial fluid

accumulation pattern, parasternal, subxiphoid, and apical approaches are all acceptable. As mentioned, the surgical drainage of pericardial effusion is more appropriate in certain patient groups such as in patients with aortic dissection, traumatic hemopericardium, purulent pericarditis, and loculated effusions.[1]

CONCLUSIONS

A stepwise, pathway-based approach to the management of pericardial disease is intended to provide guidance for clinicians in decision making and a patient-tailored evidence-based approach to medical and surgical therapy for pericardial disease.

Aortic Valvular Disease in the Cardiac Care Unit

INTRODUCTION

The aortic valve normally consists of three semilunar leaflets. It is designed to allow unrestricted blood flow from the left ventricle into the ascending aorta during systole and to prevent backflow during diastole. A pathologic state is established whenever each of these two functions is compromised: either aortic stenosis (AS) or aortic regurgitation (AR).

In AS, blood cannot flow freely out of the left ventricle during systole; in AR, the blood flows back into the left ventricle during diastole. AS or AR can be primary causes of severe illness, or they can exacerbate concomitant diseases in critically ill patients presenting to cardiac care units (CCUs).

Because there is no effective medical therapy for these conditions, severe AS and AR ultimately require surgical or transcatheter aortic valve replacement (TAVR) to achieve clinical stability and alter their natural progression. Rapid diagnosis and supportive medical therapy are necessary until definitive treatment can be provided.

With the introduction of TAVR, a true revolution has occurred. Patients with severe AS who were previously deemed too high risk to undergo surgery are now able to be treated safely and effectively. In the early days of TAVR, the

procedure was done under general anesthesia and required postprocedural care with CCU observation. However, there has been a general trend to replace general anesthesia with moderate sedation, and CCU care is often shortened or even unnecessary.[1]

AORTIC STENOSIS

ETIOLOGY AND PATHOPHYSIOLOGY

In the adult CCU, the most common etiology of AS is calcific degeneration (**Figure 35.1)** of a previously normal trileaflet aortic valve (TAV) or a congenitally bicuspid aortic valve (BAV). Calcific TAV stenosis is typically encountered among the elderly and calcific BAV stenosis in middle-aged patients. It is estimated that moderate or severe AS is present in 0.4% of all Americans, and in 2.8% of people 75 years of age or older.[2]

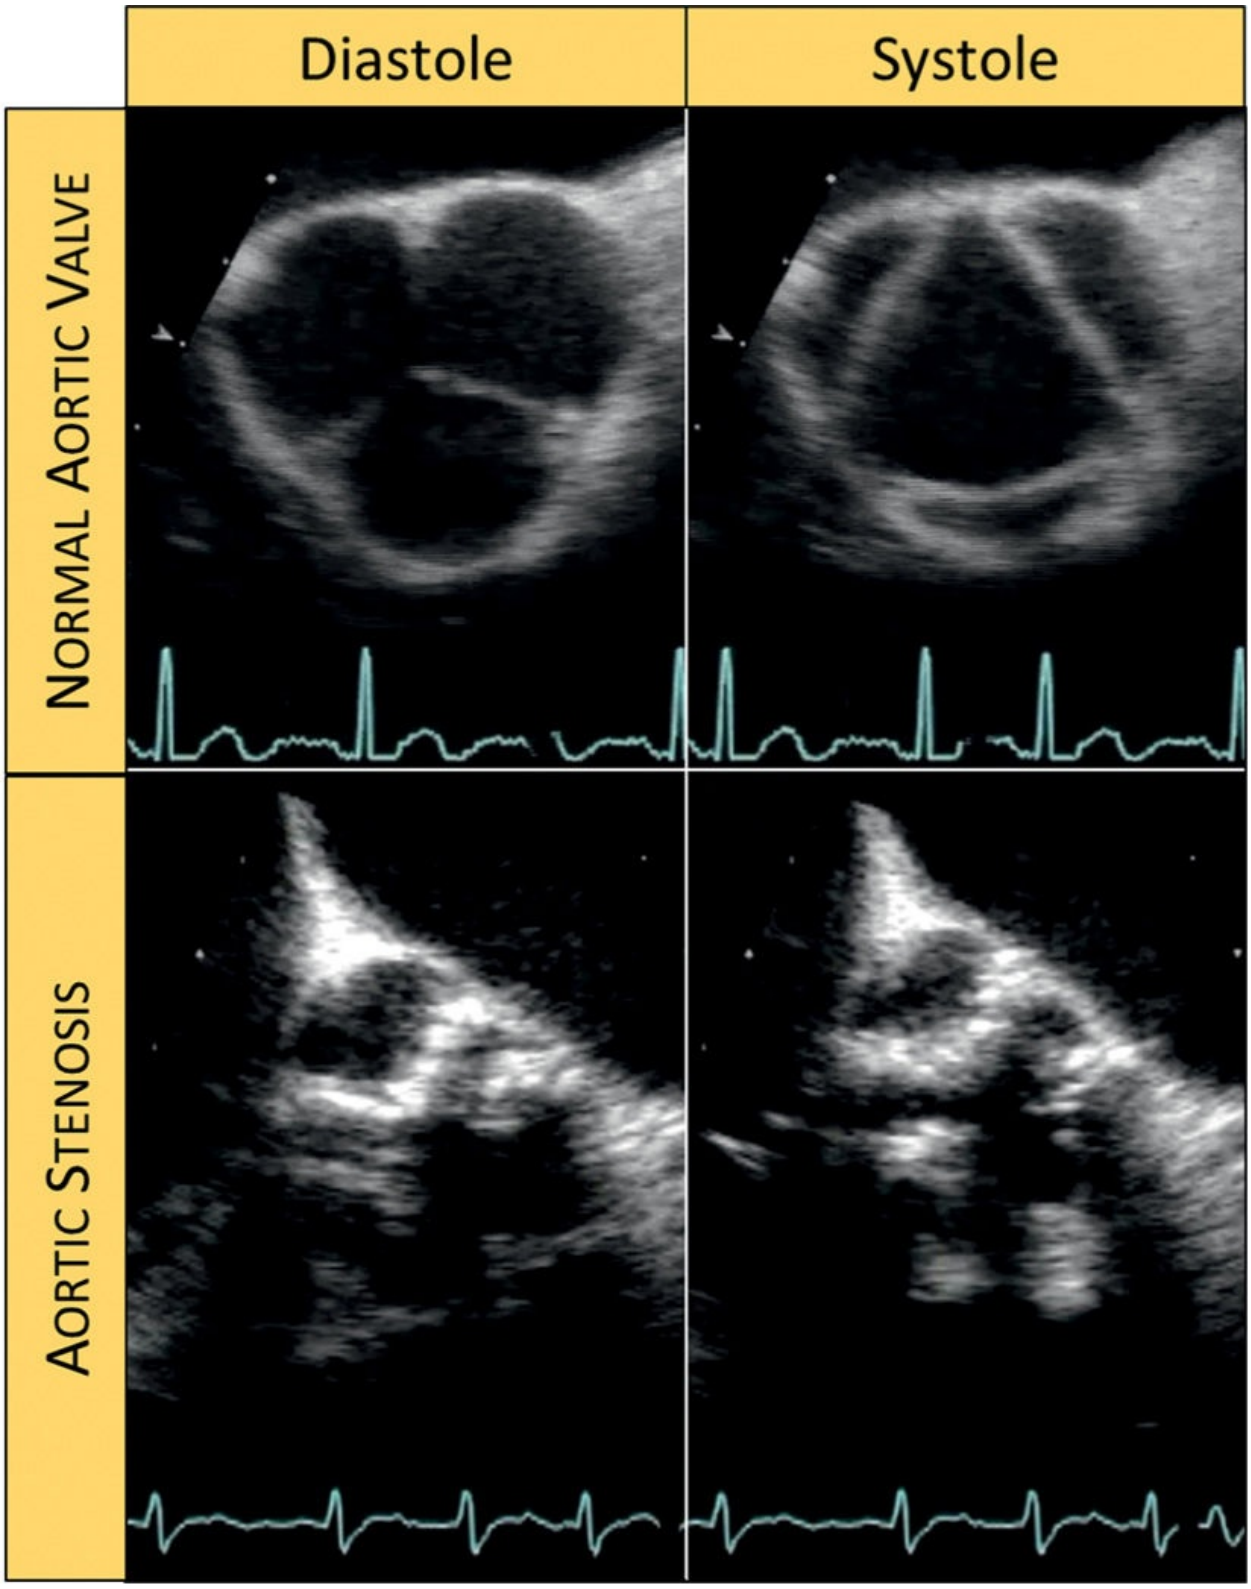

FIGURE 35.1 Aortic stenosis on echocardiography. Transesophageal echocardiogram (TEE) showing normal valve anatomy and a severely stenotic aortic valve, both in diastole and systole. Note how calcified and narrowed the stenotic valve appears.

Once thought to be the result of passive wear and tear, AS of a TAV is now understood to be a manifestation of generalized atherosclerosis, an active proliferative and inflammatory process.[3,4] Thus, this form of AS and atherosclerosis share risk factors such as smoking, hyperlipidemia, and hypertension.[5,6] In addition, disorders of calcium phosphate metabolism such as end-stage renal disease and Paget disease, as well as mediastinal radiation treatment, increase the risk for development of AS.[7]

BAV is the most common congenital heart defect, occurring in approximately 1% to 2% of all live births.[8] BAV may evolve into AS or AR and may be associated with diseases of the aorta such as aortic aneurysm, aortic dissection, and coarctation.[9]

The most important physiologic adaptation to the pressure overload from AS is left ventricular hypertrophy (LVH). This leads to concentric hypertrophy, a process in which the left ventricular (LV) chamber becomes smaller and its wall thicker; such changes decrease the wall stress and preserve left ventricular ejection fraction (LVEF) for very long periods. When LVEF starts to decrease, the underlying mechanism is an afterload-LVH mismatch (insufficient hypertrophy for the degree of AS) rather than true cardiomyopathy.

CLINICAL PRESENTATION

The classic triad of symptomatic severe AS consists of angina, syncope, and dyspnea from heart failure. AS is usually asymptomatic unless severe. The importance of recognizing the symptomatic stage of AS, as established by the seminal work by Ross and Braunwald, is the rapid rise in mortality once symptoms develop.[10] Following a latent asymptomatic period, patients who progress to severe symptomatic AS experience over 50% mortality in the next 2 to 3 years if no intervention is pursued.[11]

DIAGNOSIS

Although physical examination may establish the diagnosis, it is often unable to precisely grade AS severity. The typical findings in auscultation of AS include a systolic crescendo–decrescendo ejection murmur over the precordium that radiates to the neck, which becomes late peaking as the aortic valve becomes more stenotic. The prolonged ejection time leads to a single or, paradoxically, split second heart sound (S2), with occasional absence of S2 in severe cases.[12] Carotid upstroke is typically weak and delayed (*pulsus parvus et tardus*).

Electrocardiogram (ECG) often meets criteria for LVH and left atrial enlargement. Although chest X-ray (CXR) rarely provides direct evidence of AS, it occasionally shows aortic valve calcifications. In addition, pulmonary venous congestion is frequently seen in decompensated patients.

The primary means of diagnosing and grading AS is echocardiography, and aortic valve area (AVA) is the primary criterion of AS. When there is normal flow across the aortic valve, the magnitude of the peak and mean systolic gradient across the aortic valve is inversely related to AVA (**Table 35.1**). Additional echocardiographic findings in patients with significant AS include LVH, left atrial enlargement, and typically preserved LVEF.

TABLE 35.1 Aortic Valve Stenosis Criteria in Patient With Preserved Transvalvular Flow

	NONSTENOTIC AORTIC VALVE	MILD AS	MODERATE AS	SEVERE AS
Valve area (cm^2)	2.0–4.0	>1.5	1.0–1.5	<1.0
Valve area index (cm^2/m^2)				<0.6
Peak velocity (m/s)	<2.5	2.5–3.0	3.1–4.0	>4.0
Peak gradient (mm Hg)	<25	25–36	37–64	>64
Mean gradient (mm Hg)		<25	25–40	>40
ACC/AHA stage	A (at risk)	B (progressive)		C (asymptomatic) D (symptomatic)

ACC, American College of Cardiology; AHA, American Heart Association.

A low transvalvular gradient (mean gradient ≤30 mm Hg) does not exclude severe AS. In patients with low transaortic volume flow rate, peak and mean systolic gradients do not accurately reflect severity of AS. Low flow may occur for two separate reasons: (1) low stroke volume in the setting of small hypertrophied left ventricle with preserved LVEF and (2) low stroke volume in the setting of LV systolic dysfunction and low LVEF. Low flow is typically defined as a low LV stroke volume index of <35 mL/m^2.

In patients with low-flow, low-gradient severe AS with normal LVEF, echocardiography demonstrates small LV chamber size, abnormal diastolic

filling, and increased LV relative wall thickness. In contrast, in patients with systolic dysfunction and depressed LVEF, low transvalvular gradients are found for two reasons: either afterload-hypertrophy mismatch or concomitant cardiomyopathy (such as ischemic heart disease). Differentiating between these two groups is extremely important because the patients in the first group will benefit from aortic valve surgery, whereas those in the second group may not (**Figure 35.2**).[13]

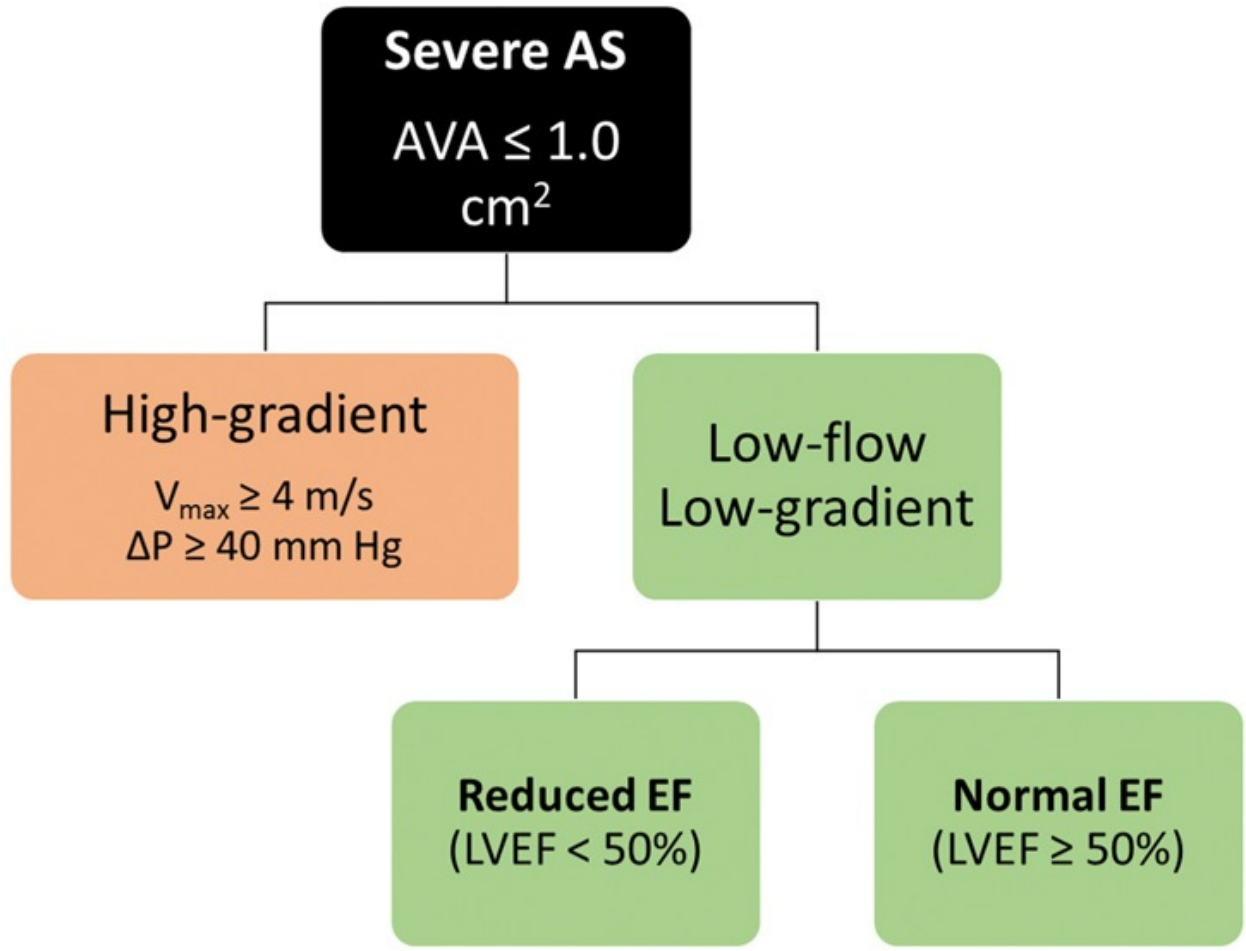

FIGURE 35.2 Three forms of AS. Flowsheet showing three different categories of severe aortic stenosis. Hemodynamic parameters (peak velocity and mean gradient) discriminate high-gradient from low-gradient severe AS. In low-gradient severe AS with reduced EF, dobutamine stress echocardiography is used to confirm true severe AS. In low-gradient severe AS with normal EF, low stroke volume, LV size and abnormal LV parameters are commonly present. AS, aortic stenosis; EF, ejection fraction; LV, left ventricular; LVEF, left ventricular ejection fraction.

To differentiate between these two groups, various LV and aortic valve parameters are assessed at rest and following intravenous infusion of increasing

amounts of dobutamine starting at 5 μg/kg/min and escalating up to 20 μg/kg/min.[14] These parameters are usually measured by echocardiography (modified dobutamine stress echocardiogram). However, these parameters may also be evaluated during cardiac catheterization.

In patients with low-gradient AS with reduced LVEF, changes in the following three parameters are measured during dobutamine stress testing: LV stroke volume, AVA, and mean gradient. If the stroke volume increases ≤20%, the patient likely has severe cardiomyopathy and is usually not a candidate for aortic valve surgery. On the other hand, if the stroke volume increases more than 20%, two scenarios are possible: (1) AVA remains essentially the same but the mean gradient increases above 30 mm Hg and (2) AVA increases by 0.2 cm^2 or more but the gradient remains essentially unchanged. In the first scenario, patients have true severe AS and will benefit from aortic valve surgery. In the second scenario, patients have pseudosevere AS due to LV cardiomyopathy; they are unlikely to benefit from aortic valve surgery (**Figure 35.3**).

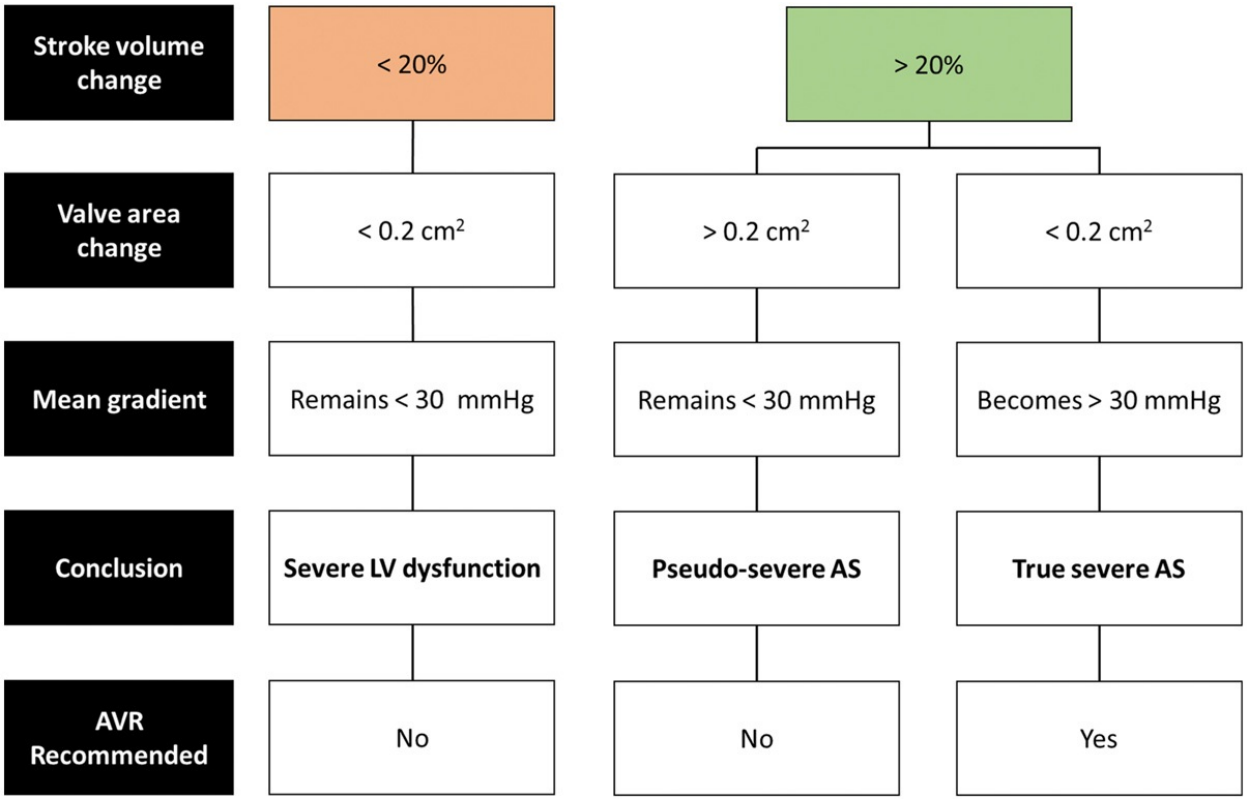

FIGURE 35.3 Dobutamine stress testing for severe low-gradient aortic stenosis with diminished LVEF. AS, aortic stenosis; AVR, aortic valve replacement.

Cardiac catheterization is usually unnecessary because echocardiography is the gold standard for diagnosis and quantification of AS. However, because coronary artery disease is common in patients with AS, coronary angiography is usually performed before surgical or percutaneous AVR. In this setting, aortic valve gradients may be evaluated using invasive hemodynamic measurements.

When comparing aortic gradients obtained by cardiac catheterization, it is the mean but not the peak aortic gradient that correlates with echocardiography. Cardiac catheterization and echocardiography measure two separate peak gradients (**Figure 35.4**).

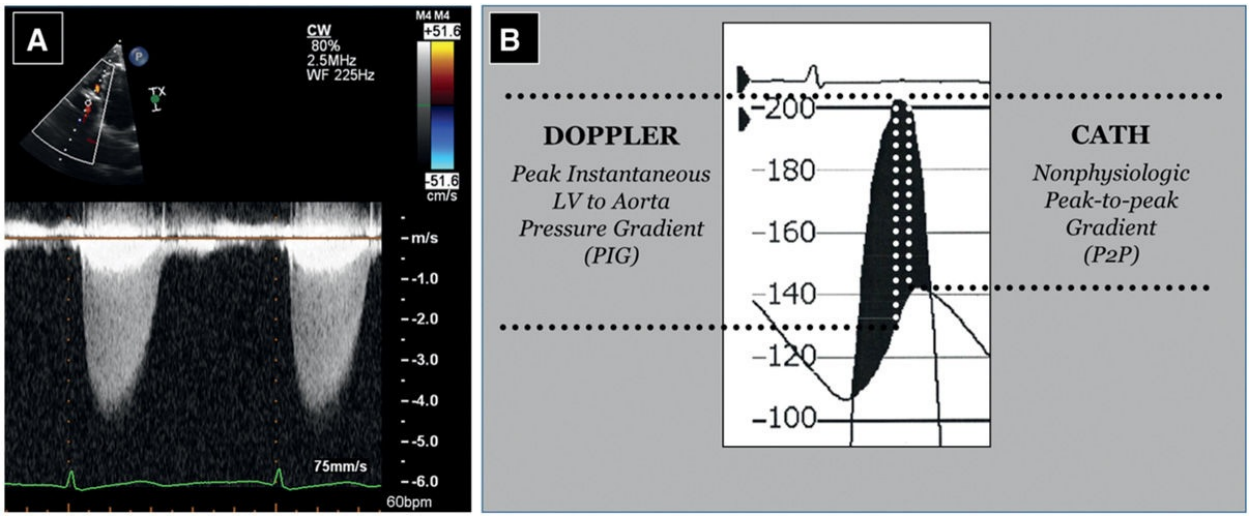

FIGURE 35.4 Aortic stenosis: echocardiography versus catheterization. Comparison between echocardiographic measurement of systolic aortic valve pressure gradient by peak velocity (A) and peak-to-peak gradient measured by cardiac catheterization (B). With simultaneous left ventricular and aortic pressure tracing, it becomes apparent that peak-to-peak gradient underestimates true maximum pressure gradient. Note the very high ventricular pressure in systole, and the delayed low-pressure peak in the aortic root (the hemodynamic basis for *pulsus parvus et tardus*). LV, left ventricular; PIG, peak instantaneous pressure gradient.

On catheterization, the so-called peak-to-peak (P2P) gradient is measured, which represents the pressure difference between the peak LV systolic pressure and the peak aortic systolic pressure. These two peaks do not occur simultaneously and are thus nonphysiologic; the more severe the AS, the greater the time difference between the two pressure peaks.

On echocardiography, the peak instantaneous pressure gradient (PIG) is measured instead; it represents the pressure difference between LV systolic and aortic pressure at the same time point. P2P is typically lower than PIG, largely due to the pressure recovery phenomenon (kinetic energy converted to potential

energy in the ascending aorta).[15]

MEDICAL THERAPY

There are no proven medical therapies for prevention or treatment of AS, and routine antibiotic prophylaxis of bacterial endocarditis in patients with AS is no longer recommended.[16]

Usually, patients with severe AS present to the CCU with clinical signs of heart failure. Pharmacologic therapy including diuretics, angiotensin-converting enzyme (ACE) inhibitors, and digitalis may be used with caution. Although intravenous vasodilators used to be contraindicated in patients with severe AS, intravenous nitroprusside has been demonstrated to relieve symptoms of heart failure in patients with severe AS and severely reduced LV systolic function.[17] In that study, intravenous nitroprusside was started at a mean dose of 14 ± 10 μg/min, and the dose was increased to a mean of 103 ± 67 μg/min at 6 hours and 128 ± 96 μg/min at 24 hours.

Patients with severe AS may also present with other critical illnesses, such as septic shock. Management of these patients can be extremely challenging owing to the narrow balance between preload and afterload. Hemodynamic compromise is common. Hypotension from severe sepsis or septic shock may initiate a spiral of death, in which low aortic pressure leads to low coronary perfusion, with further ventricular impairment that fails to pump blood against a severely stenotic valve. This negative feedback rapidly leads to cardiac arrest and should be promptly recognized so that vasopressors are administered before such cascade takes place.

SURGICAL AND PERCUTANEOUS INTERVENTIONAL THERAPY

AS is a mechanical problem that requires a mechanical intervention. AVR is the preferred therapeutic choice in patients with AS to improve symptoms and increase survival. Major indications for AVR are listed in **Table 35.2**.

TABLE 35.2 Maior Indications for Aortic Valve Replacement in Patients With Aortic Stenosis

SYMPTOMS	RECOMMENDATION FOR AORTIC VALVE REPLACEMENT	ACC/AHA STAGE	COR	LOE
	Symptomatic high-gradient severe AS (by history or exercise testing)	D1	I	B

Symptomatic	Symptomatic low-flow/low-gradient severe AS with reduced EF (confirmed by dobutamine stress echocardiography)	D2	IIa	B
	Symptomatic low-flow/low-gradient severe AS with preserved EF (if valve obstruction is considered the cause of symptoms)	D3	IIa	B
	Severe AS undergoing other cardiac surgery	C or D	I	B
Asymptomatic	Asymptomatic high-gradient severe AS with LV dysfunction (EF <50%)	C	I	B
	Asymptomatic high-gradient very severe AS (V_{max} ≥5 m/s) and low surgical risk	C	IIa	B

ACC, American College of Cardiology; AHA, American Heart Association; AS, aortic stenosis; COR, class of recommendation; EF, ejection fraction; LOE, level of evidence; LV, left ventricular; V_{max}, peak velocity.
For a complete list, refer to the 2014 AHA/ACC Valvular Heart Disease Guideline. Note the lower class of recommendation for symptomatic patients with low-flow severe AS, both with reduced and preserved EF.

Surgical aortic valve replacement (SAVR) is the standard approach, indicated for patients with acceptable surgical risk who meet indications for AVR.[13] The technical aspects are beyond the scope of this chapter, but clinicians should be familiar with the decision process when choosing a surgical prosthesis. In addition to the appropriate size, such that there is no postoperative patient–prosthesis mismatch, the valve material has significant implications for the patient. Although a bioprosthesis is considered to be less durable than a mechanical valve, it offers the advantage of not requiring systemic anticoagulation. As such, in patients who are older or who have a contraindication for anticoagulation, a bioprosthetic implant is preferred. Conversely, in younger patients who have no contraindications for anticoagulation, a mechanical valve is reasonable. Above all, this should be a shared decision process between the surgeon and the patient.

Percutaneous interventions for AS include aortic valve balloon valvuloplasty and TAVR. Balloon valvuloplasty is an effective form of therapy for congenital AS. However, balloon valvuloplasty in calcific TAV or BAV AS is rather ineffective (valve area seldom increases above 1.0 cm^2 and there is a high rate of restenosis) and has significant morbidity and mortality.

Currently, typical indications for balloon valvuloplasty in calcific AS include short-term relief of AS in patients undergoing noncardiac surgery (such as hip replacement), in those with terminal illness (such as cancer), or as a temporizing measure in patients who are rapidly decompensating from severe AS in whom durable interventions are being entertained.

TAVR has changed the landscape of therapy for AS, allowing for patients who were previously too ill for surgery to receive lifesaving therapy. Since the first percutaneous replacement was performed by Alain Cribier in 2002, there have been over 200,000 TAVR procedures performed worldwide.[18] TAVR is now approved in patients with symptomatic severe AS who are inoperable, or are either high or intermediate risk for SAVR.

TAVR was considered experimental until 2010, when the first randomized trial showed a markedly improved survival in patients who were not surgical candidates.[19] These findings were subsequently confirmed in head-to-head trials comparing TAVR with SAVR in high-risk and intermediate-risk surgical patients.[20] In addition, TAVR is currently being investigated in low-risk patients.

Consequently, concerns regarding durability of transcatheter valves in comparison with surgical valves emerged, highlighted by the limited reliable data available on TAVR durability beyond five years.[21] Still, factors like lower rates of patient-prosthesis valve mismatch in TAVR compared with SAVR[22] might skew the durability data in favor of transcatheter prosthesis. There are currently two approved device types in the United States, a balloon-expandable (Edwards Sapien family of TAVR valves) and a self-expandable valve (Medtronic CoreValve family of TAVR valves), both of which been updated with new design features to reduce paravalvular AR (**Figure 35.5**).

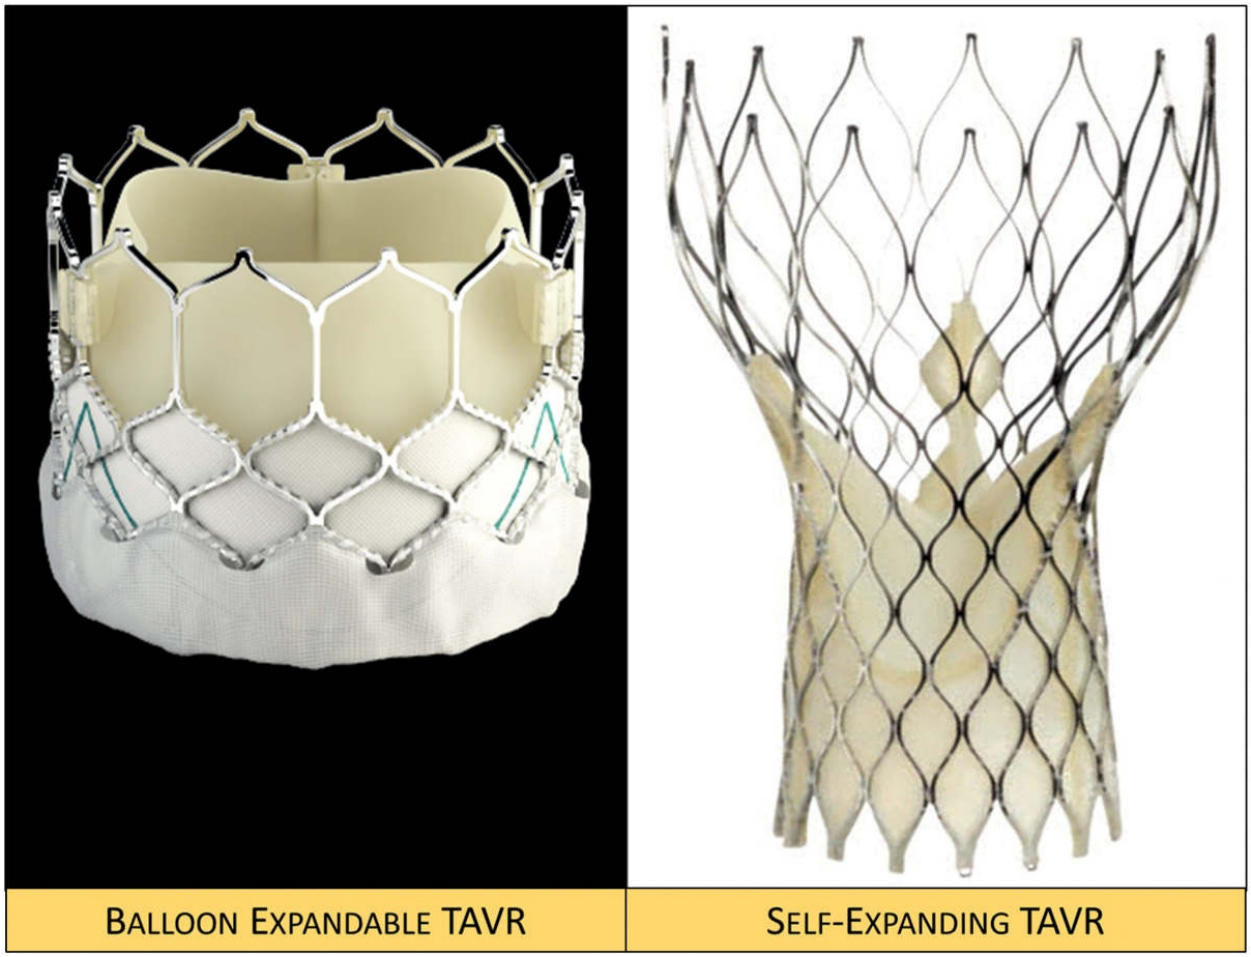

FIGURE 35.5 Transcatheter aortic valve replacement valves. Two major types of transcatheter implantable aortic valves. The balloon-expandable valve has a short and straight frame (left), whereas the self-expandable valve is longer and hourglass-shaped (right). These different metallic frames facilitate identification in routine chest radiography. TAVR, transcatheter aortic valve replacement. (Images available at the manufacturer's websites:www.tavrbyedwards.com and www.corevalve.com, respectively.)

POST-TRANSCATHETER AORTIC VALVE REPLACEMENT COMPLICATIONS

Patients who undergo TAVR are usually cared for in the CCU postprocedurally, so it is important to be familiar with the most common complications such as vascular access complications, neurologic events, conduction abnormalities, coronary artery obstruction, low cardiac output, annular rupture, and paravalvular AR.

Besides femoral access bleeding and vascular complications from the large sheaths used, patients should be closely monitored for neurologic changes given the risk of stroke from the large-profile devices advanced through the arterial system and crushing the calcified native valve.

Patients are also monitored for conduction abnormalities, specifically complete heart block from extrinsic compression of the conductions system following valve deployment. These patients routinely receive temporary venous pacemaker placement preprocedurally. Persistent heart block requiring permanent pacemaker is more common in patients with preexisting conduction system disease, especially right bundle branch block. Need for permanent pacing was previously more commonly seen in the self-expandable valve. However, with the latest generation of TAVR valve, the rate of permanent pacemaker implantation is similar between self-expanding and balloon-expandable TAVR valves.[23]

Periprocedural complications, usually diagnosed before transfer to CCU for monitoring, include coronary artery obstruction, low cardiac output, annular rupture, and paravalvular AR. Late complications include leaflet thrombosis, valvular degeneration, and infective endocarditis.

IMPACT OF SEVERE AORTIC STENOSIS ON PREGNANCY

Patients with calcific AS are seldom of child-bearing age. In patients of child-bearing age, AS is usually caused by noncalcific congenital abnormalities (such as unicuspid aortic valve). Young patients with moderate-to-severe AS should be advised against conception until AS is relieved. Those who nonetheless become pregnant may or may not develop severe symptoms. Pregnant patients with AS and mild symptoms may be managed conservatively during pregnancy with bed rest, oxygen, and β-blockers. Pregnant patients with severe symptoms may need percutaneous or surgical intervention. These procedures carry significant risk to both the mother and the unborn child.[24]

AORTIC REGURGITATION

ETIOLOGY AND PATHOPHYSIOLOGY

AR may be caused by disorders of the aortic root or the aortic valve leaflets. BAV, ascending aortic aneurysm, aortic dissection, and endocarditis are common causes of AR. Conditions predisposing the patient to aortopathies and AR include hypertension and connective tissue disorders (such as Marfan syndrome, Ehlers–Danlos syndrome, and ankylosing spondylitis). In less developed countries, rheumatic heart disease and tertiary syphilis remain important causes of AR.

In AR, the blood flows back into the ventricle through the aortic valve during diastole, joining the systemic volume that entered the left ventricle through the mitral valve. During the subsequent systole, both volumes leave the aortic valve together; the systemic volume continues into the aorta and its branches, whereas the regurgitant volume flows back into the ventricle. The cycle then repeats itself. Subsequent pathophysiology depends on whether AR is chronic or acute.

In chronic AR, the left ventricle progressively enlarges to accommodate the combined systemic stroke volume and the regurgitant volume. This remodeling often prevents significant elevation of left heart pressures. It may take years, if not decades, for patients with chronic AR to develop congestive heart failure owing to progressive LV systolic dysfunction. This adaptation contrasts with acute AR, in which there is sudden volume overload of a nondilated left ventricle, marked elevation of LV and left atrial pressures, life-threatening pulmonary edema, and even cardiogenic shock.

Patients with severe AR, whether acute or chronic, typically present to the CCU with signs and symptoms of heart failure. Although severe acute AR represents only a minority of AR cases, its often fulminant and life-threatening course necessitates CCU admission. The rest of the section on AR is devoted to severe acute AR.

CLINICAL PRESENTATION

The most common etiologies of severe acute AR are chest trauma, bacterial endocarditis, and dissection of the ascending aorta (Stanford type A aortic dissection). Less commonly, severe acute AR may result following balloon valvuloplasty for severe AS.

Patients with severe acute AR frequently present with fulminant pulmonary edema and cardiogenic shock. Patients with endocarditis will also have general signs and symptoms of a systemic bacterial illness. Patients with acute type A aortic dissection usually complain of severe chest pain, often in the setting of uncontrolled systemic hypertension.

DIAGNOSIS

In severe acute AR, there may be few or no auscultatory findings of AR; the diastolic murmur is often soft, short, or even absent because of the rapid equilibration of aortic and LV pressures during diastole. This is due to the acute nature of the disease, which precludes increased compliance of the left ventricle.

Therefore, the rapid rise in LV end-diastolic pressure limits the total regurgitant volume, explaining the underwhelming diastolic murmur and the lack of wide pulse pressure. There is, however, marked tachycardia and S3 gallop.

CXR in severe acute AR frequently reveals pulmonary congestion. ECG may show tachycardia; there may also be signs of myocardial ischemia (owing to high myocardial demand caused by very elevated LV pressures or when acute aortic dissection extends into the coronary artery ostia). When endocarditis leads to periaortic valve abscess, ECG may demonstrate varying degrees of atrioventricular conduction block.

Transthoracic and transesophageal echocardiography are the primary means of evaluating AR. Echocardiography may establish the etiology, mechanism, and severity of AR (**Figure 35.6**). The diagnostic criteria for grading the severity of AR are listed in **Table 35.3**.

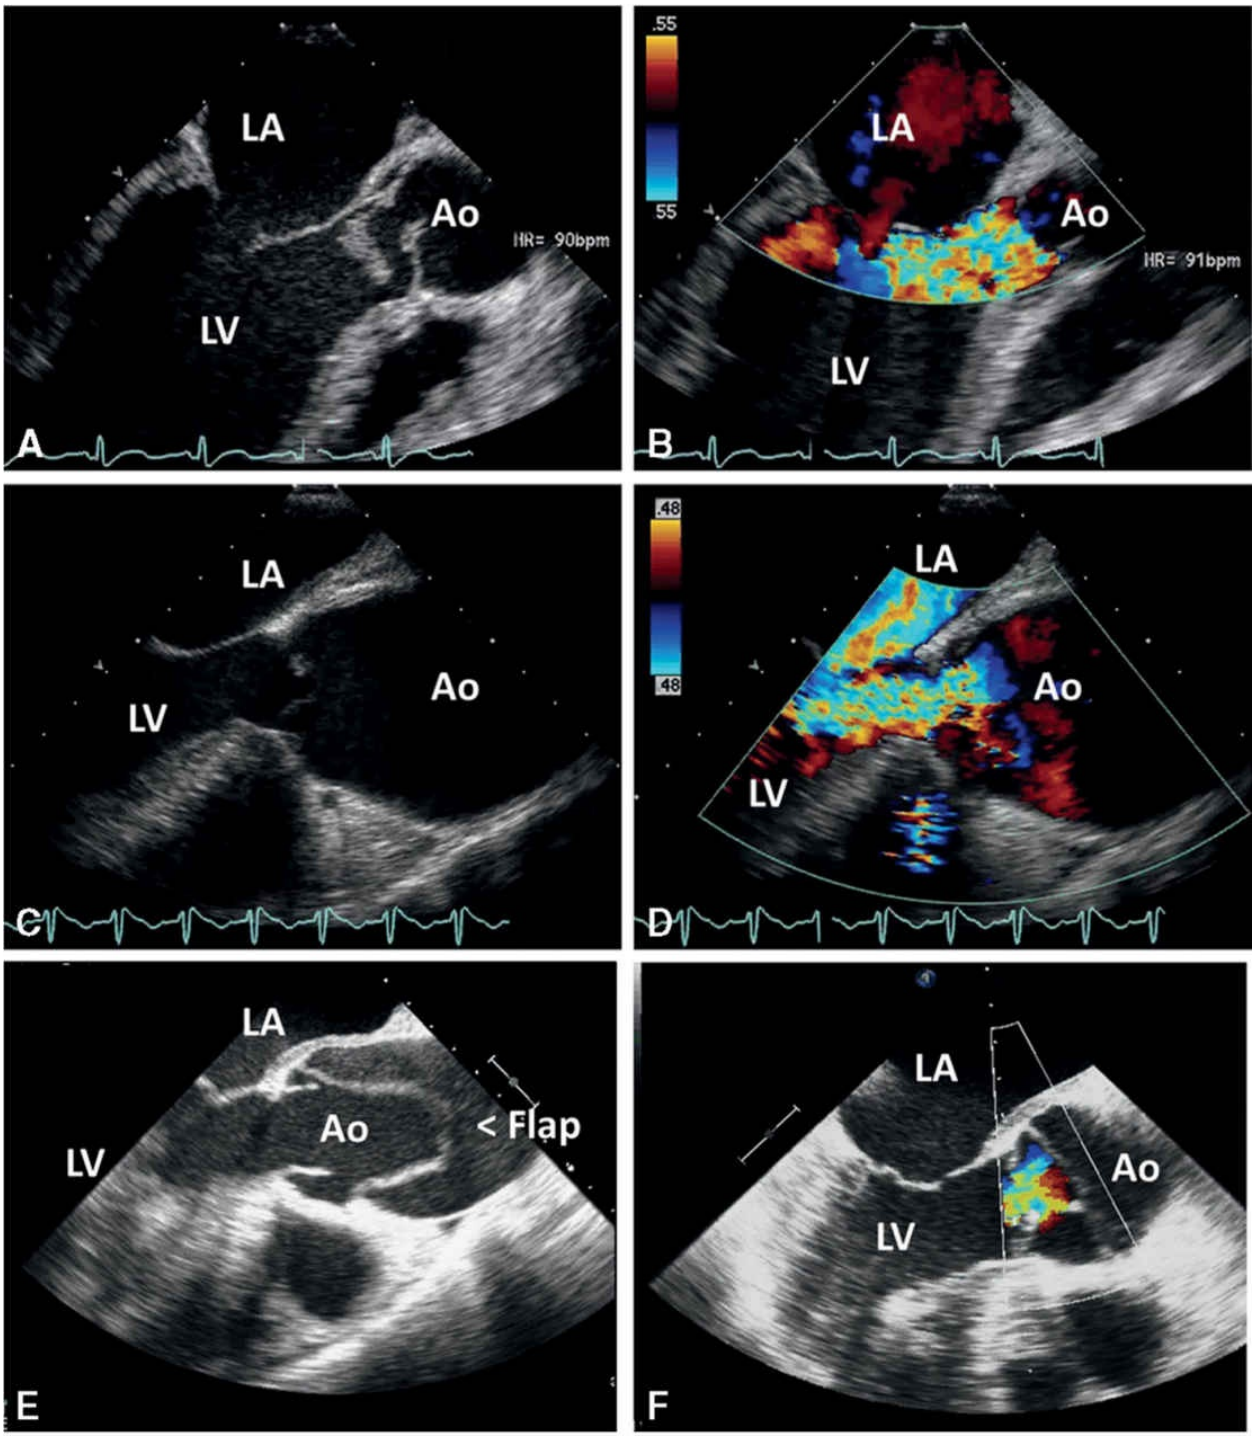

FIGURE 35.6 Aortic regurgitation on echocardiography. Causes of severe aortic regurgitation include aortic valve endocarditis (A and B), ascending aortic aneurysm (C and D), and type A aortic dissection (E and F). Ao, ascending aorta; LA, left atrium; LV, left ventricle.

TABLE 35.3 Grades of Aortic Regurgitation

	MILD	MODERATE	MODERATE–SEVERE

	AR	AR	AR	SEVERE AR
Grade	1+	2+	3+	4+
Regurgitant orifice area (cm^2)	<0.1	0.10–0.19	0.20–0.29	>0.3
Regurgitant fraction	<30%	30%–39%	40%–49%	>50%
Regurgitant volume (mL)	30	30–44	45–59	>60
Vena contracta (cm)	<0.3	0.3–0.6	>0.6	
ACC/AHA Stage	B (progressive)			C (asymptomatic) D (symptomatic)

ACC, American College of Cardiology; AHA, American Heart Association; AR, aortic regurgitation.
Note that stage A denotes a nonregurgitant aortic valve, which is at risk for aortic regurgitation (such as bicuspid aortic valve or ascending aortic aneurysm).

MEDICAL THERAPY

Severe acute AR is a life-threatening medical emergency that necessitates highest levels of CCU care. Diuretic therapy, positive end-expiratory pressure, and supplemental oxygen administration with endotracheal intubation are used to treat pulmonary edema. Afterload reduction may be achieved with the use of intravenous vasodilators (such as nitroprusside). Disease-specific therapies, if available, should also be administered (such as antibiotic therapy for endocarditis).

SURGICAL AND PERCUTANEOUS INTERVENTIONAL THERAPY

In severe acute AR, aortic valve surgery should be performed as soon as possible, especially in cases of type A aortic dissection and infective endocarditis. The standard procedure of choice is surgical AVR. At present, there is no approved percutaneous option for patients with pure AR.

Aortic valve sparing surgeries may be an alternative to surgical AVR in specialized centers. This surgery, known as the David procedure (after Tirone David, the Brazilian surgeon who conceived and first performed this technique), involves ascending aorta repair with a vascular graft, followed by coronary artery reimplantation, reconstruction of the aortic root, and reimplantation of the aortic valve.[25] This technique is better suited for young patients with genetic

syndromes associated with aortic root dilatation, and it is still not employed universally.

In-hospital and long-term survival is significantly improved in patients who promptly undergo SAVR or repair.[26] However, such intervention might be prohibitive in patients with severe embolic strokes or comorbid conditions that diminish the prospect of reasonable recovery.

Despite the excitement about transcatheter therapies in severe AS, use of TAVR in severe AR has been reported only anecdotally. A stenotic calcific aortic valve forms a solid structure for anchoring in transcatheter replacement, whereas a regurgitant aortic valve—often associated with a dilated aortic root—poses a great challenge in holding a transcatheter valve. Still, TAVR may represent a last resort in patients who present with severe symptomatic AR who are not surgical candidates.

Registry data from self-expanding TAVR (which have a larger anchoring profile than balloon-expandable valves) in patients with predominant AR show significantly increased mortality when compared with patients undergoing TAVR for severe AS (around 20%), particularly in patients in whom valvular calcification was absent.[27,28]

Furthermore, intra-aortic balloon pump (IABP) is absolutely contraindicated when significant AR is present. Diastolic counterpulsations—which are the hallmarks of IABP function—worsen AR. This, in turn, decreases effective stroke volume and cardiac output, worsening cardiogenic shock. In addition, it increases LV end-diastolic pressure and myocardial oxygen consumption, worsening pulmonary edema and myocardial ischemia. Therefore, in conditions that usually require IABP for medical stabilization (such as cardiogenic shock and refractory ischemia), use of counterpulsation is prohibitive with moderate or severe AR.

IMPACT ON PREGNANCY

The hemodynamic changes associated with pregnancy (increased cardiac output from increased heart rate and stroke volume) are more likely to decompensate patients with stenotic valvular diseases compared with those with insufficient valves, given the mechanical obstruction to blood flow in such conditions. Conversely, regurgitant lesions are better tolerated in pregnancy, and AR is generally tolerated unless it is severe.

Severe AR, whether acute or chronic, is one of the valvular heart lesions that

may be associated with high maternal and/or fetal risk during pregnancy. Pregnant women with AR who have New York Heart Association functional class III to IV symptoms, severe pulmonary hypertension (pulmonary pressure >75% of systemic pressures), and/or LV systolic dysfunction are at particular risk for maternal and fetal complications. The same is true for pregnant women having Marfan syndrome with or without AR.[24]

Patient and Family Information for: AORTIC VALVULAR DISEASE IN THE CARDIAC CARE UNIT

GENERAL CONCEPTS OF AORTIC VALVULAR DISEASE

The heart is a muscular organ whose primary function is to pump blood in our body. To accomplish this goal, several valves are present in its different chambers to prevent backflow. The aortic valve is a valve composed of three thin leaflets, separating the aorta—the largest artery in the body from which all the blood pumped out of the heart flows—and the left ventricle—the chamber that pumps blood out of the heart to the rest of the body. When the aortic valve becomes too narrowed, doctors call it aortic stenosis. When it becomes leaky, it is called aortic insufficiency.

AORTIC STENOSIS

WHAT IS THE ILLNESS?

If the aortic valve becomes too narrow, pumping blood out of the heart becomes difficult. When patients feel symptoms from this valve narrowing (called stenosis), they usually report episodes of passing out, chest pain with exertion, and shortness of breath. Usually the cause of AS is wear and tear over many years, making it harder and less flexible with aging (the reason these patients are usually elderly). However, some patients are born with malfunctioning valves, and in these cases they develop valve narrowing at a younger age.

HOW WILL THE PATIENT BE TREATED?

There are no medicines that fix AS, so an invasive procedure is usually indicated in symptomatic patients. The standard procedure is to replace the valve with a prosthesis. In some patients this is done through open heart surgery, and in others the valve is replaced through catheters.

In patients with severe AS, the disease may progress rapidly and even cause death if not treated in time. Therefore, once diagnosed, planning for receiving a new valve should be undertaken.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

If there is severe narrowing of the aortic valve, pregnancy may need to be delayed until the narrowing is relieved—usually through the use of balloon catheter inserted through the groin, threaded to the heart, and blown up inside the valve to make it larger. If already pregnant and there are symptoms (such as shortness of breath or chest pain), the patient may need to take certain medications that are effective for her but not harmful to the child. If the symptoms during pregnancy are severe, the balloon catheter treatment or even open heart surgery may be needed. These procedures carry significant risk to both the mother and the unborn child.

AORTIC REGURGITATION

WHAT IS THE ILLNESS?

AR is the medical term to describe a leaky aortic valve, allowing blood to backflow into the heart after it is pumped to the aorta. When this happens, there is extra work for the heart to pump blood forward, and this backflow may cause breathing problems from water buildup in the lungs and other parts of the body.

One of the most common causes of AR in the United States is a dilated aorta, where the valve sits. When this artery becomes too big, the valve leaflets become too far apart from each other and blood leaks back into the heart. This enlargement may happen from wear and tear in older patients, or from a loose buildup in patients born with genetic predisposition to aortic enlargement.

Another common cause for AR is infection in the valve, causing destruction of the leaflets and, consequently, leakage. Wear and tear of the valve leaflets may also cause AR, not only in older patients but also in young patients born with a malfunctioning valve. Finally, in patients born outside of the United States, long-

standing syphilis and rheumatic fever may also lead to AR.

HOW WILL THE PATIENT BE TREATED?

In patients who develop AR in a short period of time, such that the heart does not have enough time to accommodate the leakage, quick medical stabilization in an intensive care unit is necessary. However, the ultimate treatment requires valve replacement with prosthesis.

Similar to AS, a severely leaky valve of AR may be replaced through open heart surgery. However, in contrast to AS, a severely leaky valve of AR cannot be replaced using catheters in most patients.

If the AR developed slowly, the heart eventually will become large and weak trying to accommodate the backflow of blood. However, in cases of rapidly developing severe AR, the disease may cause imminent death unless appropriate medicines and, eventually, surgery for valve replacement are employed.

WHAT IF THE PATIENT IS PREGNANT OR THINKING OF BECOMING PREGNANT?

Severe leakage of the aortic valve may not be well tolerated during pregnancy and the condition may harm the unborn child. Women with severe leakage who are considering pregnancy may need to delay it until the condition is treated. If already pregnant, significant heart problems may be experienced during the pregnancy.

Mitral Valve Disease in the Cardiac Care Unit

INTRODUCTION

Severe mitral valve disease due to mitral stenosis or mitral regurgitation can lead to clinical decompensation requiring the care of a patient in the cardiac care unit setting. The backdrop of such decompensation may be chronic valve disease on which acute injury is superimposed.

MITRAL VALVE STENOSIS

ETIOLOGY AND PATHOPHYSIOLOGY OF MITRAL STENOSIS

The mitral valve is a left atrioventricular valve or bicuspid valve that lies in the annulus between the left atrium and the left ventricle. A competent mitral valve requires the coordination of all the components of the mitral valve: the valve leaflets, the chordal attachments, the annulus, the papillary muscles, and the supporting ventricular walls into which the apparatus inserts. Failure or malfunction of any component of the mitral valve apparatus with failure to open results in stenosis with difficulty of left atrial emptying into the left ventricle.

Mitral stenosis (MS) results in delayed emptying of blood from the left atrium

(LA) into the left ventricle (LV) during diastole. This can result in elevated pressures in the left atrium, pulmonary vasculature and eventually the right side of the heart, leading to pulmonary hypertension.

The Euro Heart Study Survey was specifically designed to study the management of patients with valvular heart disease and prospectively included 5001 patients from 92 centers in 25 European countries.[1,2] This survey does not represent the general population, but rather the type of valve disease seen in a European referral population for treatment of heart disease. The most common valvular etiology was degenerative disease, representing 63% of all cases of native heart disease (likely representing an aging population), with a mean age of >50 years among patients with aortic and mitral valve disease, followed by rheumatic heart disease (RHD) in 22% of all patients,[2] representing the distribution in industrialized countries.

The incidence of RHD has decreased in industrialized countries over the past 60 years, but still exists in elderly patients who were exposed to acute rheumatic fever during childhood. The incidence remains lowest in America and Western Europe (≤10 per 100,000 of the population per year), higher in Eastern Europe (>10 per 100,000), and approximated to have an incidence of 13 cases per 100,000 per year in sub-Saharan Africa.[3]

RHD is usually a consequence of rheumatic fever, caused by group A ***β***-hemolytic streptococci. As streptococcal proteins share antigenic properties with certain connective tissue proteins in the human host, the immune response that is mounted against the streptococci can lead to progressive and delayed valve damage. RHD causes mitral commissural adhesion; thickened, calcified, immobile mitral valve leaflets; and fibrosis, thickening, shortening, fusion, and calcification of the chordae tendineae (**Figures 36.1 and 36.2**). The male to female ratio for RHD is approximately 1:2. RHD remains prevalent in developing countries. Approximately 60% of patients with acute rheumatic fever will develop RHD.[3]

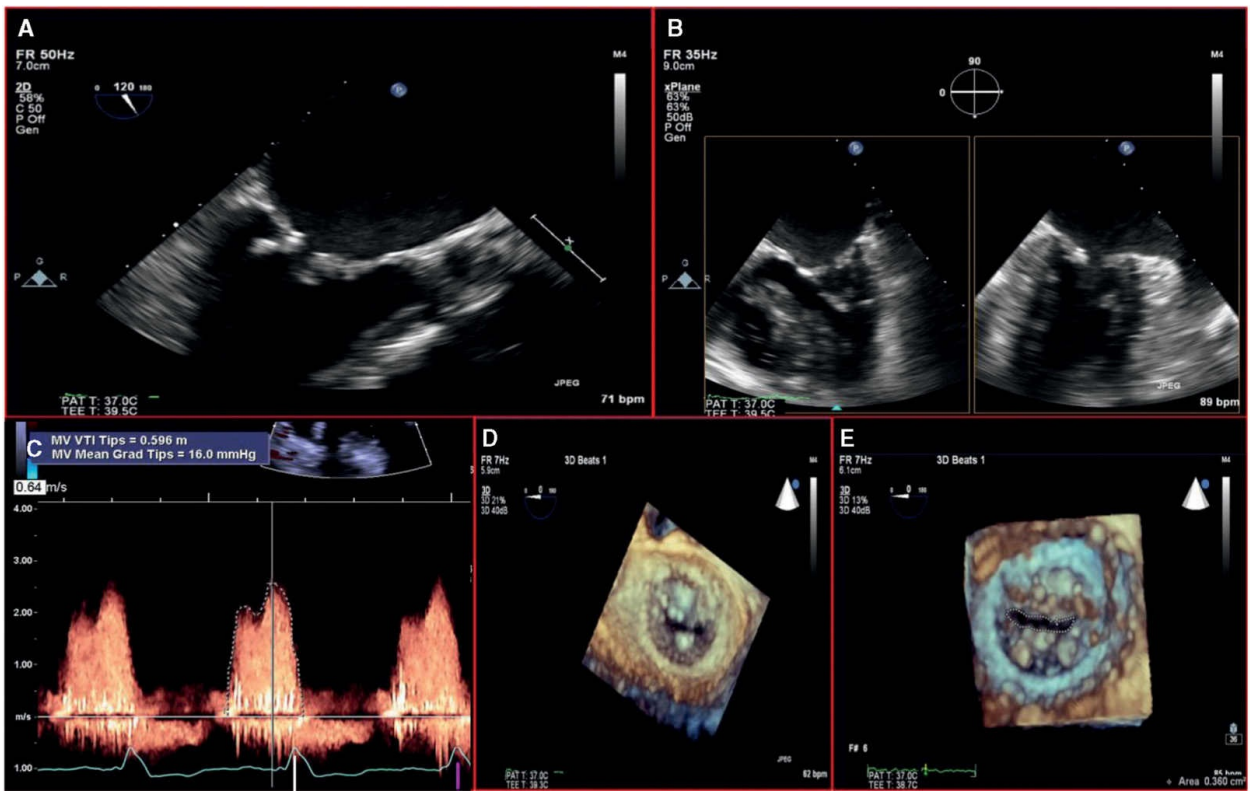

FIGURE 36.1 Severe mitral stenosis. A, A midesophageal view of the mitral valve via transesophageal echocardiogram (TEE). The mitral valve is thickened and shows restrictive leaflet motion. B, A biplane view on TEE of the mitral valve, again showing restricted leaflet motion. C, Demonstrates transmitral mean gradients are 16 mm Hg, consistent with very severe mitral stenosis. D and E, 3D images of severe mitral stenosis with severely restricted mitral valve motion. By planimetry, the mitral valve area was calculated to be about 0.4 cm^2.

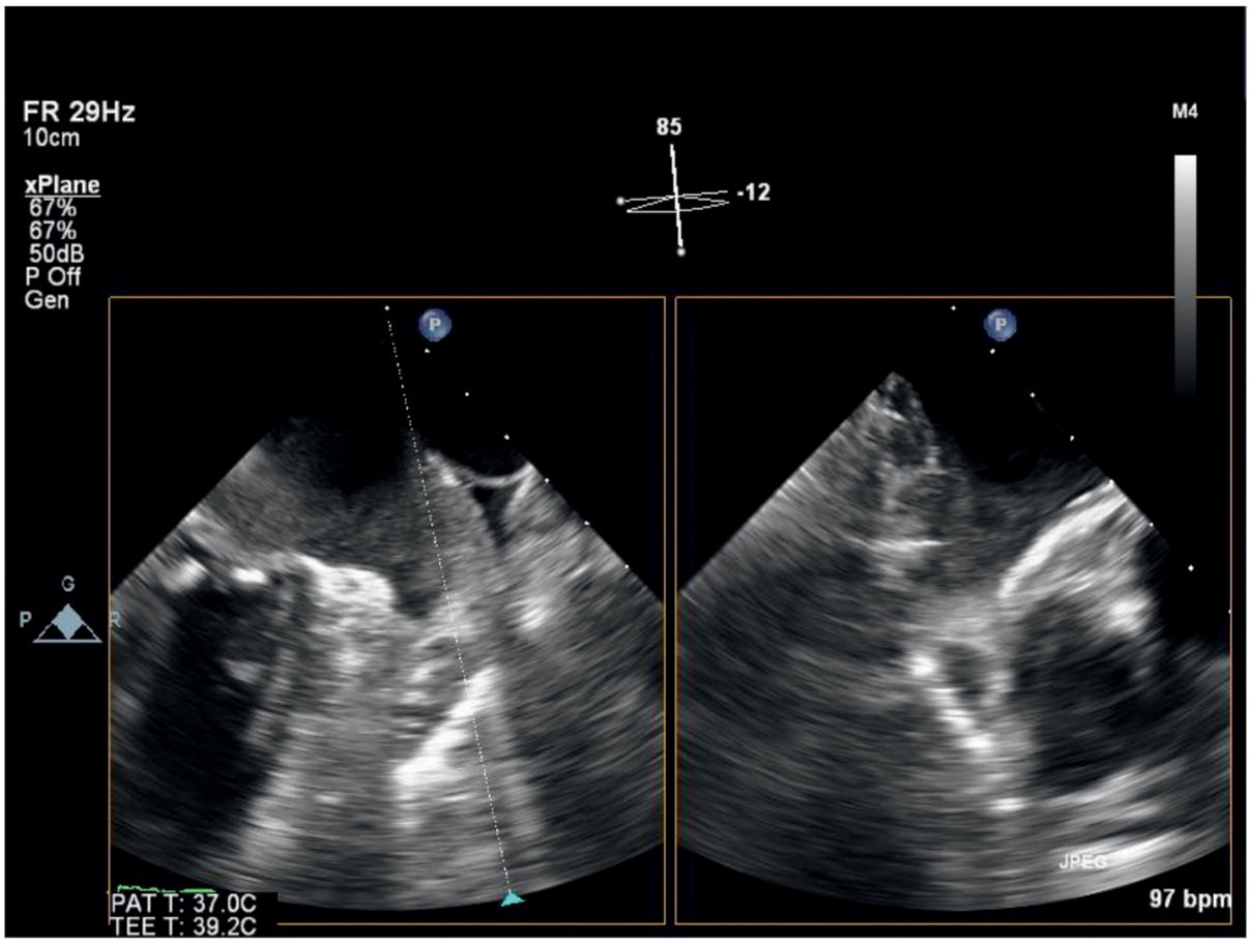

FIGURE 36.2 Severe mitral stenosis with fresh left atrial thrombus in the left atrial appendage, visible on a biplane view acquired by TEE in the midesophgeal view. Smoke is also visible in the dilated left atrium consistent with a low-flow state.

Etiologies, aside from degenerative valvular disease and RHD, include infective endocarditis, inflammatory disease, and congenital heart disease. These account for less than 10% of all cases of valvular heart disease.[1]

The normal mitral valve area in an adult measures approximately 4 to 6 cm^2. Patients may become symptomatic with shortness of breath as the valve area decreases over time. The diastolic gradient across the valve may increase, resulting in LA enlargement. Often, patients may have an acute event such as development of a rapid atrial arrhythmia (such as atrial fibrillation [AF]) that precipitates heart failure and decompensation of the patient requiring intensive medical care. Often, AF in the setting of MS is a highly prothrombotic state, marked by stasis of blood in the LA and left atrial appendage where thrombus can form. This puts the patient at risk for systemic thromboembolism.

Medical and interventional approaches to the management of patients with

valvular MS depend on accurate diagnosis of the cause and stage of the disease process.

CLINICAL PRESENTATION OF MITRAL STENOSIS

Patients with severe MS can have elevated LA and pulmonary pressure causing dyspnea and other signs and symptoms of congestive heart failure. The severity of symptoms is related to the transmitral gradient in diastole.[4–6] In turn, the magnitude of the mitral gradient is the result of interplay between the mitral valve area and the blood flow. Doubling the blood flow will quadruple the gradient. The heart's compensatory mechanisms such as left atrial enlargement may fail in the setting of rapid heart rates induced by exercise, pregnancy, hyperthyroid crisis, fever, or tachyarrhythmia (ie, AF).

DIAGNOSIS

Classic auscultatory findings of MS include loud first heart sound (S1), an opening snap (OS) after the second heart sound (S2), and a diastolic rumble. The duration of the S2–OS interval is inversely related to the severity of MS (a shorter interval suggests more severe MS). In patients with normal sinus rhythm, there is also an end-diastolic ("presystolic") accentuation of the rumble.

The electrocardiogram may demonstrate signs of LA enlargement characterized by wide, saddle-shaped P-wave in leads I and II (so-called P mitrale) as well as late, deep P-wave inversion in lead V1. AF is frequently present and there may be signs of right ventricular hypertrophy.

A transthoracic echocardiogram (TTE) is indicated in patients with signs and symptoms of MS. By TTE one can establish the diagnosis, determine the morphology of the mitral valve (to determine suitability for mitral commissurotomy), quantify hemodynamic severity (mean pressure gradient, mitral valve area, and pulmonary artery pressure), and assess concomitant valvular lesions.

Chest X-ray usually demonstrates LA enlargement with straightening of the left cardiac silhouette. Right ventricular enlargement, signs of pulmonary venous congestion, and mitral valve calcification are frequently observed.

Cardiac catheterization is not necessary for the diagnosis of MS in most instances because hemodynamic data can be acquired from a careful TTE, performed when the heart rates and blood pressures have been optimized, and there is optimal time for diastolic filling of the left ventricle.

GRADING OF MITRAL STENOSIS

The 2009 guidelines from the American Society of Echocardiography defined mitral stenosis with mean gradients of <5 mm Hg, MVA of >1.5 cm^2 as being mild mitral stenosis; mean gradient of 5 to 10 mm Hg, MVA 1.0 to 1.5 cm^2 as moderate stenosis; mean gradient of >10 mm Hg, MVA < 1.0 cm^2 as severe mitral stenosis.[7] The 2014 American Heart Association/American College of Cardiology (AHA/ACC) guideline for the management of patients with valvular heart disease took this even further, applying grading of valvular disease as stages across a clinical continuum: stage A for patients at risk of MS; stage B as patients with progressive MS with mitral valve area > 1.5 cm^2, possible mild to moderate left atrial enlargement; stage C as asymptomatic severe MS, with MVA ≤ 1.5 cm^2, often severe left atrial enlargement and elevated pulmonary artery pressures; stage D as symptomatic severe MS, with MVA ≤ 1.5 cm^2, severe left atrial enlargement, pulmonary hypertension, exertional dyspnea, and decreased exercise tolerance(**Table 36.1**).[5]

TABLE 36.1 Stages of MS Per the ACC/AHA Guidelines[5]

STAGE/DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
Stage A: at risk of MS	Mild valve doming during diastole	Normal transmitral flow velocity	None	None
Stage B: progressive MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA > 1.5 cm^2	Increased transmittal flow velocities MVA > 1.5 cm^2 Diastolic pressure half-time < 150 ms	Mild-to-moderate LA enlargement Normal pulmonary pressure at rest	None
Stage C: asymptomatic severe MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤ 1.5 cm^2 MVA ≤ 1.0 cm^2 with very severe MS	MVA ≤ 1.5 cm^2 (MVA ≤ 1.0 cm^2 with very severe MS) Diastolic pressure half-time ≥ 150 ms Diastolic pressure half-time ≥ 220 ms with very severe MS	Severe LA enlargement Elevated PASP > 30 mm Hg	None
	Rheumatic valve changes with	MVA ≤ 1.5 cm^2 MVA ≤ 1.0 cm^2 with		

Stage D: symptomatic severe MS	commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤ 1.5 cm^2	very severe MS Diastolic pressure half-time ≥ 150 ms Diastolic pressure half-time > 220 ms with very severe MS	Severe LA enlargement Elevated PASP > 30 mm Hg	Decreased exercise tolerance Exertional dyspnea

The transmitral mean pressure gradient should be obtained to further determine the hemodynamic effect of the MS and is usually >5 to 10 mm Hg in severe MS; however, due to the variability of the mean pressure gradient with heart rate and forward flow, it has not been included in the criteria for severity.
LA, left atrial; LV, left ventricular; MS, mitral stenosis; ms, milliseconds; MVA, mitral valve area; PASP, pulmonary artery systolic pressure.

The mean pressure gradient is highly dependent on the transvalvular flow and diastolic filling period and may vary greatly with change in heart rate. The diastolic pressure half-time depends on the degree of mitral obstruction and the compliance of the LV and LA and other measures of mitral valve area. Medical optimization and reevaluation in an intensive care setting may be necessary for a patient who presents with acute decompensation.

MEDICAL THERAPY FOR MITRAL STENOSIS

Patients with MS often present to the cardiac care unit (CCU) with clinical signs of heart failure, frequently in the setting of AF. Optimizing medical therapy can alleviate symptoms and prevent systemic thromboembolism. Congestion secondary to heart failure (HF) may need intravenous diuretic therapy. Heart rate control with ***β***-blockers, certain calcium channel blockers (such as verapamil and diltiazem), and digitalis can be beneficial in patients with MS and AF to control rapid ventricular response and to allow greater time for diastolic filling of the LV.

Anticoagulation is indicated in patients with MS who present with AF, whether it is paroxysmal, persistent, or permanent. This is particularly true in a patient with a prior embolic event who is at higher risk for a repeat thromboembolic event and certainly if the patient is diagnosed with a left atrial thrombus. Intravenous heparin may be indicated with bridging to a vitamin K antagonist such as warfarin. There is as of yet insufficient large-scale data to attest to the efficacy of non–vitamin K oral anticoagulants in preventing thromboembolism in valvular AF.

PERCUTANEOUS INTERVENTION FOR MITRAL STENOSIS

In the absence of LA thrombus or moderate-to-severe MR and favorable valve

morphology, percutaneous mitral balloon commissurotomy is recommended for the following: (1) symptomatic patients with severe MS; (2) symptomatic patients with mitral valve area > 1.5 cm^2 if there is evidence of hemodynamically significant MS based on pulmonary artery wedge pressure > 25 mm Hg or mean mitral valve gradient > 15 mm Hg during exercise; (3) asymptomatic patients with very severe MS (mitral valve area ≤ 1.0 cm^2, stage C); (4) asymptomatic patients with severe MS with new onset of AF. Percutaneous mitral balloon commissurotomy is also indicated in symptomatic patients (New York Heart Association [NYHA] class III to IV) with severe MS with suboptimal valve anatomy and are high-risk candidates for surgery.

Transthoracic echocardiography can help detect whether the valve has structural characteristics favorable for percutaneous mitral balloon commissurotomy. The Wilkins score captures the degree of leaflet deformity, scoring leaflet mobility, degree of thickening of the subvalvular chordal apparatus, leaflet thickening, and leaflet calcification on a score of 1 to 4. A summed score of 8 or less predicts a more favorable outcome with valvuloplasty than those with a higher score, although a high score does not preclude valvuloplasty (**Table 36.2**).[8]

TABLE 36.2 The Wilkins Score/Mitral Valvuloplasty Score[8]

GRADE	MOBILITY	SUBVALVULAR THICKENING	THICKENING	CALCIFICATION
1	Highly mobile valve with only leaflet tips restricted	Minimal thickening just below the mitral leaflets	Leaflets near normal in thickness (4–5 mm)	Single area of increased echo brightness
2	Leaflet mid and base portions have normal mobility	Thickening of chordal structures extending up to one-third of the chordal length	Mid leaflets normal, considering thickening of margins (5–8 mm)	Scattered areas of brightness confined to leaflet margins
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending to the distal third of the chords	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the mid portion of the leaflets
4	No or minimal forward movement of the leaflets in diastole	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue

Mitral valve score = leaflet mobility + valve thickening + calcification + subvalvular thickening. Each item is graded from 1 to 4 to yield a score from 4 to 16. A score of 8 or less predicts a more favorable outcome than those with a higher score, but

higher scores do not preclude mitral valvuloplasty.

Transesophageal echocardiography (TEE) should be performed on patients considered for percutaneous mitral balloon commissurotomy to better define the leaflet anatomy and to perform direct planimetry of the mitral valve. Three-dimensional (3D) imaging can be used to optimize the plane at which direct planimetry is performed. Detailed views of the LA and left atrial appendage can be obtained to assess for concomitant left atrial thrombus.

SURGICAL INTERVENTION FOR MITRAL STENOSIS

If percutaneous intervention is unavailable or the valve morphology is unfavorable for balloon valvuloplasty, appropriate patients are referred for surgical intervention.

As per the 2014 AHA guidelines, patients with very severe MS (MVA ≤ 1.0 cm^2), who are symptomatic (stage D), and have morphology unfavorable for percutaneous mitral balloon commissurotomy should be considered for mitral valve repair or replacement.[5]

If a patient with *severe* (mitral valve area ≤ 1.5 cm^2) or *moderate* (mitral valve area 1.6 to 2.0 cm^2) MS is undergoing a cardiac surgery for other operative indications (eg, aortic valve disease, coronary artery disease [CAD], tricuspid regurgitation [TR], aortic aneurysm), *concomitant* mitral valve surgery is recommended.

Mitral valve surgery and excision of the left atrial appendage may be considered for patients with severe MS who have had recurrent embolic events while receiving adequate anticoagulation.

PROGNOSIS OF MITRAL STENOSIS

AF, LA thrombus formation, and systemic thromboembolism (such as ischemic stroke) are important contributors to morbidity and mortality of MS.

IMPACT ON PREGNANCY

Often pregnancy is the first time that a patient with rheumatic MS becomes symptomatic due to a physiologic increase in intravascular volume, cardiac output, and heart rate. Percutaneous mitral balloon commissurotomy can be performed during pregnancy, but diagnosis and treatment before pregnancy is ideal.

MITRAL REGURGITATION

ETIOLOGY AND PATHOPHYSIOLOGY

Mitral regurgitation (MR), also known as mitral insufficiency or mitral incompetence, is one of the most common acquired valvular heart diseases. MR is a disorder where the mitral valve does not close properly during the systolic phase. Its onset may be acute or chronic, and the etiology can stem from any process that disturbs the architecture of the mitral valve apparatus.

Failure of any component of the mitral valve apparatus can result in failure of leaflet coaptation and regurgitation of blood during systole into the LA rather than being ejected out of the left ventricular outflow tract, across to the aortic valve into the systemic circulation to perfuse important organs.

Defining the etiology of MR is important because it influences the management and prognosis of such patients. Diseases that are primarily structural in origin are managed differently than those with primarily functional MR.

In MR, blood exits the LV both antegrade—through the left ventricular outflow tract (systemic stroke volume)—and retrograde—through the mitral valve (regurgitant volume). During diastole, the regurgitant volume meets in the LA with the systemic volume returning through the pulmonary veins. The combined volume then enters the LV through the mitral valve. This process leads to volume overload of the left heart.

CLINICAL PRESENTATION

In chronic MR, there is progressive enlargement of the LA and the LV to accommodate the combined systemic stroke volume and regurgitant volume. This remodeling often prevents significant elevation of left heart pressures; consequently, it may take years, if not decades, for the patient to develop congestive heart failure (due to progressive left ventricular systolic dysfunction) and AF (due to left atrial enlargement). In contrast, acute-on-chronic or acute MR can present with flash pulmonary edema requiring intensive care support and urgent intervention.

CHRONIC MITRAL REGURGITATION (PRIMARY VS SECONDARY)

In primary MR, a problem with one of the components of the valve, including the leaflets, chordae tendinae, or papillary muscles, causes valve incompetence

and regurgitation of blood from LV to LA during the systolic phase. Common causes of primary MR include mitral prolapse, due to myxomatous degeneration in a younger population or problems such as fibroelastic deficiency disease in older population, infective endocarditis or myxomatous degeneration. Other etiologies for primary MR include connective tissue disorder, rheumatic heart disease, cleft mitral valve, and radiation heart disease.

In contrast, *secondary (functional)* MR occurs where the mitral valve is normal but the supporting structures for the valve are abnormal. An abnormal or dilated LV can cause papillary muscle displacement and leaflet tethering. Annular displacement or dilatation as well as wall motion abnormalities due to myocardial ischemia or infarction can prevent leaflet coaptation. With secondary MR, restoration of mitral competence is not by itself curative.

ACUTE MITRAL REGURGITATION

It is estimated that there are approximately 2.5 million patients with moderate-to-severe or severe MR in the United States at present. Although acute MR represents only a minority of these cases, every health care professional working in the CCU setting should become proficient in diagnosing and managing this often life-threatening form of MR. In acute MR, there is sudden volume overload of nondilated left heart chambers leading to marked elevation of left atrial pressures, life-threatening pulmonary edema, and eventually cardiogenic shock.

The leading causes of acute MR are bacterial endocarditis (**Figures 36.3, 36.4, and 36.7**), papillary muscle rupture (traumatic or following myocardial infarction; **Figure 36.5**), and chordal rupture in the setting of preexisting myxomatous valve degeneration (**Figure 36.6**) and mitral valve prolapse.

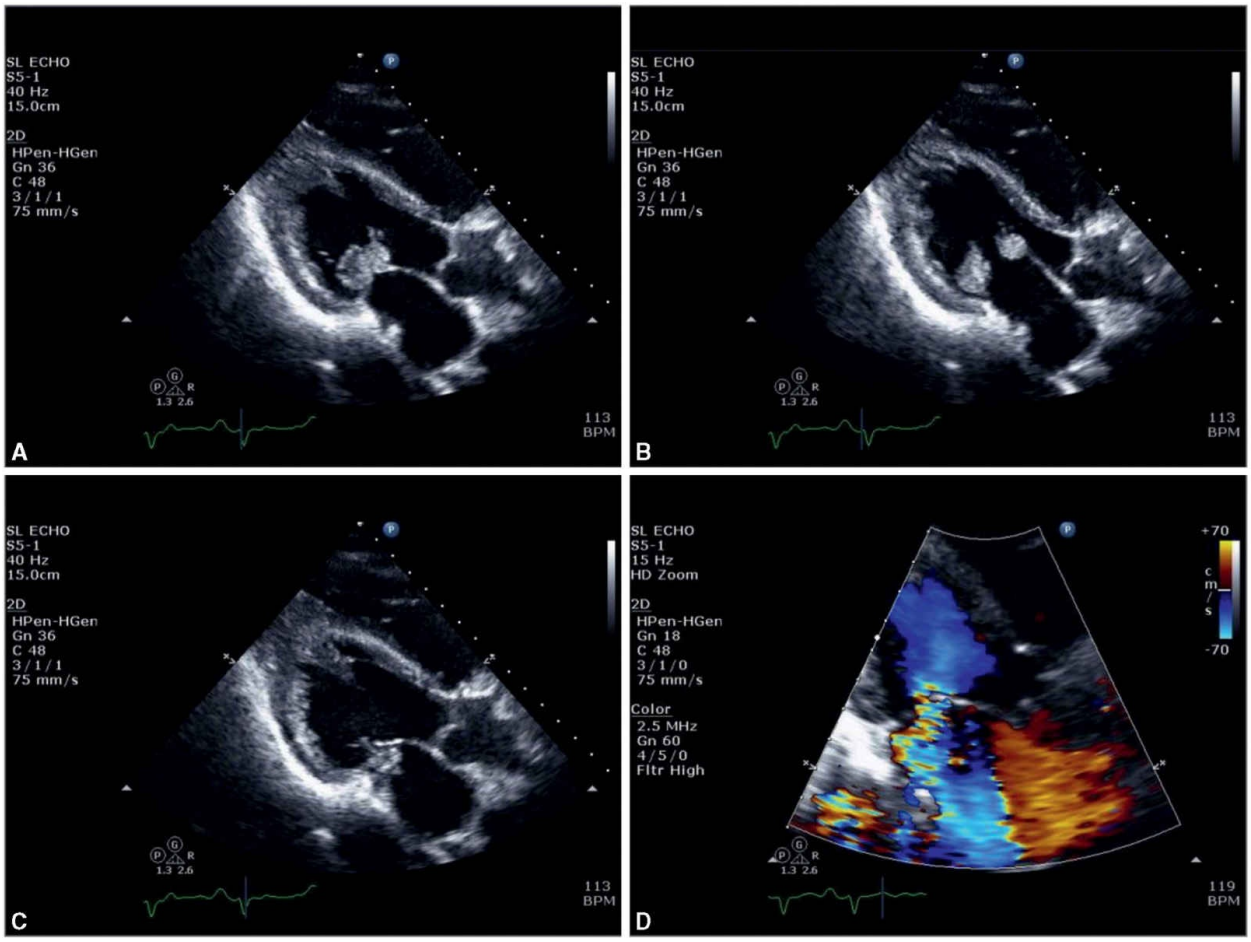

FIGURE 36.3 Large bileaflet mitral valve endocarditis with severe mitral regurgitation seen in the parasternal long-axis view on transthoracic echocardiogram TTE). A–C, Large mobile vegetations on both the anterior and posterior mitral valve leaflets, disrupting coaptation of the mitral valve and prolapsing into the left atrium. D, Resulting severe jet of eccentric mitral regurgitation.

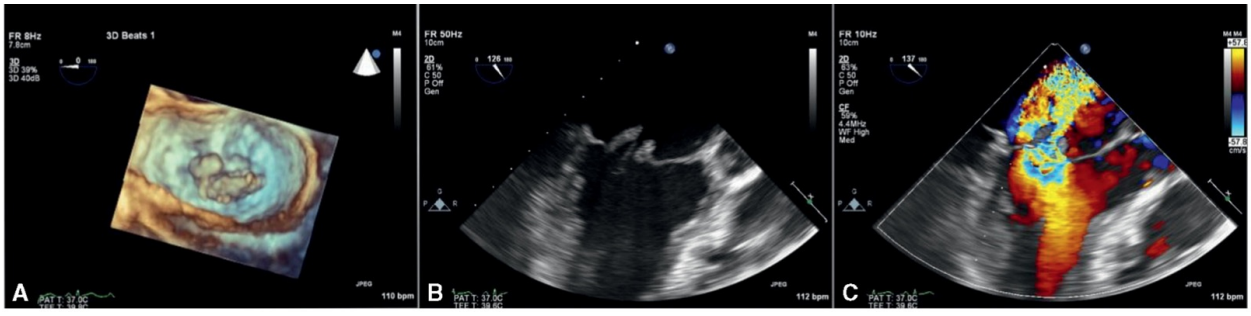

FIGURE 36.4 Bileaflet mitral valve endocarditis as seen on transesophageal echocardiogram (TEE). A TEE was obtained of the bileaflet vegetations seen in transthoracic echocardiogram in Figure 36.3. A, A 3D view of the mitral valve obtained on TEE in the midesophageal view, where the prolapse of the vegetations into the left atrium is visible at the coaptation plane. B, A 2D view of the mitral valve on TEE. C, Color Doppler of severe jet of eccentric mitral regurgitation.

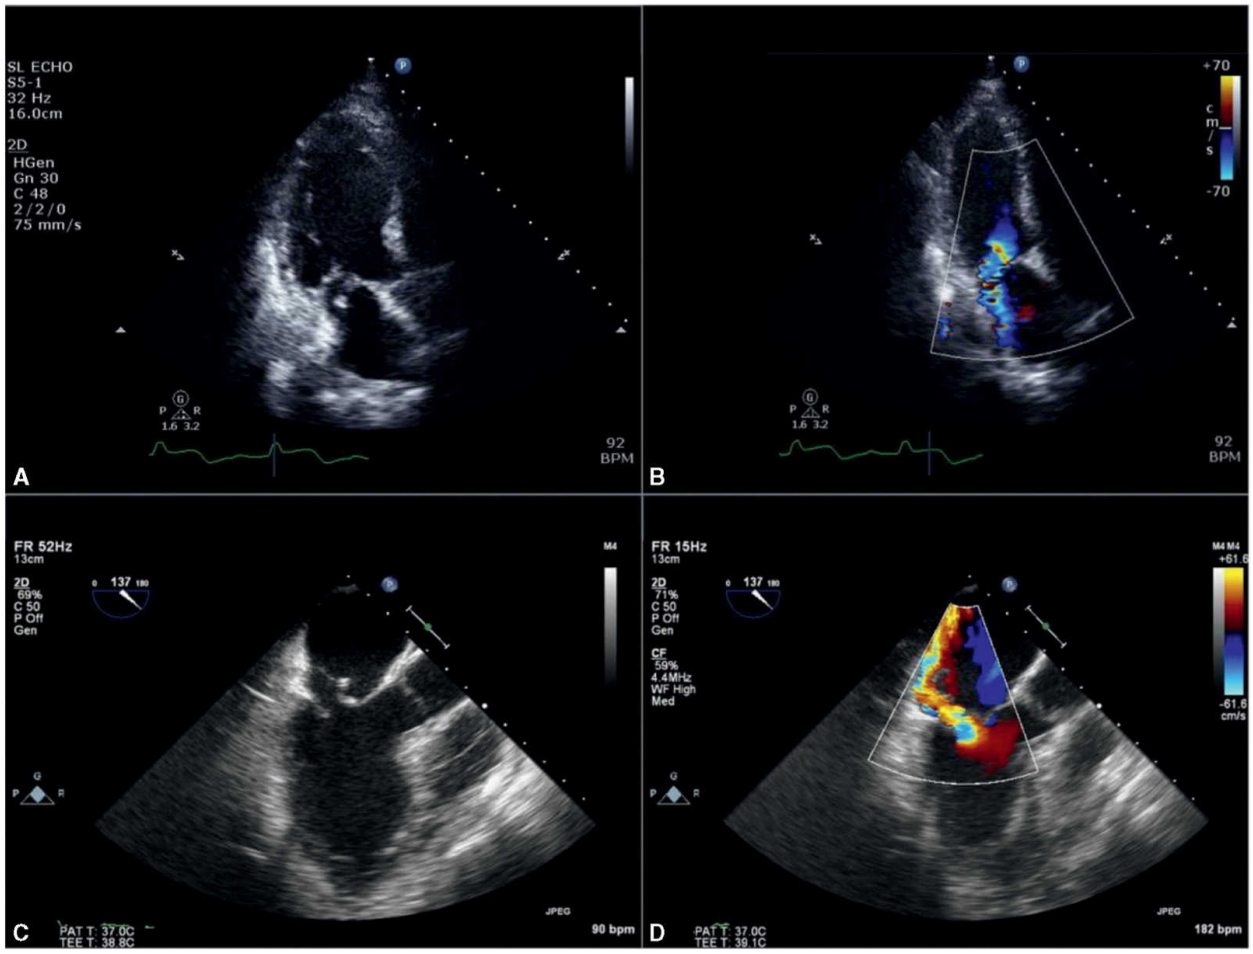

FIGURE 36.5 Flail mitral valve with papillary muscle rupture from inferior myocardial infarction (MI). A, A transthoracic echo image of the mitral valve in the apical five-chamber view. A density can be seen prolapsing into the left atrium, which was confirmed to be a papillary muscle during cardiac surgery. B, The same view with eccentric severe mitral regurgitation. C and D, Transesophageal echo images in the midesophageal view where the prolapse of the ruptured papillary muscle is evident.

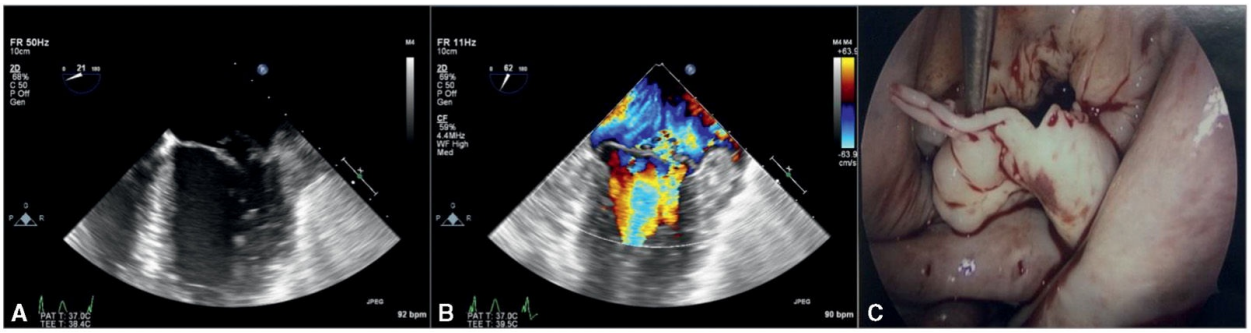

FIGURE 36.6 A and B, Midesophageal views on TEE. A myxomatous mitral valve can be seen with severe mitral regurgitation and flail posterior mitral valve (primarily P2). C, The flail leaflet as seen in the operating room during mitral valve surgery.

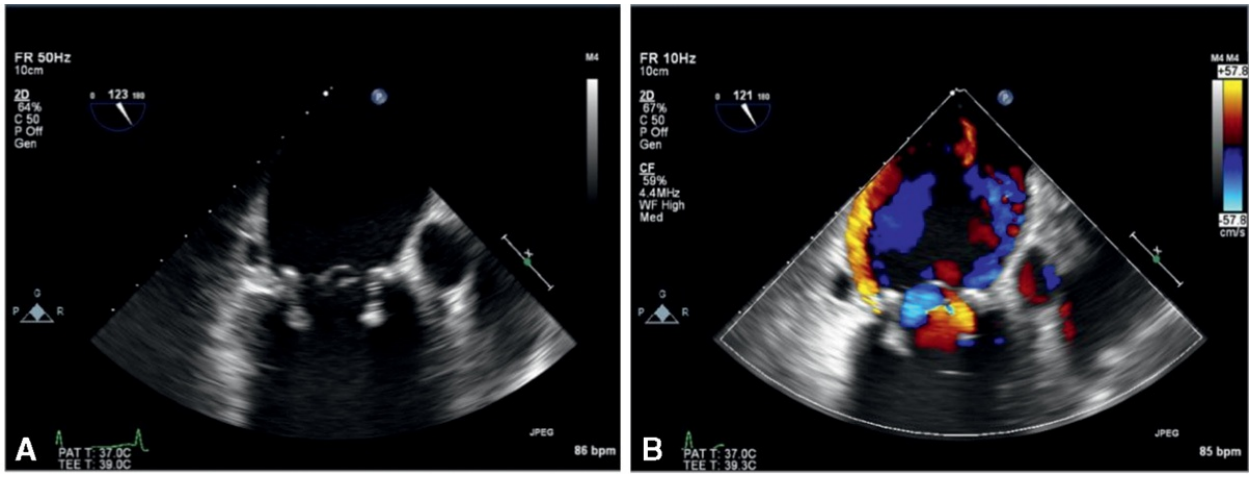

FIGURE 36.7 A, A transesophageal echo at the midesophageal position where a bioprosthetic mitral valve has a soft tissue echo density. This was prosthetic valve endocarditis. B, Associated moderate eccentric paravalvular mitral regurgitation that resulted from destruction of the valve.

Irrespective of the cause, patients with severe, acute MR frequently present with fulminant pulmonary edema and cardiogenic shock. Patients with endocarditis will present with general signs and symptoms of a systemic bacterial illness. Nontraumatic papillary muscle rupture is a mechanical complication that usually occurs 3 to 5 days after acute myocardial infarction (**Figure 36.5**).

Posteromedial papillary muscle (which usually has solitary blood supply from either the right coronary or the left circumflex artery) ruptures more frequently than the anterolateral one (which is usually supplied by both the left anterior descending and circumflex arteries).

SEVERITY OF MITRAL VALVE REGURGITATION

In addition to defining etiologic and anatomic mechanisms of MR, assessment of its severity and its hemodynamic impact on risk stratification determine the timing of intervention. The recent American College of Cardiology/American Heart Association (ACC/AHA) guidelines to help grade the severity of MR are summarized in **Table 36.3**.

TABLE 36.3 Stages of MR Per the ACC/AHA Guidelines[5]

STAGE/DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS[a]	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
	Mild mitral valve	No MR jet or small		

Stage A: at risk of MR	prolapse with normal coaptation Mild valve thickening and leaflet restriction	central jet area < 20% LA on Doppler Small vena contracta < 0.3 cm	None	None
Stage B: progressive MR	Severe mitral valve prolapse with normal coaptation Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior IE	Central jet MR 20%–40% LA or late systolic eccentric jet MR Vena contracta < 0.7 cm Regurgitant volume < 60 mL Regurgitant fraction < 50% ERO < 0.40 cm^2 Angiographic grade 1–2+	Mild LA enlargement No LV enlargement Normal pulmonary pressure	None
Stage C: asymptomatic severe MR	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior IE Thickening of leaflets with radiation heart disease	Central jet MR > 40% LA or holosystolic eccentric jet MR Vena contracta ≥ 0.7 cm Regurgitant volume ≥ 60 mL Regurgitant fraction ≥ 50% ERO ≥ 0.40 cm^2 Angiographic grade 3–4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension may be present at rest or with exercise C1: LVEF > 60% and LVESD < 40 mm C2: LVEF ≤ 60% and LVESD ≥ 40 mm	None
Stage D: symptomatic severe MR	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Prior IE Thickening of leaflets with radiation heart disease	Central jet MR > 40% LA or holosystolic eccentric jet MR Vena contracta ≥ 0.7 cm Regurgitant volume ≥ 60 mL Regurgitant fraction ≥ 50% ERO ≥ 0.40 cm^2 Angiographic grade 3–4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension present	Decreased exercise tolerance Exertional dyspnea

[a]Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category are present in each patient. Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.
ERO, effective regurgitant orifice; IE, infective endocarditis; LA, left atrium/atrial; LV, left ventricular; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; MR, mitral regurgitation.

DIAGNOSIS

In any patient with *chronic primary MR*, TTE is indicated for baseline structural

and functional evaluation of the heart. The mitral valve apparatus and leaflets can be visualized in detail, with color Doppler evaluation and hemodynamic assessment of MR.

Severe primary MR may be marked by a central jet of MR that is >40% LA or a holosystolic eccentric jet of MR, a vena contracta ≥ 0.7 cm, a regurgitant volume ≥ 60 mL or an effective regurgitant orifice (ERO) ≥ 0.4 cm^2.[5] TEE is also a helpful tool in primary MR to establish anatomic structures and guide valvular repair.

In any patient with chronic secondary MR, TTE is indicated to evaluate the extent and location of wall motion abnormalities and to assess global LV function, severity of MR, and magnitude of pulmonary hypertension. Severe secondary MR may be marked by an ERO ≥ 0.2 cm^2, as adverse outcomes are associated with a smaller calculated ERO as compared to primary MR, regurgitant volume ≥ 30 mL. The MR will likely progress due to associated progression of LV dysfunction and adverse remodeling. There is often underestimation of the ERO by 2D echo-derived flow convergence due to the often crescentic shape of the regurgitant orifice in secondary MR.[5]

In *severe acute MR*, there may be few or no auscultatory findings of MR per se; the systolic murmur is often soft, short, or even absent because there is rapid equilibration of left ventricular and left atrial pressures during systole. Other frequent findings include tachycardia and S3 gallop. Chest X-ray (CXR) in severe, acute MR routinely shows signs of pulmonary congestion. ECG may show tachycardia; there may also be signs of myocardial infarction when acute MR is caused by papillary muscle rupture. Transthoracic and transesophageal echocardiography are the primary means of evaluating MR. Echocardiography can establish the etiology, mechanism, and severity of MR.

ECHOCARDIOGRAPHY FINDINGS

Echocardiography has several important roles in MR: (1) Evaluation of the etiology of MR; (2) Grading the severity of MR; (3) Assessment of its impact on overall cardiac function, especially left ventricular function; (4) Guidance for further management, including timing of surgical intervention. TTE is the modality of choice for evaluation and follow-up of MR and global cardiac function. TEE plays an important role when differences exist between clinical assessment and TTE findings, or when mitral valve surgery is needed. Defining the etiology of MR is important because this influences management and

prognosis of such patients. Diseases that are primarily structural in origin are managed differently as compared with functional MR.

TREATMENT

There are different treatment options based on the MR type. As described earlier, *chronic primary MR* is mainly due to a dysfunctional valve. A prolonged and severe chronic primary MR will cause subsequent volume overload, myocardial damage, HF, and eventual death. Hence, correction of the MR in this group is "curative" and every effort should be made to repair the valve.

However, if it is the *chronic secondary type*, MR is secondary to myocardial disease (ie, ischemic, nonischemic, and idiopathic myocardial diseases; severe LV dysfunction, etc.). Hence, mitral valve repair by itself is not curative. Thus, efforts should be focused on treatment of the causes of chronic secondary MR such as revascularization or treating other underlying medical conditions as well as management of HF (ie, standard guideline-directed medical therapy for HF [including ACE inhibitors, ARBs, ***β***-blockers, and/or aldosterone antagonists as indicated], and cardiac resynchronization therapy with biventricular pacing for symptomatic patients who meet the indications for device therapy). Mitral valve surgery could be considered in patients with severe and chronic secondary MR who are undergoing other cardiac surgery like coronary artery bypass grafting (CABG) or aortic valve replacement (AVR), as well as severely symptomatic patients with persistent symptoms despite optimal guideline-directed medical therapy for HF.

Severe acute MR is a life-threatening medical emergency that requires the highest level of care in the CCU. Acute events such as an ST elevation myocardial infarction can lead to disruption of normal mitral valve anatomy, such as rupture of a mitral valve papillary muscle. Such a mechanical complication leads to an incompetent mitral valve, severe MR, heart failure, and possibly requirement of intubation to provide respiratory support and intravenous medications to provide intensive medical therapy.

Endotracheal intubation, oxygen administration, and diuretic therapy are used to treat pulmonary edema. Afterload reduction may be achieved with the use of intravenous vasodilators (such as nitroprusside). Disease-specific therapies, if available, should also be administered (such as coronary revascularization and anti-ischemic medical therapy).

CARPENTIER'S SURGICAL CLASSIFICATION OF MITRAL VALVE

PATHOLOGY

Carpentier's surgical classification of mitral valve pathology merits discussion as one works with cardiac surgery colleagues to characterize the mitral valve. Carpentier divided MR into three categories based on the opening and closing motions of both leaflets:

A. Type I, annular dilatation: Type I MR occurs despite normal leaflet motion. This can be due to annular dilatation seen in dilated cardiomyopathy.
B. Type II, excessive leaflet motion: Type II regurgitation refers to MR that occurs because of leaflet prolapse. This may be due to simple elongation of the leaflets, with prolapse into the LA.
C. Type IIIa refers to valvular and subvalvular thickening that can restrict mitral leaflet motion. Mitral annular calcification and thickening of the subvalvular apparatus are seen with increasing age, or as the sequelae of RHD.
D. Type IIIb, restricted leaflet motion: When leaflet motion is restricted, with displacement of the papillary muscles, this is referred to as Type IIIb MR. The most common culprit is dilated cardiomyopathy, where enlargement of left ventricular chamber is accompanied by elongation of papillary muscles and their displacement toward the apex, relative to the mitral valve leaflets.

PERCUTANEOUS INTERVENTIONAL THERAPY AND MITRAL VALVE SURGERY

Severe acute MR often requires percutaneous insertion of the intra-aortic balloon pump (IABP), which is threaded through the femoral artery into the descending thoracic aorta with its tip just distal to the origin of the left subclavian artery. Significant coexisting aortic regurgitation is a contraindication for IABP insertion. IABP and the medical therapies described in Chapters 17 and 19 are usually only palliative.

The patient may require urgent surgery to repair or replace the mitral valve. For the first time, the 2014 ACC/AHA Guidelines incorporated percutaneous mitral valve repair into their recommendations.[5] Transcatheter mitral valve repair may be considered for severely symptomatic patients (NYHA Class III/IV) with chronic severe primary MR (stage D), who have a reasonable life expectancy but a prohibitive surgical risk because of severe comorbidities. The anatomy of the mitral valve, however, has to lend itself to a mitral valve clip.

IMPACT ON PREGNANCY

Severe MR, whether acute or chronic, is one of the valvular heart lesions that may be associated with high maternal and/or fetal risk during pregnancy. Pregnant women with MR who have NYHA functional class III–IV symptoms, severe pulmonary hypertension (pulmonary pressure > 75% of systemic pressures), and/or LV systolic dysfunction are at particular risk for maternal and fetal complications.

Patient and Family Information for: MITRAL VALVE DISEASE IN THE CARDIAC CARE UNIT

GENERAL CONCEPTS OF MITRAL VALVE DISEASE

The mitral valve is an important valve through which blood flows from the left atrium (LA) into the left ventricle (LV). The LV is the main heart pump for the body. Mitral stenosis (MS) occurs when the valve does not open well, impeding blood flow. Mitral regurgitation (MR) occurs when the valve does not close well, resulting in backflow of blood into the LA.

MITRAL STENOSIS

WHAT IS MY ILLNESS?

If the mitral valve becomes too narrow, it takes a long time for blood to empty from the LA into the LV. There can be many reasons for this including simply advancing age and degeneration of the mitral valve. If you have had rheumatic fever as a child, that may result in thickening of the mitral valve later in life.

HOW WILL I BE TREATED?

Mild MS may be treated with medications to keep your heart rate from beating too rapidly because this gives time for blood to drain from the LA into the LV. If MS becomes severe, and you have symptoms such as severe shortness of breath or heart failure, you may be referred for mitral balloon commissurotomy (also referred to as a mitral valvuloplasty). In this procedure, a balloon on a catheter is used to open up the mitral valve further through your leg in the cardiac

catheterization laboratory. If your MS cannot be treated with mitral balloon commissurotomy, you may be referred for mitral valve surgery performed by a cardiac surgeon.

WHAT IF I AM PREGNANT OR THINKING OF BECOMING PREGNANT?

If you have mild MS, you may be able to work with your physician during your pregnancy. If, however, you have severe MS, the degree of volume overload that you experience during pregnancy may put you in danger of developing severe shortness of breath and heart failure. Management of your MS and seeing your cardiologist is prudent and you may have to delay pregnancy until the narrowing of your mitral valve is relieved.

MITRAL REGURGITATION

WHAT IS MY ILLNESS?

MR describes a leaky mitral valve that results in backflow of blood from the LV into the LA. In primary MR, there is a problem with the mitral valve. Common causes of primary MR include mitral prolapse due to myxomatous degeneration in a younger population or problems such as fibroelastic deficiency disease in older population, infective endocarditis, or myxomatous degeneration. Secondary MR occurs when the mitral valve is normal but its supporting structures are abnormal. Sudden MR can occur from complications of bacterial endocarditis, papillary muscle rupture (eg, after a heart attack), or chordal rupture from preexisting valve degeneration. In acute MR, there is sudden volume overload of nondilated left heart chambers leading to marked elevation of left atrial pressures, life-threatening pulmonary edema, and possibly even shock.

HOW WILL I BE TREATED?

In patients who develop MR over a short period of time, such that the heart does not have enough time to accommodate the leakage, medical stabilization in an intensive care setting may be necessary. Mitral valve surgery may be needed to repair or replace the mitral valve. New therapies are on the horizon for specific types of mitral valve disease such as percutaneous mitral valve clips.

WHAT IF I AM PREGNANT OR THINKING OF BECOMING PREGNANT?

Severe leakage of the mitral valve may not be well tolerated during pregnancy. Women with severe leakage who are considering pregnancy may wish to delay it until the condition is treated, and until a long discussion occurs with a cardiologist as to their options.

Tricuspid and Pulmonic Valvular Disease in the Cardiac Care Unit

The tricuspid valve (TV) used to be called “the forgotten valve.” In recent years, the prevalence of TV disease and, in particular, tricuspid regurgitation (TR) has become apparent. Moderate or severe TR is present in 15% of patients referred to echocardiography, and it is strongly associated with heart failure and death.[1] This chapter focuses on TR, which is by far the most common lesion of right-sided valvular heart disease in the cardiac care unit (CCU) setting. In addition, we briefly discuss the pulmonic valve.

TRICUSPID REGURGITATION

ETIOLOGY AND PATHOPHYSIOLOGY

TR is most often functional, secondary to pulmonary hypertension (PHT), right ventricular (RV) remodeling, and tricuspid annular (TA) dilatation.[2]

PHT (usually >50 mm Hg) may be secondary to left heart failure, cor pulmonale, or pulmonary vascular disease. It results in elevated RV pressure, which may cause RV remodeling (both dilatation and distortion of the normal RV shape) and RV failure. RV remodeling causes papillary muscle displacement (similar to functional mitral regurgitation) and TA dilatation, TV leaflet tethering, and malcoaptation resulting in TR. TR in turn causes RV volume

overload, which combined with pressure overload causes further RV remodeling and TR progression, resulting heart failure, and if left unchecked, death. RV pressure and volume overload may also be caused by pulmonic valve disease.

TA dilatation may also be caused by right atrial dilatation secondary to atrial fibrillation, even in the absence of PHT. Worsening PHT and permanent atrial fibrillation are the most common cause of TR progression.[3]

Several disease processes directly affect the TV and may cause primary TR (**Table 37.1**). TV endocarditis is most often seen in IV drug abuse patients and may lead to destruction and perforation of the valve leaflets and chordal rupture, as well as septic pulmonary emboli. TR is common in rheumatic heart disease (prevalent now mainly in developing countries), especially in patients with mitral valve disease, and may appear years after successful mitral valve surgery (**Figure 37.1**).[2] In rheumatic patients TR is often functional, but may also be due to rheumatic involvement of the TV leaflets with leaflet thickening, restriction, and shortening. In Ebstein anomaly, the abnormal TV is displaced toward the RV apex, resulting in atrialization of the RV with a small dysfunctional RV, large right atrium (RA), and TR. In carcinoid syndrome, fibrous plaques may cause thickening and significant shortening of the TV leaflets resulting in severe TR.

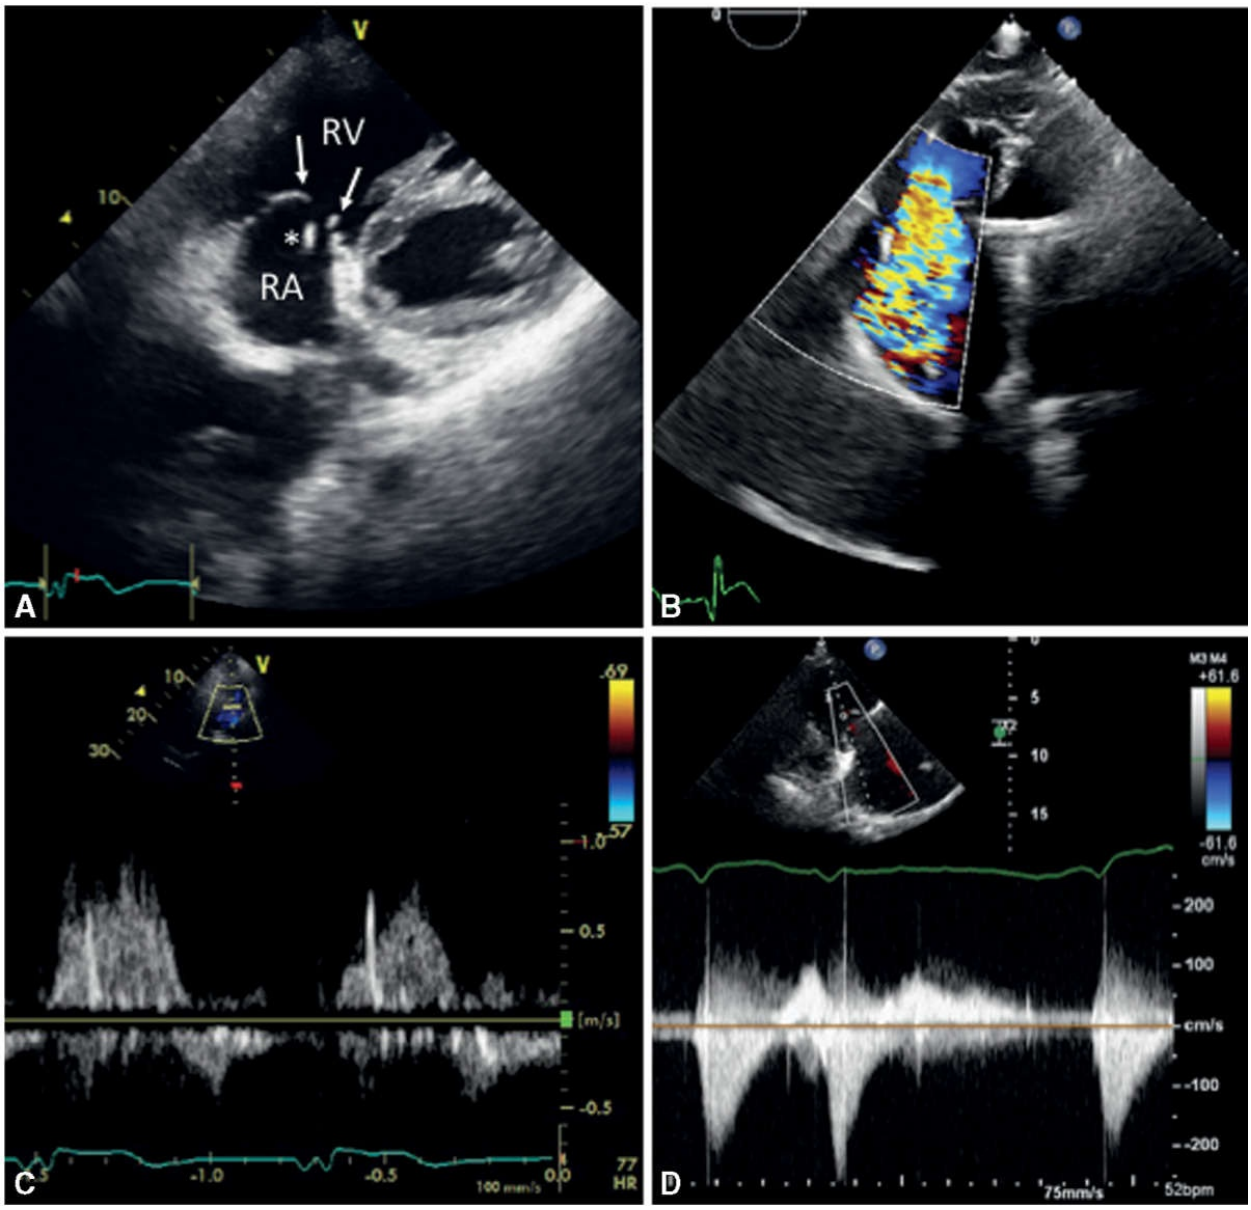

FIGURE 37.1 Tricuspid regurgitation. A, A 67-year-old woman with rheumatic heart disease and heart failure after mitral and aortic valve replacement. Parasternal short-axis view. TV leaflets *(arrows)* are thickened and restricted with severe malcoaptation. B, Modified four-chamber view showing severe TR on color Doppler. C, Pulsed wave Doppler of the hepatic veins (subcostal view) showing systolic flow reversal. D, Continuous wave Doppler (RV inflow view) showing a dense, triangular, low-velocity jet. RA, right atrium; RV, right ventricle; *, pacemaker electrode.

TABLE 37.1 Etiology of Tricuspid Regurgitation

Secondary (functional)
Primary
- Infective endocarditis (IV drug abuse)
- Rheumatic
- Pacemaker/ICD leads

Congenital (Ebstein anomaly)
Carcinoid
Myxomatous (prolapse, ruptured chords)
Trauma (blunt or penetrating)
Repeated endomyocardial biopsies in heart transplants
Prosthetic valve failure

Pacemaker and implantable cardioverter-defibrillator (ICD) leads are increasingly identified as a cause of TR, due to leaflet perforation, interference with TV closure, or with the subvalve apparatus (**Figure 37.2**).

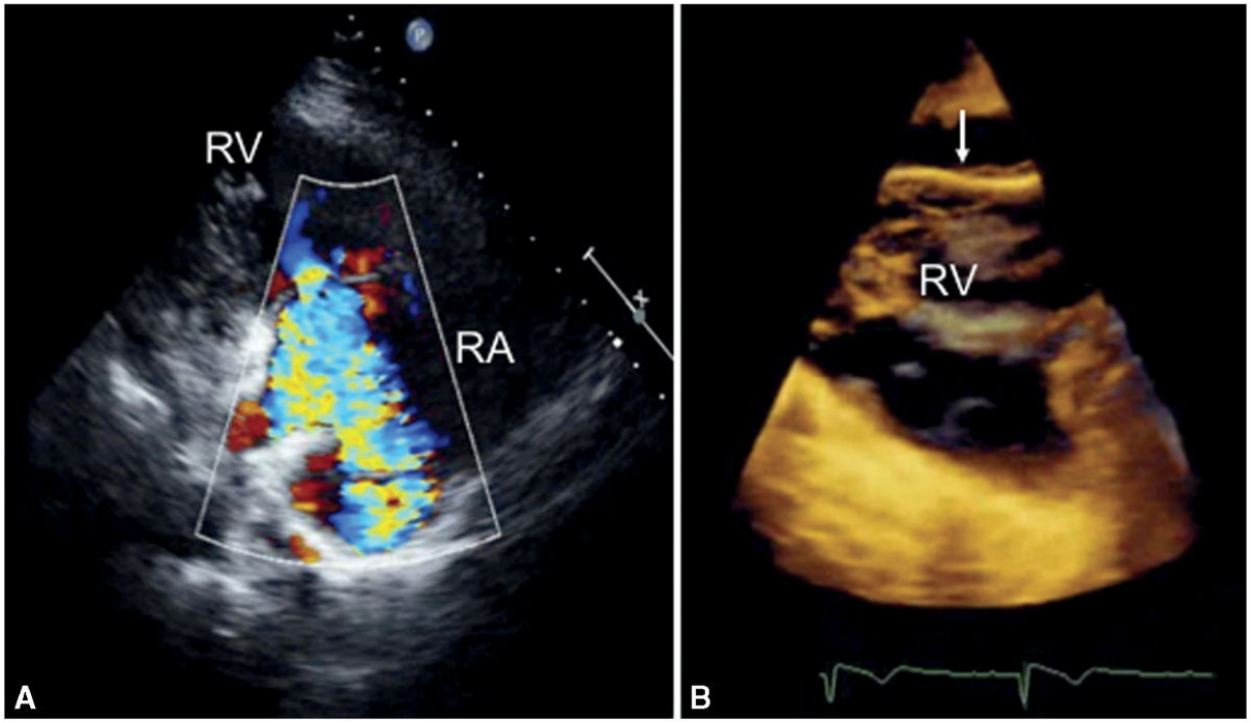

FIGURE 37.2 Tricuspid regurgitation after permanent pacemaker implantation. A, Severe symptomatic TR in a 48-year-old woman who had a pacemaker implantation with an RV lead after mitral valve replacement. RV inflow view. B, Transgastric 3D TEE showing the pacemaker electrode lodged in the subvalve apparatus. At surgery, the pacemaker electrode was found piercing and displacing the papillary muscle. TR resolved after repositioning of the electrode and TV annuloplasty. RA, right atrium; RV, right ventricle; arrow, pacemaker electrode; TEE, transesophageal echocardiography.

CLINICAL PRESENTATION

Patients with severe TR may be asymptomatic, especially when PHT and RV dysfunction are absent. With cor pulmonale or heart failure, dyspnea and fatigue are usually present. In the CCU setting, TR is most often seen in the setting of acute decompensated heart failure with dominant right heart failure, volume

overload, peripheral edema, and ascites. Right upper abdominal pain may be present secondary to a congested liver.

TR may sometimes complicate RV infarction. Such patients can present with a low-output state, hypotension, and right heart failure that can be resistant to inotropic therapy.[4]

In patients with right-sided endocarditis and TR, right heart failure may be absent initially if pulmonary pressure is normal, but may appear later as the RV eventually fails.

DIAGNOSIS

The clinical findings in severe TR are usually pathognomonic. Giant V waves are usually present in the jugular venous pulse, and are best seen in the sitting position. The liver may be distended, tender, and, most importantly, pulsatile. A right ventricular heave can be felt in the left parasternal area. When placing two hands, one on the left parasternal area and the other on the liver, a “seesaw” motion can be felt. In systole, the RV partially empties into the jugular and hepatic veins through the incompetent TV, producing a parasternal descent with jugular V waves and hepatic expansion. During diastole, the systemic veins empty into the RA and RV, producing RV parasternal lift and liver contraction. A left parasternal holosystolic murmur can sometimes be heard, which is typically augmented by inspiration (Carvallo sign).

Transthoracic echocardiography is key in the diagnostic workup of TR. In functional severe TR, there is usually RV dilatation, TA dilatation (>3.5 cm) and malcoaptation of the leaflets. Large TV vegetation and leaflet destruction are usually seen with TV endocarditis and TR. Color flow Doppler usually shows a large jet in the RA, with systolic flow reversal in the hepatic veins. In patients with wide-open TR, estimation of pulmonary artery systolic pressure using the TR jet velocity is inaccurate, due to equalization of systolic pressures in the RA and RV and difficulty in estimating RA pressure accurately. Spectral continuous-wave Doppler typically shows a low-velocity triangular TR flow (**Figure 37.1D**).

MEDICAL THERAPY

Patients with acute decompensated heart failure and secondary severe functional TR may respond well to heart failure therapy aimed to reduce PHT and eliminate volume overload. TR may regress considerably in such patients due to reverse

remodeling of the RV and the TA. Diuretics, angiotensin-converting enzyme inhibitors, and resynchronization therapy, when indicated, can reverse TR in patients with left ventricular failure. In patients with pulmonary arterial hypertension (PAH), RV failure, and functional TR, successful PAH therapy has been associated with improvement in TR severity and better outcome.[5]

Prolonged antibiotic therapy is indicated in TV endocarditis, but severe TR will usually not regress with medical treatment.

SURGICAL THERAPY

In patients with functional TR undergoing left heart surgery, and in particular mitral valve surgery, concomitant TV surgery should always be considered.[2] TR may persist and even progress years after mitral valve replacement, especially in patients with rheumatic heart disease. In such patients, concomitant TV repair with a ring annuloplasty should be considered when there is more than mild TR, with a dilated TA (≥3.5 cm) or with permanent atrial fibrillation.

TV surgery is more challenging with isolated TR, and surgical outcome in these patients used to be poor. In symptomatic patients with isolated severe TR, surgery (repair or replacement with a bioprosthetic valve) should be considered early when significant PHT is absent and RV function is still preserved.[6]

TV surgery is indicated in TV endocarditis and uncontrolled infection (persistent bacteremia despite antibiotic therapy >7 to 10 days or resistant organisms such as fungi). In such cases, all the infected tissue should be thoroughly excised, and the valve should be repaired, if possible. When the pulmonary pressure is normal, patients can tolerate severe TR after valve excision for several months or years, but eventually the RV will usually fail. IV drug addicts undergoing TV replacement are at high risk for recurrent endocarditis of the prosthetic valve if not successfully rehabilitated.

TRICUSPID STENOSIS

Tricuspid stenosis (TS) is rarely seen in the CCU. The etiology is almost always rheumatic, usually in conjunction with TR, mitral valve disease, and sometimes aortic valve disease as well. Patients may present with effort intolerance and fatigue due to a low-output state, but typically without dyspnea despite the accompanying mitral valve disease. In severe long-standing cases, cardiac

cirrhosis may also be present. On physical examination, neck veins are distended, the liver congested, and ascites, splenomegaly, and peripheral edema are usually present as well. Echocardiography typically shows thickened TV leaflets with restricted opening and turbulent diastolic flow on color flow Doppler (**Figure 37.3**). In significant TS, mean Doppler TV gradient is ≥5 mm Hg.[7] The RA and inferior vena cava are dilated, and inspiratory collapse of the inferior vena cava absent.

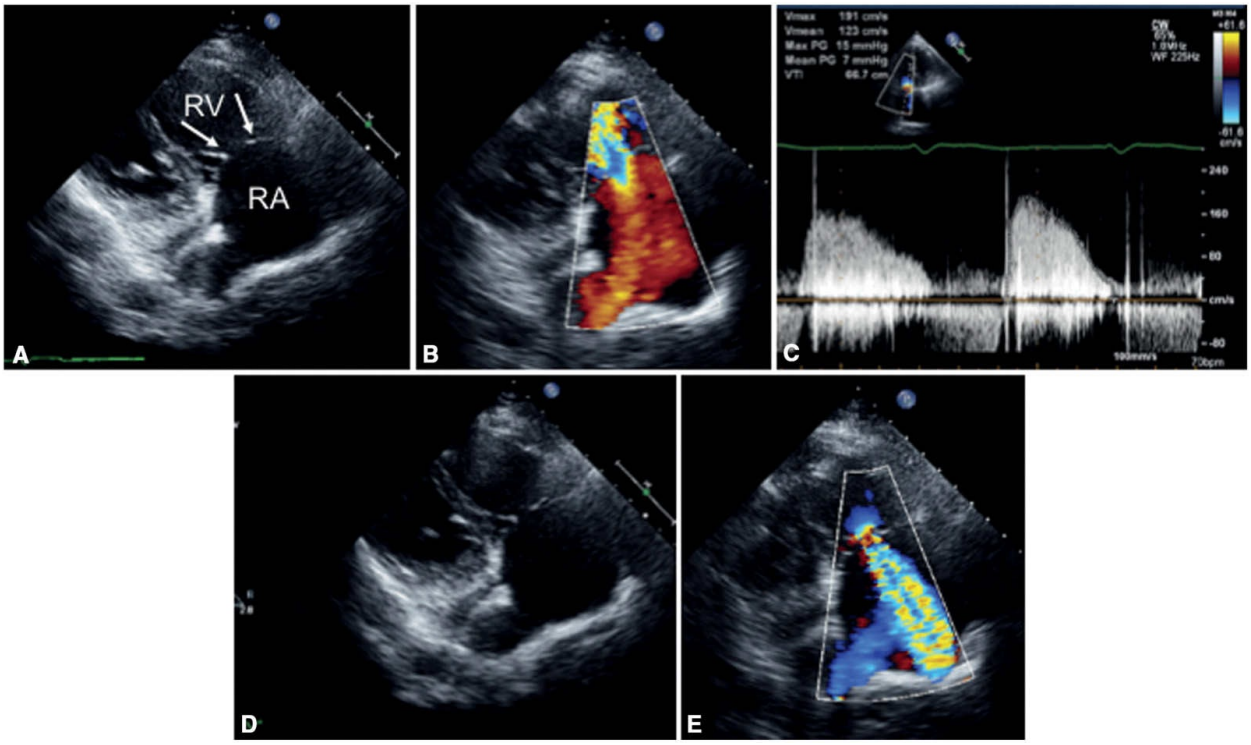

FIGURE 37.3 Tricuspid stenosis and regurgitation. A 47-year-old man with rheumatic TV disease, moderate TS, and severe TR. The patient had concomitant mitral and aortic disease. A, RV inflow view diastolic frame showing thickened restricted TV leaflets (arrows). B, Diastolic color Doppler frame showing a turbulent RV inflow. C, Continuous wave Doppler showing a mean diastolic tricuspid gradient of 7 mm Hg. D, RV inflow, systolic frame, showing severe malcoaptation of the TV leaflets. E, Color Doppler, systolic frame, showing severe TR. RA, right atrium; RV, right ventricle.

Sodium restriction and diuretics may reduce volume overload and improve liver function. In selected patients without significant TR, balloon valvuloplasty can be beneficial. In patients with significant symptomatic TS, TV commissurotomy or replacement with a bioprosthetic valve may be necessary, usually with concomitant mitral or aortic valve surgery.

PULMONIC STENOSIS

Pulmonic stenosis (PS) is rarely seen in the CCU setup. The etiology is usually congenital, and PS is usually mild in adults. Mild PS does not progress with time, but moderate PS can progress to severe PS in 20% of the patients due to calcification of the valve. Rarely, PS may be caused by carcinoid plaque deposition, with or without pulmonic regurgitation. Severe PS causes RV pressure overload and may result in effort intolerance, RV failure, and functional

TR. On auscultation, a pulmonic systolic ejection murmur is heard in the second left intercostal space. When the valve is pliable, an ejection click can be heard as well. P2 may be diminished when the valve is dysplastic or calcified.

The pulmonic valve (PV) can be visualized on echocardiography using the parasternal short-axis view or parasternal RV outflow view, or the subcostal short-axis view. When PS is caused by commissural fusion, the valve leaflets appear thin and systolic doming may be evident (**Figure 37.4**). With dysplastic valves, the leaflets are thickened and may calcify with time. The PV gradient can be estimated using continuous wave Doppler. Severe PS is defined as maximal PV jet velocity > 4 m/sec (peak gradient > 64 mm Hg).[7] When trying to estimate systolic pulmonary artery pressure in patients with PS, using TR velocity and the Bernoulli equation, one must remember to subtract the pulmonic gradient from the RV estimated systolic pressure.

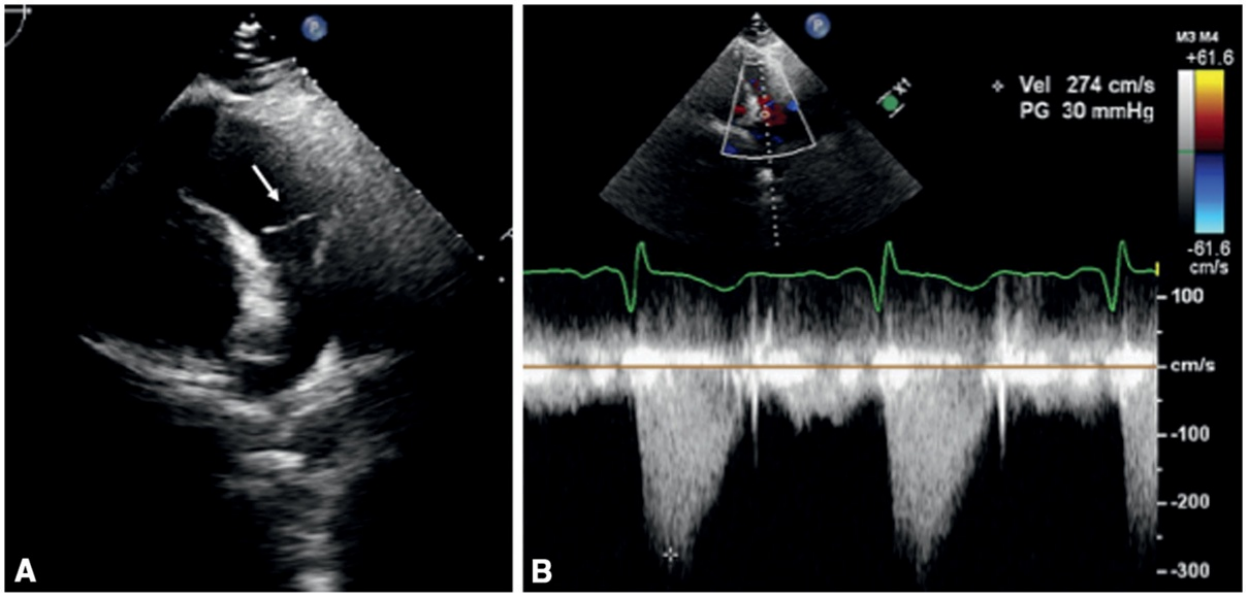

FIGURE 37.4 Pulmonic stenosis. A, Short-axis view, showing nonthickened pulmonic valve leaflets (arrow). B, Continuous wave Doppler showing increased pulmonic flow velocity and a peak pulmonic gradient of 30 mm Hg, corresponding to mild pulmonic stenosis. In this case, estimated peak systolic RV pressure, using TR velocity, was 43 mm Hg but pulmonary artery pressure was normal (43 – 30 = 13 mm Hg).

In young patients with symptomatic or severe PS and a pliable PV, balloon valvuloplasty may be beneficial. Percutaneous transcatheter PV implantation is indicated in patients with symptomatic PS (<65% expected exercise capacity) and maximal PV jet velocity > 3.5 m/sec, or in asymptomatic patients with peak

jet velocity > 4 m/sec or RV systolic pressure greater than two-thirds of systemic systolic pressure.

PULMONIC REGURGITATION

Pulmonic regurgitation (PR) is usually caused by PHT and secondary dilatation of the PV annulus or pulmonary artery and is usually nonsevere. Infective endocarditis can cause PR but it rarely affects the PV. Rarely PR can be caused by carcinoid plaques. Severe PR in adults is usually due to congenital heart disease, and seen mainly in patients with repaired tetralogy of Fallot or after PV valvuloplasty. Severe PR is usually well tolerated unless PHT is also present, which may then lead to RV failure and TR. On auscultation, a typical Graham Steell high-pitched decrescendo murmur is heard in the left 2 to 4 intercostal space in patients with concomitant PHT. Unlike in aortic regurgitation, the pulse pressure is not widened in PR. When pulmonary pressure is normal, the murmur is low pitched. The PR murmur is accentuated during inspiration, and the second heart sound may be widely split due to delayed RV emptying.

Echocardiography may show RV dilatation and diastolic flattening of the interventricular septum in patients with severe PR and RV volume overload. Color flow Doppler shows the regurgitant jet, which is wide in severe AR (**Figure 37.5**). Continuous wave Doppler of the PR jet can be used to estimate pulmonary artery diastolic pressure using the end diastolic PR velocity, similar to the way the TR jet is used to estimate pulmonary artery systolic pressure. With severe PR, the continuous wave diastolic Doppler signal is dense, with a steep deceleration reaching the baseline before the end of diastole.

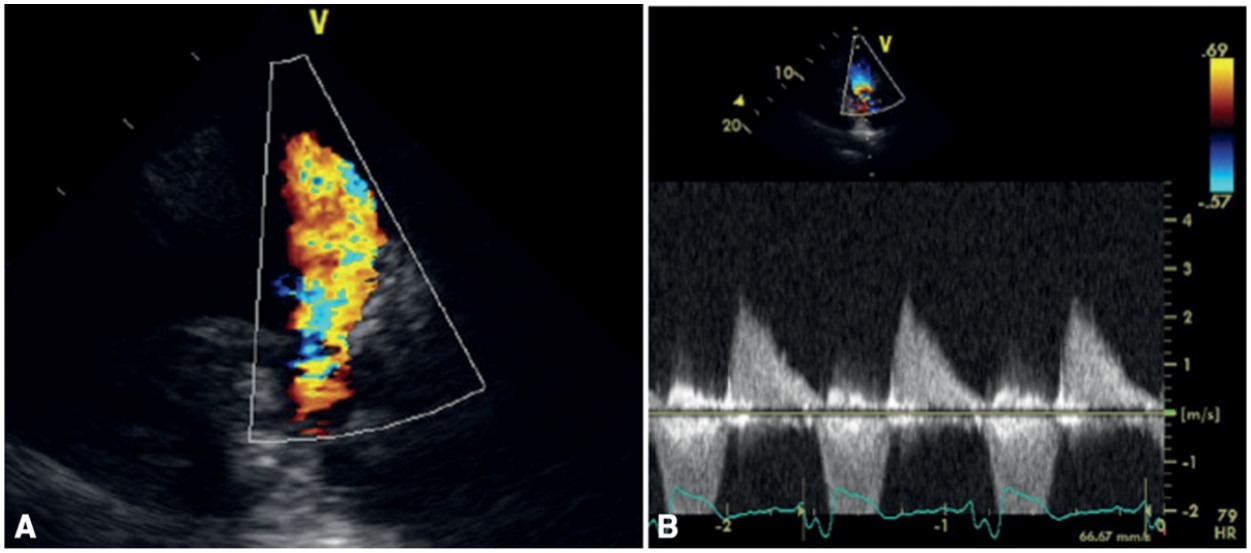

FIGURE 37.5 Pulmonic regurgitation. A 23-year-old patient with severe pulmonic regurgitation (PR) after repair of tetralogy of Fallot. A, Color Doppler short-axis view showing a wide PR jet. B, Continuous wave Doppler showing a dense diastolic signal with steep deceleration and a triangular shape. Moderate pulmonic stenosis was present in this case as well.

Percutaneous transcatheter PV implantation is indicated in patients with severe symptomatic PR, progressive RV dilatation or dysfunction, or with progressive TR.

Patient and Family Information for: TRICUSPID AND PULMONIC VALVULAR DISEASE IN THE CARDIAC CARE UNIT

There are two valves on the right side of the heart. The tricuspid valve (TV) is located between the two chambers in the right heart—the right atrium, which receives unoxygenated blood from the veins in the body, and the right ventricle. The right atrium delivers the blood through the tricuspid valve to the right ventricle, which pumps the blood through the pulmonic valve, the second valve in the right heart, to the lungs. In the CCU, tricuspid regurgitation (TR), a leaky tricuspid valve, is the most common of all right heart valves conditions. We focus, therefore, on TR.

TRICUSPID REGURGITATION

WHAT IS MY ILLNESS?

One of your heart valves, the tricuspid valve (TV) is leaking. This condition is called “tricuspid regurgitation” or sometimes “tricuspid insufficiency.” This causes blood from the right heart pumping chamber, the right ventricle, to leak back into the right atrium and from there to the veins in your body, instead of going forward to the lungs.

Because of the leak, you may notice that the veins in your neck are dilated and pulsating with the heartbeat. You may also have a painful liver from the blood flowing back to it, under the rib cage on your right side. Your legs may be swollen from excess salt and water in your body.

The most common cause of your condition is failure of the left side of your

heart, which overloads the right side of the heart as well. Any condition that causes high pressure in the arteries of your lungs may cause overload of your right heart and TR. Another possible cause of TR is infection of the valve with germs from your bloodstream, which can damage the valves and cause it to leak. These germs can get into your bloodstream if you shoot drugs.

HOW WILL I BE TREATED?

Your doctors may choose to treat you with medications such as diuretics. These drugs can remove excess fluids from your body through the kidneys, which will cause the right ventricle to get smaller and the TR to reduce. Other heart failure medications and medications to lower the pressure in the lung arteries may help as well. If you have infection of the valve, you will be treated with antibiotics delivered through your veins.

Your doctors may decide to refer you to a surgeon for an open heart surgery to treat your leaky TV and other dysfunctional heart valves, if necessary. In this case, your valve may be repaired or replaced, usually with a bioprosthesis. A bioprosthetic valve is made from either pig or cow tissue. Unlike a metal prosthesis, it does not require medications to prevent clotting of the valve, but it may last for a shorter period. Nevertheless, a bioprosthetic TV usually lasts for 15 years and even more.

In any case, complete abstinence from illicit drugs is mandatory to prevent reinfection of your valve, which could be fatal.

WHAT IF I AM PREGNANT OR THINKING OF BECOMING PREGNANT?

If you have a leaky TV and normal pressure in your lung arteries, and you have good function of your left and right ventricles, then most likely your pregnancy will be well tolerated. Otherwise, you need to consult with your doctor about the risk for you and your baby during pregnancy.

Infective Endocarditis

Infective endocarditis (IE) refers to the infection of the endocardium or heart endothelium, which may include heart valve endocardium or mural wall endocardium. In the United States, 10 to 15 new cases of IE per 100,000 persons are reported annually.[1] There has been a steady increase in the incidence of IE over the last decade. Despite the recent advances in medical and surgical therapies, IE continues to be a life-threatening disease. A recent study reports 15% to 20% in-hospital mortality and about 40% 1-year mortality for patients diagnosed with IE.[2] Up to 20% to 50% patients have cardioembolic complications like stroke.[3]

ETIOLOGY

RISK FACTORS

Table 38.1 summarizes the common risk factors associated with IE. In general, preexisting native valve disease or prosthetic material can serve as a nidus for bacterial seeding. Conditions predisposing to transient bacteremia (like hemodialysis, poor dentition) and causing immune suppression (like diabetes mellitus) are also important identifiable risk factors. Patients with a prosthetic valve or prosthetic material, congenital heart disease, previous history of IE, and cardiac transplantation valvulopathy are at the highest risk of developing IE. As per current guidelines, routine antibiotic prophylaxis is recommended only for

this subgroup of patients.

TABLE 38.1	Risk Factors of Infective Endocarditis
Patient-Related Factors	
Age	Highest incidence for age > 60 years
Male gender[4]	2- to 3-fold higher prevalence in men
Comorbid Conditions	
Acquired valvular disease	Rheumatic heart disease (most commonly mitral valve), degenerative valve disease (aortic valve sclerosis or stenosis), mitral annular calcification, prior IE
Congenital heart disease	Mitral valve prolapse, bicuspid aortic valve, ventricular septal defect, tetralogy of Fallot
Prosthetic valves	Mechanical valves (especially in first 3 months of implantation), bioprosthetic valves
Cardiovascular implantable electronic device (CIED)[5,6]	Device/lead infection and endocarditis
Intravascular devices	Intravascular catheters and probes can cause bacteremia
Diabetes mellitus	Higher risk of IE and poor response to treatment
End-stage renal disease requiring hemodialysis	Calcific valvular disease, immune impairment, transient bacteremia with intravenous access
HIV infection	Higher risk of IE, occasionally unusual organisms like Salmonella
Others	
Intravenous drugs abuse	Common cause of right-sided IE (tricuspid valve) but can also cause left-sided IE
Poor dentition	IE caused by oral flora

IE, infective endocarditis.

MICROBIOLOGY

Staphylococcus aureus is the most common organism isolated from blood cultures of patients with IE. It is the most common cause of acute IE, nosocomial endocarditis, and endocarditis associated with intravenous drug abuse. Other common bacteria include *Streptococcus viridans* and coagulase-negative Staphylococci (usually found in normal skin flora). Enterococci and

Streptococcus bovis are usually associated with genitourinary and intestinal source, respectively. Gram-negative bacilli, HACEK organisms (*Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*), fungi, and polymicrobial infection account for a small number of IE cases. Occasionally, no organisms can be isolated in patients with established IE (culture-negative endocarditis).[7,8]

PATHOPHYSIOLOGY

The pathogenesis of endocarditis involves three steps.[9] First is transient bacteremia, which can be spontaneous, associated with invasive procedures that break mucosal or skin integrity, or caused by noncardiac infection. Next, the bacteria adhere to the endocardium. Bacterial deposition is facilitated by preexisting valve disease and platelet aggregates on the damaged endothelial surface and/or foreign/prosthetic material. Highly virulent bacteria (such as *Staphylococcus aureus*) have the ability to infect structurally normal valves. The third step involves bacterial proliferation and inflammation resulting in vegetation formation, valve destruction, and spread into the surrounding cardiac tissue. The latter can result in intracardiac fistula and abscess formation. Vegetations are typically friable resulting in embolization causing tissue infarction as well as metastatic infection. Ongoing intravascular infection also results in a high burden of circulating immune complexes that produce immunologic phenomena of IE (such as glomerulonephritis).

CLASSIFICATION

Based on clinical presentation, native valve endocarditis can be divided into acute and subacute IE.

Acute IE classically refers to rapidly progressive IE with acute clinical presentation. Distant metastatic infection is common. It is typically caused by highly virulent organisms such as *Staphylococcus aureus*. Acute IE can be fatal in days to weeks despite appropriate medical therapy.

Subacute IE usually has an indolent course, extending over weeks to months. It is typically caused by organisms with lower virulence like streptococci. Distant metastatic infection is less common.

Prosthetic valve endocarditis (PVE) and cardiovascular implantable electronic device (CIED) endocarditis are divided into early and late.[6]

Early PVE refers to endocarditis within the first 60 days of the prosthetic

valve or CIED implantation. The prosthetic material and tissue–suture interface are not endothelialized during this timeframe. They can get infected during implantation or get seeded during any transient bacteremia.

Late PVE refers to endocarditis more than 60 days after the prosthetic valve implantation. Late infection occurs as a result of hematogenous bacterial spread with pathogenesis resembling that of native valve endocarditis.

Health care associated IE (nosocomial IE) refers to IE diagnosed 48 hours after admission to hospital, with no signs of IE on presentation to the hospital, or associated with any procedure within last 4 weeks.

CLINICAL FEATURES

Symptoms

Fever is the most common symptom seen in > 90% of the patients. It can be low grade in the beginning of acute IE or in subacute IE. Other symptoms include chills, night sweats, weight loss, malaise, myalgia, abdominal pain, cough, shortness of breath, and pleuritic chest pain.

Signs

New cardiac murmur is the most common sign present in endocarditis. Cardiac murmurs are heard because blood regurgitates through a damaged or perforated valve.

Vascular lesions of IE typically present as petechiae on skin or mucosal surfaces and should be specifically looked for. Subungual, dark linear streaks (splinter hemorrhages) can be seen, likely representing an embolic phenomenon. Janeway lesions are nontender, erythematous macules on palms or soles. Histologically, they are microabscesses with neutrophil infiltration due to embolism.

Osler nodes are tender, subcutaneous, violaceous nodules on distal finger and toe pads.

Roth spots are exudative, edematous hemorrhagic lesions of the retina with a pale center.

Splenomegaly can be seen in patients with subacute IE.

The source of bacteremia should be identified and eradicated if possible. This

includes careful dental examination and diagnosis of ongoing periodontal disease.

ELECTROCARDIOGRAM (ECG) AND LABORATORY STUDIES

New conduction abnormalities (like atrioventricular block, bundle branch block, or complete heart block) can be seen on ECG due to bacterial invasion and involvement of the paravalvular area.[10] Uncommonly, coronary embolic phenomena can manifest as acute myocardial ischemia.

Routine laboratory findings are nonspecific for endocarditis but reflect an ongoing inflammation. These include leukocytosis, anemia, elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), hypergammaglobulinemia, hypocomplementemia, and positive rheumatoid factor. Glomerular damage due to circulating immune complexes results in microscopic hematuria and proteinuria; occasionally, full-blown glomerulonephritis can be seen.

Noncardiac imaging studies such as X-rays, CT scans, and MRI can be useful in evaluating embolic phenomena due to IE (including strokes, abdominal organ infarcts, septic lung emboli, etc.) as well as exploring metastatic infection sites.

DIAGNOSIS

It is imperative to make an early diagnosis of IE because delayed initiation of treatment is associated with higher mortality and risk of embolic complications including stroke.[11] IE should be suspected in any patient with fever, bacteremia, and/or endocarditis risk factors.

In all patients suspected for IE, three sets of blood cultures should be drawn from different venipuncture sites with at least 1 hour between the first and the last sets. Transthoracic echocardiogram (TTE) should also be done as soon as possible to assess for the presence of vegetations, valvular regurgitation, and other complications of IE (**Figure 38.1**). Transesophageal echocardiogram (TEE) has a higher sensitivity for IE and its complications compared to TTE. It is recommended in all patients with suboptimal TTE images and in high-risk patients, even if TTE is negative. These include (but are not limited to) patients with suspected paravalvular involvement, prosthetic heart valves, CIED, and *Staphylococcus aureus* bacteremia without known source (**Figure 38.2**).[3,7,12]

Other cardiac imaging modalities for diagnosing IE (such as cardiac CT scan and nuclear techniques) are evolving and are supplemental at this stage.

MODIFIED DUKE CRITERIA

Modified Duke Criteria (see **Tables 38.2 and 38.3**)[13] use clinical, microbiologic, radiologic, and echocardiographic factors to stratify patients into definite IE, possible IE, and rejected categories. Current American Heart Association/American College of Cardiology (AHA/ACC) guidelines for IE support using Modified Duke Criteria in all patients with suspected IE.[7] These criteria have been extensively validated for left-sided native valve endocarditis. They likely have lower sensitivity for right-sided IE, prosthetic valve endocarditis, and CIED endocarditis.

TABLE 38.2 Modified Duke Criteria

Definite Infective Endocarditis

• Pathologic criteria:
  • Microorganisms demonstrated by culture or histologic examination of a vegetation that has embolized, or an intracardiac abscess specimen;
  • Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

• Clinical criteria:
  • 2 major criteria; or
  • 1 major criterion and 3 minor criteria; or
  • 5 minor criteria

Possible Infective Endocarditis
• 1 major criterion and 1 minor criterion; or 3 minor criteria
Rejected
• Firm alternative diagnosis; • Resolution of IE syndrome with antibiotic therapy for <4 days; • No pathologic evidence of IE at surgery or autopsy with antibiotic therapy for <4 days; • Criteria for possible IE are not met.

TABLE 38.3 Definition of Major and Minor Criteria

Major Criteria
Blood culture positive for IE

• Typical microorganisms consistent with IE from 2 separate blood cultures (*Streptococcus viridans*, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*, or community-acquired enterococci) or
• Persistently positive blood cultures defined as follows:
  • At least 2 positive cultures of blood samples drawn > 12 hours apart or
  • All 3 or a majority of ≥4 separate cultures of blood (with first and last sample drawn at least 1 hour apart)
  • Single positive blood culture for *Coxiella burnetii* or anti–phase I IgG antibody titer ≥ 1:800

Evidence of endocardial involvement Echocardiogram positive for IE, which is defined as follows: • Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or • Abscess; or • New partial dehiscence of prosthetic valve; or • New valvular regurgitation.
Minor Criteria
Predisposition, predisposing heart condition, or intravenous drug use
Fever (temperature > 38°C)
Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with IE.

IE, infective endocarditis.

Complications of IE are common and have been shown to increase morbidity and mortality. **Table 38.4** summarizes potential IE complications.

TABLE 38.4 Complications Related to Infective Endocarditis

Cardiac • Heart failure • Conduction abnormalities • Perivalvular abscess • Pericarditis • Intracardiac fistulas • Coronary embolization	**CNS** • Embolic stroke • Mycotic aneurysm • Intracranial hemorrhage • Cerebral abscess • Meningitis
Pulmonary • Pulmonary embolism	**Renal** • Glomerulonephritis • Renal infarction
Musculoskeletal and Others • Limb ischemia • Septic arthritis • Splenic infarct	**Complications Related to Therapy** • Ototoxicity or nephrotoxicity from aminoglycoside antibiotics • Drug fever • Intravenous catheter thrombosis

CNS, central nervous system.

MANAGEMENT

Management of IE can be broadly divided into antimicrobial therapy and surgical therapy. However, given the complexity of this disease a multispecialty management approach is needed, which includes infectious disease specialist, cardiologist, cardiac surgeon, and cardiac anesthesiologist (if surgical therapy is planned).

ANTIMICROBIAL THERAPY

General Principles

It is essential that blood cultures are obtained before initiating antimicrobial therapy. Antimicrobial therapy should always be parenteral, bactericidal, and prolonged to ensure bacterial eradication. Synergistic antimicrobial agents should be used to increase the efficacy. In most cases, especially in patients who are clinically unstable, empirical, broad-spectrum antimicrobial regimen is recommended. Specific antimicrobial therapy should be substituted once the specific pathogen has been isolated from blood cultures. It is reasonable to obtain at least two sets of blood cultures every 24 to 48 hours until bloodstream infection has cleared to assess the response to the antimicrobial therapy. Duration of the therapy is usually up to 6 weeks. These days are counted from the first negative blood culture. Temporary discontinuation of anticoagulation is recommended for patients with IE, especially if complications like embolic stroke occur. It is also important to monitor patients' renal function and liver function during the treatment because antibiotic dosage needs to be adjusted according to creatinine clearance and hepatic impairment. Patients can finish their therapy as outpatients provided they are able to manage the intravenous access and follow up diligently.

Specific antimicrobial regimens have been suggested by recent 2015 American Heart Association (AHA)/Infectious Disease Society of America (IDSA) statement on IE management.[7] **Tables 38.5 and 38.6** show the recommended antibiotics regimen for the most common bacterial species —*Streptococcus viridans* or *Streptococcus bovis*, and *Staphylococcus aureus*.

Antibiotic therapy should be adjusted as necessary based on bacterial susceptibility.

TABLE 38.5 Antibiotic Regimen for Native Valve Endocarditis[7]

REGIMEN	MEDICINE	DOSAGE	DURATION	COMMENT
***Streptococcus viridans* or *Streptococcus bovis* (Highly Penicillin-Susceptible Organisms)**				
1	Penicillin G or	12–18 million units IV/day in 4 or 6 equally divided doses	4 weeks	
	Ceftriaxone	2 g/day IV/IM in 1 dose		
2	Penicillin G or	12–18 million units IV/day in 6 equally divided doses	2 weeks	
	Ceftriaxone plus	2 g/day IV/IM in 1 dose		
	Gentamicin	3 mg/kg/day IV/IM in 1 dose		
3	Vancomycin	Consider loading dose Load: 15–25 mg/kg or 25–30 mg/kg (severe infection) Maintenance: 15–20 mg/kg q8–12h (infuse each 1 g over at least 1 hour to avoid infusion-related red man syndrome)	4 weeks	Patient unable to tolerate ceftriaxone or penicillin Use actual body weight for dosing. Target trough Concentrations (before the 4th dose): >10 mg/L: always optimal to prevent resistance 15–20 mg/L: for IE dosing adjustment based on trough Nephrotoxicity and ototoxicity are rare without a concomitant offending agent.
Staphylococcus aureus				
1	Nafcillin or oxacillin	12 g/day IV in 4 or 6 equally divided in doses	6 weeks	Methicillin sensitive
2	Cefazolin	6 g/day IV in 3 equally divided doses	6 weeks	For nonanaphylactic penciling allergy
		Consider loading dose Load: 15–25 mg/kg or		Methicillin resistant Use actual body weight for dosing. Target trough Concentrations (before the 4th dose):

3	Vancomycin	25–30 mg/kg (severe infection) Maintenance: 15–20 mg/kg q8–12h (infuse each 1 g over at least 1 hour to avoid infusion related red man syndrome)	6 weeks	>10 mg/L: always optimal to prevent resistance 15–20 mg/L: for IE Dosing adjustment based on trough Nephrotoxicity and ototoxicity are rare without a concomitant offending agent.

TABLE 38.6 Antibiotic Regimen for Prosthetic Valve Endocarditis[7]

REGIMEN	MEDICINE	DOSAGE	DURATION	COMMENT
***Streptococcus viridans* or *Streptococcus bovis* (Highly Penicillin-Susceptible Organisms)**				
1	Penicillin G or	24 million units IV/day in 4–6 equally divided doses	6 weeks	
	Ceftriaxone With or without	2 g/day IV/IM in 1 dose		
	Gentamicin	3 mg/kg/day IV/IM in 1 dose	2 weeks	
2	Vancomycin	Same as above	6 weeks	Patients unable to tolerate ceftriaxone or penicillin
Staphylococcus aureus				
1	Nafcillin plus	12 g/day IV in 6 equally divided doses	≥6 weeks	Methicillin sensitive
	Rifampin plus	900 mg/day IV in 3 equally divided dose		
	Gentamicin	3 mg/kg/day IV/IM in 2–3 equally divided doses	2 weeks	
2	Vancomycin plus	Same as above	≥6 weeks	Methicillin resistant
	Rifampin plus	900 mg/day IV in 3 equally divided dose		
	Gentamicin	3 mg/kg/day IV/IM in 2–3 equally divided doses	2 weeks	

HACEK organisms are gram-negative fastidious bacilli that grow very slowly on standard blood culture media.[3] Patients with HACEK endocarditis should be treated with intravenous ceftriaxone, ampicillin, or ciprofloxacin for 4 weeks.

Fungal endocarditis is rare and most commonly due to *Candida* or *Aspergillus* species. Current guidelines recommend two-phase antimicrobial treatment with surgical management. The first phase involves intravenous antifungal therapy for 6 weeks followed by the second long-term suppressive period with oral antifungal medications.

SURGICAL THERAPY

The basic principle of surgical therapy is to debride infected and nonviable tissue, as well as to reconstruct the involved cardiac area and restore the competency of the damaged valve. Although randomized control data are limited, single-center observational studies show the decrease in in-hospital mortality and embolic complications with early surgery in selected patients with IE.

Early surgery (during initial hospitalization) is indicated in IE patients with signs or symptoms of heart failure due to valve dysfunction, endocarditis caused by highly resistant organisms such as fungi, and intracardiac complications of IE causing abscess or heart block. Persistent bacteremia despite appropriate antimicrobial treatment is also an indication for surgery. Surgery is considered with recurrent embolic events and persistent vegetations despite antimicrobial therapy and in patients with large mobile vegetations.[12,14]

Right-sided endocarditis carries better prognosis with antimicrobial therapy compared with left-sided endocarditis, but can also require surgical intervention. Valve replacement should be avoided in intravenous drug users given the risk of subsequent device infection with continued intravenous drug use. Valve repair rather than replacement should be performed when feasible for right-sided endocarditis.[7]

CIED endocarditis: In patients with CIED endocarditis, retained hardware (generator and leads) can lead to higher rate of infection relapse. Complete device and lead removal are recommended for all patients with definite CIED infection, as evidenced by valvular and/or lead endocarditis. Any patient with occult staphylococcal bacteremia or with persistent occult gram-negative bacteremia despite appropriate antibiotic therapy should also be considered for device explant. Current AHA/Heart Rhythm Society (HRS) guidelines recommend at least 14 days of antibiotics before reimplantation. Reimplantation of CIED should be done on the contralateral side.[6]

INFECTIVE ENDOCARDITIS PROPHYLAXIS

Revised 2007 AHA guidelines[15] recommend IE prophylaxis for patients with cardiac conditions associated with the highest risk of adverse events: patients with a prosthetic valve (including bioprosthetic valves); patients with previous history of IE; patients with unrepaired cyanotic congenital heart disease (including patients who underwent palliative procedures); patients with repaired congenital heart disease with residual defect at the site of prosthetic material; patients with completely repaired congenital heart disease with prosthetic material (first 6 months after the procedure); and cardiac transplant recipients with valvular disease.

Antibiotic prophylaxis is recommended only for dental procedures that involve manipulation of the gingival tissues, periapical region of teeth, or perforation of oral mucosa as well as procedures on respiratory tract or infected skin, skin structures, or musculoskeletal tissue. Antibiotic prophylaxis is not recommended for genitourinary or gastrointestinal tract procedures unless there is an ongoing infection. Recommended prophylaxis regimens are listed in **Table 38.7**.

TABLE 38.7 Infective Endocarditis Prophylaxis Regimen[15]

SITUATION	MEDICATION	DOSE (SINGLE DOSE 30 TO 60 MIN BEFORE PROCEDURE)
Oral	Amoxicillin	2 g po
Unable to take oral medication	Ampicillin or	2 g IM/IV
	Cefazolin or ceftriaxone	1 g IM/IV
Allergic to penicillin—oral	Cephalexin or	2 g po
	Clindamycin or	600 mg po
	Azithromycin or clarithromycin	500 mg po
Allergic to penicillin—not able to take oral medication	Cefazolin or ceftriaxone or	1 g IM/IV
	Clindamycin	600 mg IM/IV

Patient and Family Information for: INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) refers to infection of the inner lining of the heart or heart valves. IE, if not diagnosed and treated early, could lead to death and/or grave complications.

CAUSES AND RISK FACTORS

The highest incidence of IE has been noted in individuals over 60 years of age. IE is more common in patients with preexisting heart valve disease or structural heart disease. These could be congenital (present since birth) or acquired during the lifetime. Diabetes, HIV, or any low-immunity state decrease the body's ability to fight infection and are associated with increased IE risk. Poor dental hygiene, external catheters, frequent dialysis, and intravenous drug abuse can directly introduce bacteria to bloodstream, which can result in heart valve infection. At last, bacteria can easily attach to any foreign material in the body, like a prosthetic valve or pacemaker lead, and cause infection.

HOW DOES INFECTIVE ENDOCARDITIS DEVELOP?

Bacterial invasion to the bloodstream due to various reason, is usually the first step of the IE. Next, bacteria get attached to the damaged heart tissue, prosthetic valve, or pacemaker lead. Some aggressive strains of bacteria can infect structurally normal heart valves as well. Finally, bacteria grow and cause damage to the surrounding heart tissue. Bacterial growth leads to development of vegetation, an infected tissue attached to the inner lining of the heart, heart

valves, or foreign material (like a pacemaker lead). Further spread of the infection can lead to heart tissue destruction and pus accumulation (abscess).

SIGNS AND SYMPTOMS

Most common symptoms include fever, chills, night sweats, weight loss, shortness of breath, fatigue, or chest pain. The physician can hear a heart murmur due to blood leakage through the damaged valves. Vegetations that have developed due to IE can break off and obstruct the blood supply to other organs; stroke is a well-known complication of IE.

DIAGNOSIS

Blood culture and ultrasound imaging of the heart (echocardiogram) are the two most important tests for diagnosis of IE. Several blood cultures are collected from the patient and repeated after treatment is started to document clearance of the infection. Echocardiogram should be done as soon as possible if IE is suspected. Other imaging studies like CT scan or MRI of the head, chest, or abdomen may also be necessary to rule out other organ involvement or distant spread of infection.

COMPLICATIONS

Heart valve malfunction, congestive heart failure, and abscess formation are known complications of IE. IE can also cause a stroke. Infection can spread outside the heart causing pus collection in different organs including the spine.

TREATMENT

IE management usually needs a multi-pronged approach with the help of infectious disease specialists, cardiologists, and cardiac surgeons. Proper antibiotic therapy and surgery in appropriate cases are the key for successful management of IE. Antibiotics should be started early but typically after the

blood cultures are drawn. The antibiotic therapy is tailored to specific bacterial species cultured from the blood. Any primary source of infection and infected foreign material should be identified and treated. The antibiotic therapy is usually prolonged and intravenous.

Many patients with IE are considered for early surgical intervention. These include but are not limited to patients with heart valve damage causing heart failure or heart abscess formation. Damaged valves may need to be replaced during the surgery. Cardiac surgery is usually a high-risk procedure in this situation but provides the best chance for recovery. The infected pacemaker and leads should be removed.

PROPHYLAXIS

Prophylactic antibiotics are recommended for patients who are at the highest risk of developing IE, including patients with prior IE, some types of congenital heart disease, patients with a prosthetic heart valve, and heart transplant patients with valve disease. Only certain procedures require antibiotic prophylaxis (such as invasive dental procedures or procedures on infected skin). Typically, the prophylaxis consists of a single dose of oral antibiotic given 30 to 60 minutes before the procedure.

Percutaneous Therapy for Valvular Heart Disease

INTRODUCTION

Patients with both acute and chronic presentations of severe valvular heart disease are frequently encountered in the intensive care setting due to heart failure and cardiogenic shock. In these patients, medical therapy can reduce symptoms of congestion and optimize their hemodynamic state, but an interventional or surgical approach to correct the valvular lesion is often required for a durable solution. Many intensive care patients are poor candidates for open heart surgery due to comorbidities. Some high-risk patients who are not surgical candidates may benefit from percutaneous interventions. Over the past decade, percutaneous interventions for valvular heart disease have rapidly expanded such that many patients can be successfully treated without an open surgical approach. Additionally, a minority of stable patients who undergo percutaneous valvular therapies on an elective basis will require intensive care in the immediate postprocedure period for monitoring and treatment of procedural complications. For these reasons, the practice of modern critical care cardiology requires an in-depth understanding of percutaneous therapies for valvular heart disease.

BALLOON AORTIC VALVULOPLASTY

Severe aortic stenosis (AS), defined as an aortic valve area < 1.0 cm^2 with mean aortic valve gradient > 40 mm Hg and peak aortic valve velocity > 4.0 m/s, manifests with symptoms of heart failure, syncope, and angina. Occasionally, severe AS results in cardiogenic shock. Medical therapy in patients with severe AS is challenging due to the balance necessary between adequate preload and afterload in the setting of a severe obstruction to left ventricular outflow. Patients treated with medicines alone without subsequent aortic valve replacement (AVR) have a very poor prognosis. In the Placement of Aortic Transcatheter Valves (PARTNER) trial, the 1-year survival of medically treated patients with severe AS was only 50%.[1] Interestingly, at 5 years all except one patient died on medical management including aortic valvuloplasty without aortic valve replacement.[2]

For over two decades, before availability of transcatheter aortic valve replacement (TAVR), balloon aortic valvuloplasty (BAV) was the only percutaneous therapy for severe AS. BAV was developed in the 1980s and initially suggested as an alternative to surgical aortic valve replacement (SAVR), but was quickly recognized as inadequate therapy due to inadequate increase in aortic valve area and almost certain restenosis within a few months.[3] BAV is performed by obtaining percutaneous femoral artery access and passing a wire retrograde across the aortic valve and into the left ventricle. A balloon advanced over the wire across the aortic valve is then inflated inside the aortic valve with the aim of disrupting calcific deposits within the valve and reducing the severity of AS. BAV can also be performed antegrade via femoral venous access and transseptal puncture across the interatrial septum in patients with insufficient iliofemoral arterial anatomy for the conventional retrograde approach. In most patients treated with BAV, the mean aortic valve gradient by transthoracic echocardiogram decreases by 50% and the aortic valve area significantly increases by 0.2 to 0.5 cm^2.[4] BAV can generally be performed with moderate rates of major complications. Procedural mortality ranges from 1% to 5% and is typically a result of aortic regurgitation while 30-day mortality ranges from 6% to 10% and is a consequence of heart failure among other comorbid conditions. Vascular complications occur in 1% to 2% of cases in modern practice. Despite favorable hemodynamic results in the early postprocedure period, many patients suffer from recurrent severe AS after BAV. Between 24% and 76% of patients

have been found to have restenosis of the aortic valve within 6 months after BAV, and some reports have shown restenosis as early as 2 hours after BAV.[5] Long-term outcomes after BAV without subsequent AVR are poor and similar to those of patients with severe AS treated medically. The probability of freedom from death or AVR at 1, 2, and 3 years after BAV is 40%, 19%, and 6%, respectively in a historical series.[6]

In the modern era of TAVR, BAV has been performed with increasing frequency as bridging therapy before TAVR. Between 1998 and 2010, the use of BAV increased by 158% corresponding to the advent of TAVR during that period.[7] However, even in the modern era the long-term outcomes after isolated BAV remain poor with high rates of recurrent AS and death in patients who are not treated with subsequent valve replacement. The survival of patients undergoing BAV alone remains significantly worse compared with patients who undergo BAV as a bridge to eventual TAVR. BAV may be considered as a bridging therapy in patients with severe AS admitted to the intensive care unit with heart failure, respiratory failure, or cardiogenic shock refractory to medical therapy. BAV is most useful in patients with a temporary contraindication to AVR (sepsis, multisystem organ failure, ventilator-dependent respiratory failure, coagulopathy, etc.) or in patients in whom the contribution of AS to their symptoms is uncertain. In these cases, BAV may offer a window to achieve cardiopulmonary stability or symptom improvement that may allow for bridging to subsequent AVR. BAV without plans for subsequent AVR is not a definitive therapy for severe AS and should be considered palliative.[4,8,9]

TRANSCATHETER AORTIC VALVE REPLACEMENT

In the past decade, TAVR has revolutionized the care of AS patients because it has become an established alternative to SAVR in patients with severe AS who are at more than low surgical risk (**Figure 39.1**).[10] “High risk” for SAVR is commonly defined as a Society of Thoracic Surgeons predicted risk of operative mortality (STS PROM risk score) of 8% to 15%, unsuitable anatomy for open surgery such as porcelain aorta or prior chest radiation, or significant frailty.[11] Most patients considered for TAVR are elderly with the mean age of participants in TAVR clinical trials being over 80 years of age.[1,12,13] Patients considered for TAVR often have multiple comorbidities that may have important implications

on prognosis. For this reason, patient selection is the most important aspect of a successful TAVR program. Careful clinical and geriatric risk assessment including frailty by a comprehensive heart valve team is the standard of care before TAVR in order to select patients with an anticipated benefit in terms of symptoms and longevity. The heart valve team approach to selecting patients for TAVR carries a class I indication in the most recent American College of Cardiology (ACC)/American Heart Association (AHA) guidelines.[11] Clinical risk stratification is typically performed using risk scores designed for cardiac surgery populations (STS PROM risk score or Euroscore), but it is important to recognize that these risk scores do not assess certain factors unique to TAVR, such as aortic annulus sizing, iliofemoral vascular anatomy, and coronary ostia height, among others. Risk prediction tools specific for TAVR have been proposed but have not yet been widely adopted.[14,15] In general, TAVR should not be performed in patients with a life expectancy of <12 months due to a competing noncardiac condition. Attention to risk factors such as frailty, cognitive performance, and functional status is important to select patients with the greatest anticipated benefit from TAVR. Although TAVR has conventionally been applied to patients with degenerative calcific AS of a tricuspid aortic valve, it has been used effectively in carefully selected cases of severe bicuspid AS, aortic regurgitation, and within failed prior SAVR bioprosthesis as a so-called valve-in-valve TAVR.

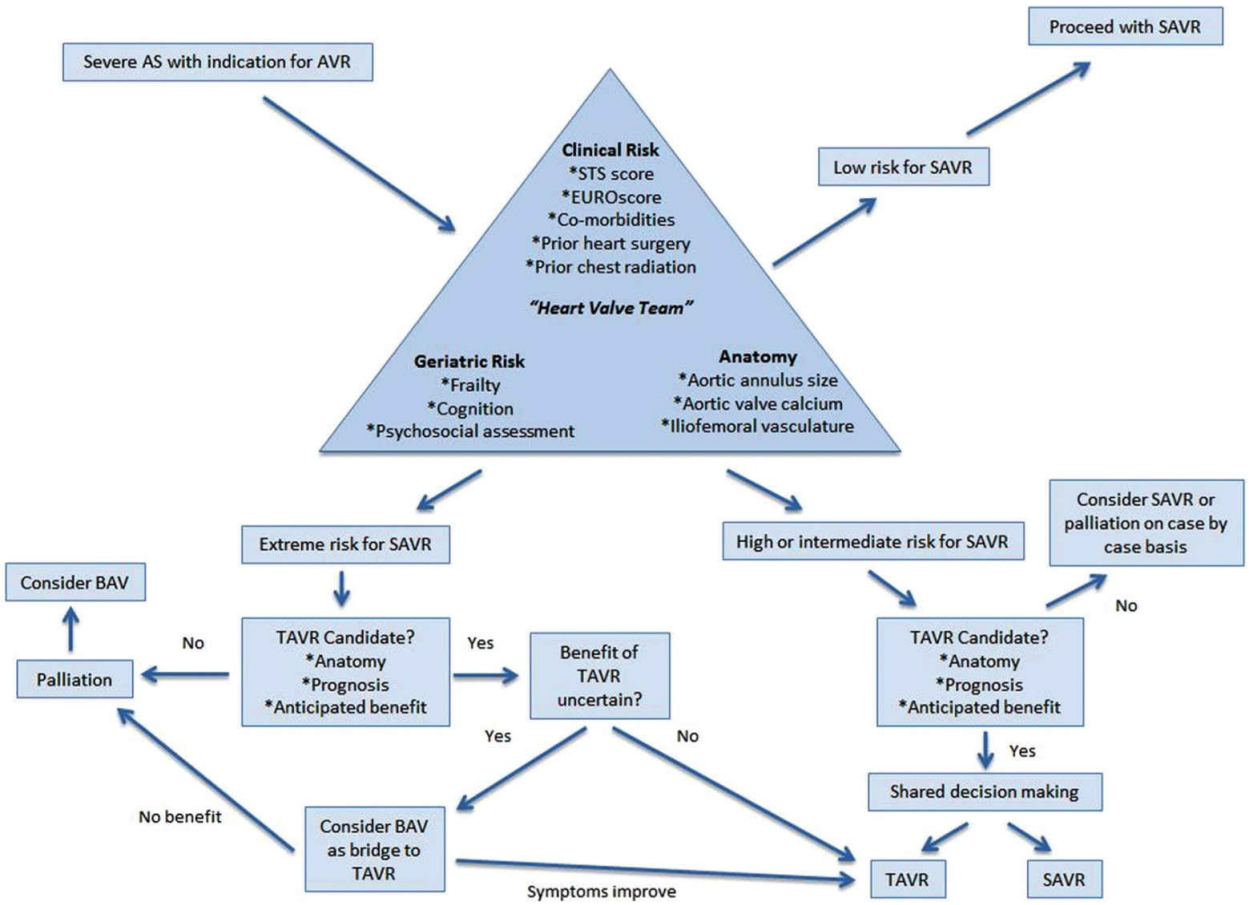

FIGURE 39.1 Decision algorithm for the interventional management of severe aortic stenosis. AS, aortic stenosis; AVR, aortic valve replacement; BAV, balloon aortic valvuloplasty; SAVR, surgical aortic valve replacement; STS, Society of Thoracic Surgeons; TAVR, transcatheter aortic valve replacement.

In the United States, there are two TAVR systems commercially approved by the Food and Drug Administration (FDA) and a number of other devices currently available in clinical trials. The Edwards Sapien 3 valve[1] (Edwards Lifesciences, Irvine, CA) and the Medtronic Evolut R[16] (Medtronic, Minneapolis, MN) are the predominant TAVR platforms used in contemporary practice. Both are FDA approved for use in patients with extreme risk or high risk for SAVR. The Edwards S3 and Sapien XT valves have recently gained FDA approval in intermediate risk patients as well. However, prior generations of these valves (the Edwards SAPIEN XT valve and the Medtronic CoreValve, respectively) have only limited applications in modern practice. During TAVR, a bioprosthetic stent-mounted valve is deployed through a transcatheter system within the native aortic valve annulus (**Figure 39.2**). Unlike SAVR in which the native aortic valve is excised and replaced, during TAVR the leaflets of the native aortic valve remain in situ and are pushed aside during valve deployment.

Edwards S3 valves are “balloon expandable” valves (BEV), which are bovine tissue valves deployed by inflation of a balloon mounted within the valve. The Medtronic system is a porcine tissue valve that is a “self-expandable” valve (SEV) that does not require balloon inflation. BEV and SEV have distinct advantages and disadvantages, but most TAVR centers have experience with both systems. BEV may be better suited for patients at risk for paravalvular leak (eccentric aortic valve annulus, heavy annular calcification, high left ventricular outflow tract to aorta angulation), whereas SEV may be better in patients at risk for coronary occlusion during TAVR due to low clearance of the coronary ostia.[10] Only one randomized controlled trial has directly compared outcomes of the Edwards SAPIEN XT valve and the Medtronic CoreValve.[17] In 241 patients randomized 1:1 to the Edwards SAPIEN XT and the Medtronic CoreValve, the Edwards SAPIEN XT valve group had a higher rate of successful device implantation, lower rate of aortic regurgitation, and lower rate of permanent pacemaker implantation. Despite these differences, mortality at 30 days was similar between the two groups.

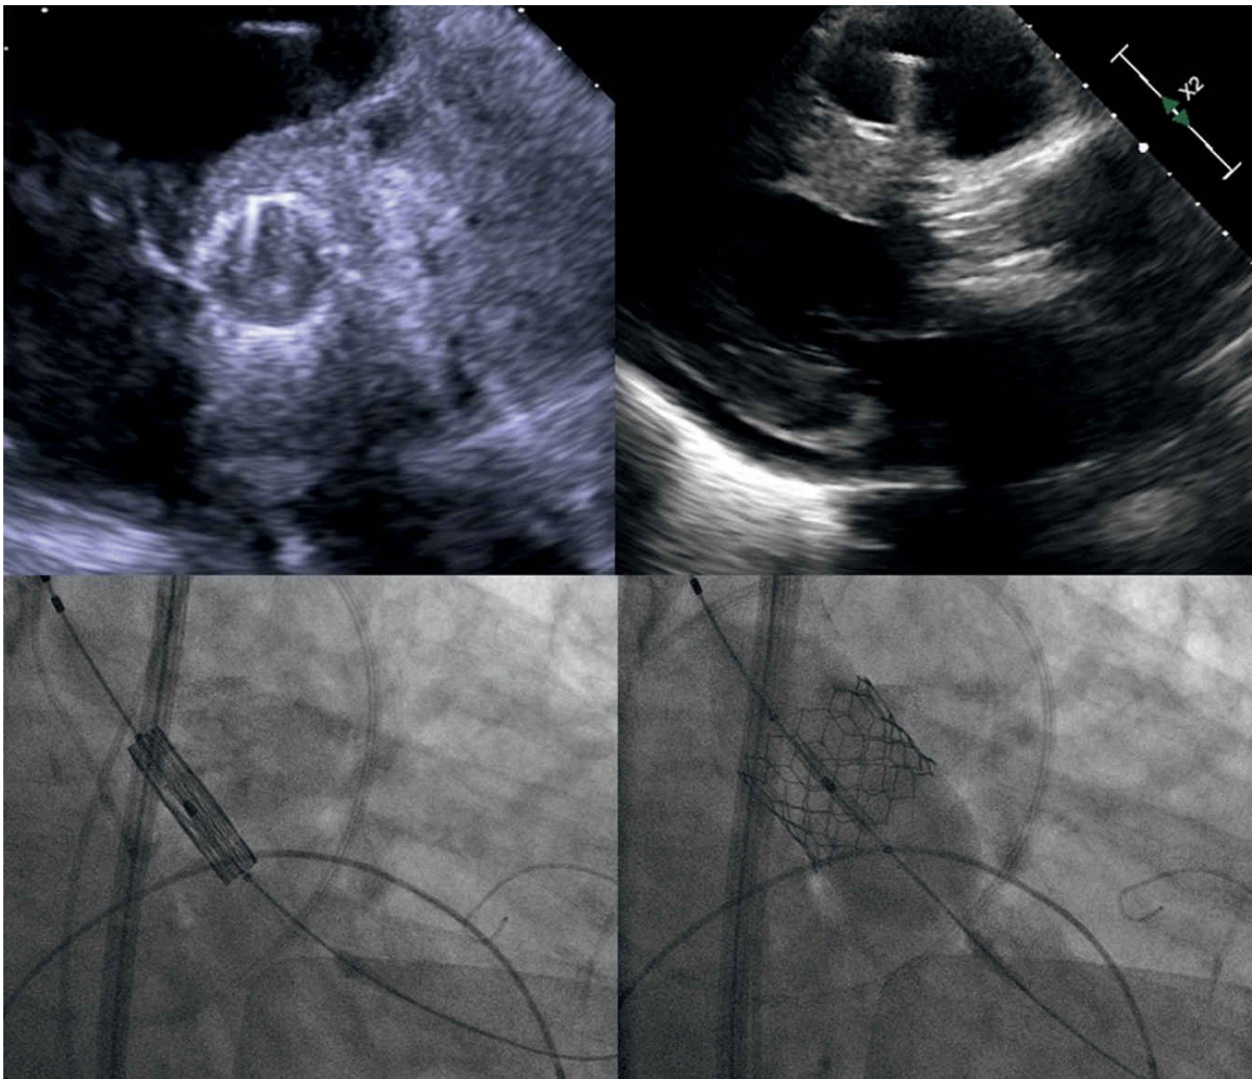

FIGURE 39.2 Echocardiography and fluoroscopy of the transcatheter aortic valve. Caval-aortic implantation of an Edwards transcatheter aortic valve for severe aortic stenosis. Top left—short-axis view of the Edwards valve by echo. Top right—long-axis view of the Edwards valve by echo. Bottom left—fluoroscopy of the Edwards valve before deployment. Bottom right—fluoroscopy of the Edwards valve during deployment with the balloon fully expanded.

Most TAVR procedures (almost 90%) are performed these days by percutaneous femoral artery access ("transfemoral TAVR"), which does not require routine surgical cut-down to expose or repair the femoral access site. However, in the minority of patients in whom the iliofemoral vessels are inadequate to accommodate a percutaneous TAVR (minimal lumen area < 6 mm^2), TAVR can be successfully performed using surgical access via the ascending aorta ("transaortic TAVR") or the left ventricular apex ("transapical TAVR"). Carotid artery and axillary/subclavian artery access for TAVR with a

surgical arterial exposure and repair have also been used with success. Rarely, TAVR can be performed by accessing the descending aorta via the adjacent inferior vena cava (“caval-aortic TAVR”) with percutaneous femoral vein access in patients in whom surgical access carries excessive risk and the iliofemoral arterial anatomy is inadequate to accommodate a transfemoral system. Surgical access for TAVR is associated with increased risk of adverse events, longer hospital stays, and increased short- and long-term mortality due to the more invasive nature of this procedure. Since the early days of TAVR, the proportion of cases performed by a transfemoral approach has increased substantially as the delivery sheaths have decreased from 24 French (8 mm external diameter) to 14 French (<5 mm diameter) over time.

It is critical to understand the complications of TAVR that may manifest intraprocedurally or during the index hospital stay. Intraprocedural complications such as aortic annular rupture, left ventricular perforation, valve embolization, bleeding, and vascular injury can be life threatening and require immediate attention by the procedural team including the interventional cardiologist and cardiac surgeon. However, a number of complications may develop in the immediate postprocedure period. Coronary ostia occlusion may not be immediately detected and can present as an acute myocardial infarction with chest pain, ischemic ECG changes, a major rise in cardiac biomarkers, and electrical or hemodynamic instability. Coronary occlusion is typically the consequence of the native aortic valve leaflet occluding the coronary ostia because it is pushed against the aortic annulus and aortic sinuses during deployment of the TAVR valve. However, myocardial infarction after TAVR due to underlying coronary artery disease (CAD) or coronary occlusion is exceedingly rare with rates < 0.5%.

Stroke is a feared complication after TAVR that occurs in 2% to 4% of cases. Most post-TAVR strokes occur within 5 days of TAVR and are related to manipulation of the native aortic valve, aortic arch, or aortic annulus. The risk of stroke after TAVR is similar between BEV and SEV and between femoral and nonfemoral access types.[18] Additionally, the rate of stroke after TAVR is similar to the rate of stroke in the SAVR arm of the PARTNER A trial and the SAVR arm of the CoreValve High Risk Study.[12,13] Embolic protection filter devices are currently under investigation as a way to mitigate the risk of stroke after TAVR, but these devices are not yet widely adopted for clinical use.

Paravalvular leak (PVL) after TAVR is a complication associated with increased long-term mortality. In a secondary analysis of the PARTNER trial,

patients with moderate/severe PVL after TAVR had a 35% mortality rate at 12 months compared with 22% mortality in patients with mild PVL and 16% mortality in patients with trace or no PVL (log-rank $P < 0.0001$).[19] In that study, moderate/severe PVL was an independent risk factor for all-cause 1-year mortality in a multivariate risk adjusted model. Risk factors for PVL include anatomic considerations that contribute to poor apposition of the TAVR valve with the aortic valve annulus (annulus geometry and calcification, left ventricular outflow tract–aorta angle), prosthesis undersizing, and poor valve position either too high or too low in the annulus. Although even moderate severity PVL is associated with increased mortality, the rate of significant PVL is now much less frequent with newer generation valves and increased operator experience (<5% with both the Edwards S3 valve and the Medtronic Evolut R).[20,21]

Conduction system disease is a common complication after TAVR due to the close proximity of the aortic valve annulus to the AV node and His bundle. Patients with high-grade AV block after TAVR often require critical care monitoring with a temporary pacemaker. New left bundle branch block is common after TAVR and is of uncertain clinical significance.[22] Conduction system disease requiring a new permanent pacemaker implantation within 30 days after TAVR occurs in 3% to 4% of patients treated with BEV and nearly 20% of patients treated with SEV in early trials.[1,12,16] However, pacemaker implantation rates are lower in next generation SEVs currently being tested in clinical trials.

Survival after TAVR is superior to survival among medically treated patients with severe AS and comparable to survival among SAVR in high-risk surgical patients. In large registries from the United States and Europe, mortality at 30 days after TAVR is 5% to 12% and 1-year survival is 76% to 85%.[10] TAVR valves appear to be durable without significant valve deterioration at follow-up intervals up to 5 years. Longer-term follow-up data are not widely available because of the relative youth of the procedure, although there is no evidence to date that TAVR valves are any less durable than SAVR bioprosthetic valves. This issue will merit careful scrutiny in the coming years as TAVR is tested in younger and lower-risk populations.

A recently recognized concern is the risk of leaflet thrombosis early after TAVR. During an ongoing clinical trial, a patient who suffered a post-TAVR stroke was noted to have reduced leaflet mobility of the TAVR valve by computed tomography (CT), which prompted concern that subclinical leaflet

thrombosis may be a risk factor for stroke after TAVR. In a subsequent retrospective analysis, reduced leaflet motion by CT was detected in up to 40% of patients after TAVR, although the clinical significance of this finding remains uncertain.[23] Interestingly, patients treated with therapeutic anticoagulation had return of normal leaflet motion suggesting that early anticoagulation after TAVR may reduce the risk of leaflet thrombosis. The role of anticoagulation in the post-TAVR setting is the topic of ongoing investigation in multiple clinical trials and registries.

BALLOON MITRAL VALVULOPLASTY

Severe mitral stenosis (MS) is characterized by mitral valve area < 1.5 cm^2, pressure half-time of ≥150 ms in diastole, a transmitral mean pressure gradient of > 5 to 10 mm Hg, and pulmonary hypertension by echocardiography.[11] The most common cause of hemodynamically significant MS is rheumatic heart disease. Calcific MS is increasingly recognized to be an import lesion in the United States.[24] In any event, MS is a far less common valvular lesion in the developed world compared with degenerative calcific AS. In the developing world, however, severe MS remains a prevalent cause of cardiovascular morbidity and mortality with over 15 million people affected with rheumatic heart disease annually.[25] Severe MS can be a challenging lesion to treat in the intensive care unit due to associated low cardiac output, pulmonary hypertension, pulmonary edema, and cardiogenic shock in severe cases. Additionally, patients with MS are often poorly tolerant of the increased chronotropy due to either endogenous catecholamine surge or pharmacologic therapy with chronotropic–inotropic medications. These patients often require correction of the valvular lesion to achieve cardiopulmonary stability.

Unlike BAV, percutaneous balloon mitral valvuloplasty (BMV), which was first introduced by Inoue in the 1980s, is effective and durable therapy for MS. BMV offers excellent long-term durability with survival free of cardiac death, repeat BMV, mitral valve surgery, or functional impairment of 69% at 7 years and 30% at 20 years.[26,27] Moreover, redo BMV can be performed with excellent safety and durability in patients with prior BMV who have restenosis of the mitral valve.[28,29] BMV can be safely performed with procedural mortality < 0.5% and severe mitral regurgitation in < 5% of cases.[25] In randomized

controlled trials, BMV has shown comparable rates of success and restenosis when compared with surgical commissurotomy.[30] Therefore, in the 2014 ACC/AHA guidelines on the management of valvular heart disease, BMV has a class I indication in patients with symptomatic severe MS and favorable valve morphology and a class IIa indication even in asymptomatic patients with very severe MS and favorable valve morphology for BMV.[11] These guidelines highlight the importance of patient selection by echocardiographic assessment of the mitral valve morphology. This assessment is typically performed using the Wilkins score, also termed the "splittability" score.[31] The Wilkins score incorporates echocardiographic assessment of four parameters (mitral valve leaflet mobility, leaflet thickness, leaflet calcification, and subvalvular chordal thickening), each graded on a scale of 1 to 4, creating an overall score ranging from 4 to 16. Patients with a Wilkins score ≤ 9 are most suitable for BMV, whereas those with a Wilkins score > 9 should be considered for mitral valve surgery. Contraindications for BMV include inadequate valve morphology for BMV, left atrial thrombus, severe mitral regurgitation (MR), or concomitant valvular disease or CAD that would favor open surgery over percutaneous therapy (severe tricuspid valve disease, severe aortic valve disease, or CAD necessitating bypass surgery).

During BMV, a 14 French venous sheath and a 5 French arterial sheath are placed in the femoral vessels. The procedure is performed via transseptal puncture across the interatrial septum, and the dumbbell-shaped Inoue balloon is advanced anterograde through the left atrium and across the mitral valve. The balloon is inflated from the distal (left ventricular) edge to the proximal (left atrial) edge with a designed waist in the middle portion with the aim of reducing the severity of MS by disrupting the mitral valve commissures.[30] A successful procedure is one in which the mitral valve area post-BMV is >1.5 cm^2 and the degree of MR is not more than mild.[32] Procedural complications of the BMV include cardiac perforation (up to 2%) and transient ischemic attack or stroke (2% to 3%).

PERCUTANEOUS MITRAL VALVE REPAIR

Mitral valve regurgitation is one of the most common valvular lesions encountered in the cardiac intensive care unit. The severity of MR is characterized by several echocardiographic parameters: it is considered severe in

the presence of a central MR jet > 40% of the left atrium, a holosystolic eccentric MR jet, a regurgitant volume of ≥ 60 mL, a regurgitant fraction ≥ 50%, a vena contracta ≥ 0.7 cm, and/or an effective regurgitant orifice of > 0.40 cm^2.[11] Degenerative MR (DMR), or "primary MR," is a lesion caused by valvular pathology (redundant and myxomatous leaflet tissue, endocarditis, rheumatic heart disease, and others) resulting in severe valvular regurgitation. In these patients, MR is often the primary cardiac pathology and symptoms of heart failure can be treated with successful valve repair or replacement. Additionally, observational data suggest improved survival with surgical repair compared with medical therapy in patients with severe symptomatic DMR. Contrary to DMR, functional MR (FMR) (also termed "secondary MR") is caused by failure of mitral valve leaflet coaptation due to annular dilatation or apical tethering of the subvalvular apparatus due to left ventricular enlargement. In these patients, MR is considered secondary to underlying myocardial dysfunction and treatments to improve cardiac symptoms require attention to both the MR and the underlying myocardial dysfunction. In FMR patients, surgery has not been shown to improve survival but has been used to palliate symptoms of heart failure in those who remain symptomatic despite optimal medical therapy. The role of mitral valve surgery in patients with FMR is controversial because it is not clear that the benefits of mitral valve surgery truly outweigh the risks.

Figure 39.3 depicts the decision algorithm for the interventional management of severe MR.

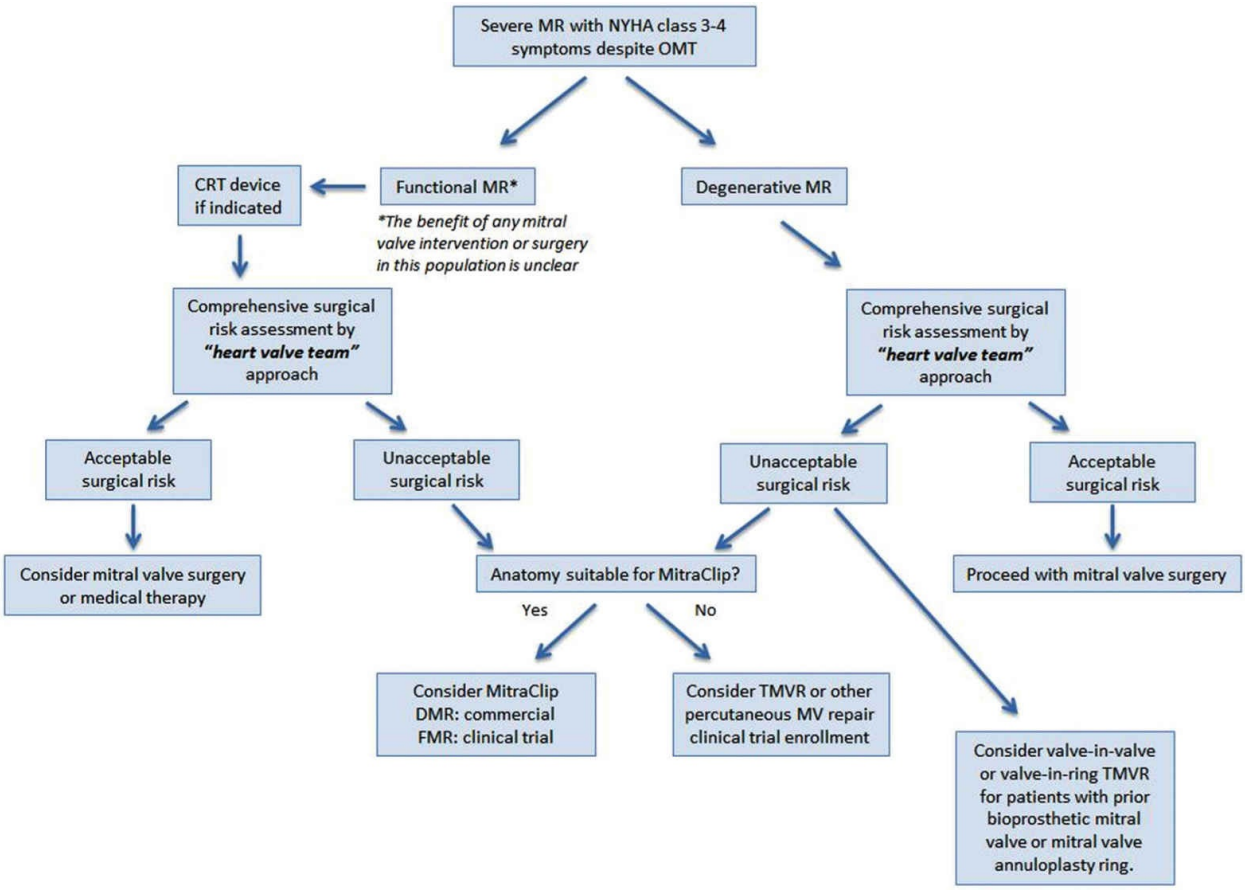

FIGURE 39.3 Decision algorithm for the interventional management of severe mitral regurgitation. CRT, cardiac resynchronization therapy; FMR, functional mitral regurgitation; MR, mitral regurgitation; NYHA, New York Heart Association; OMT, optimal medical therapy; TMVR, transcatheter mitral valve replacement.

A number of percutaneous devices for mitral valve repair have been or are currently under investigation, but the most widely adopted device is the MitraClip system (Abbott, Abbott Park, IL).[33] The MitraClip is a percutaneous approach that mimics the surgical Alfieri stitch first described in 1991. In the Alfieri stich procedure, a suture is placed between the medial scallops of the anterior and posterior mitral valve leaflets (A2 and P2 leaflets) creating a double-orifice mitral valve, which reduces the degree of MR. In the MitraClip procedure, a 24-French sheath is placed in the right femoral vein and the MitraClip device (cobalt–chromium metal alloy clip covered in polypropylene fabric) is advanced transseptally across the interatrial septum into the left atrium. Using transesophageal echocardiogram (TEE) guidance, the opened clip is positioned in the left ventricle and retracted to capture the mitral valve leaflets within the arms of the clip, and the clip is then closed (**Figure 39.4**). The degree

of MR and MS are assessed by TEE, and if the result is satisfactory the clip is released and left in place (**Figure 39.5**). The operator may reposition and regrasp the mitral valve leaflets up until the clip is released from the delivery system, but after the clip is released from the delivery system it cannot be repositioned. In about 40% of cases, two clips are needed to achieve a satisfactory result.[34]

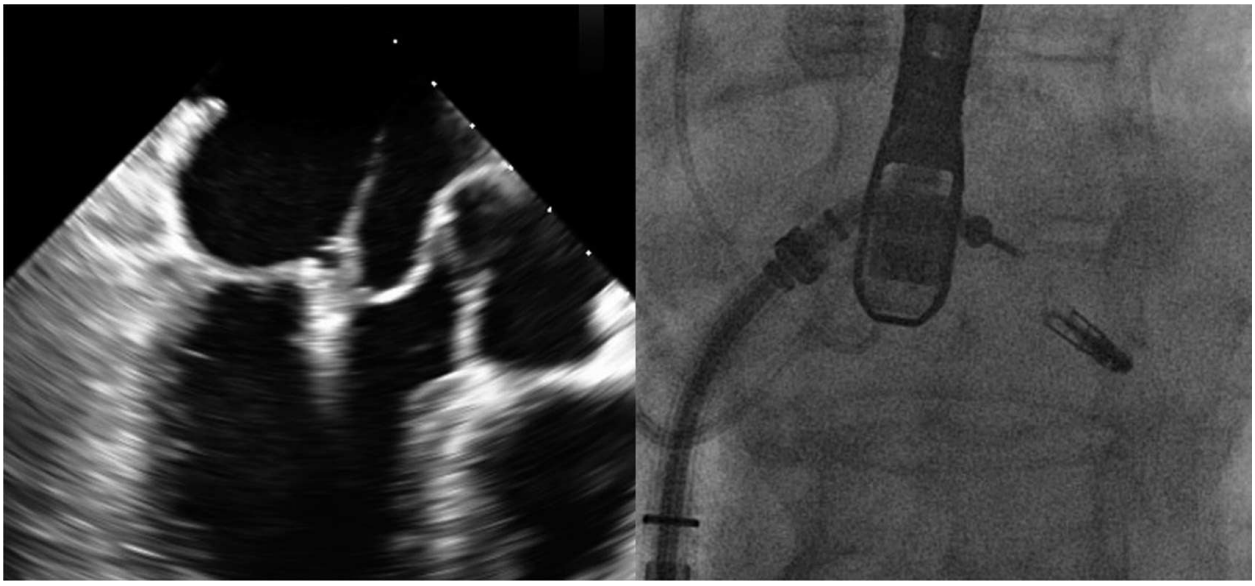

FIGURE 39.4 Echocardiography and fluoroscopy of the "MitraClip" percutaneous mitral valve repair device. Percutaneous mitral valve repair with the MitraClip device in the setting of heart failure due to severe mitral regurgitation from prolapse and flail of the posterior mitral valve leaflet. Left—Intraoperative transesophageal echo demonstrating the MitraClip device grasping the anterior and posterior leaflets of the mitral valve before deployment. Right—Fluoroscopy of the MitraClip device after deployment.

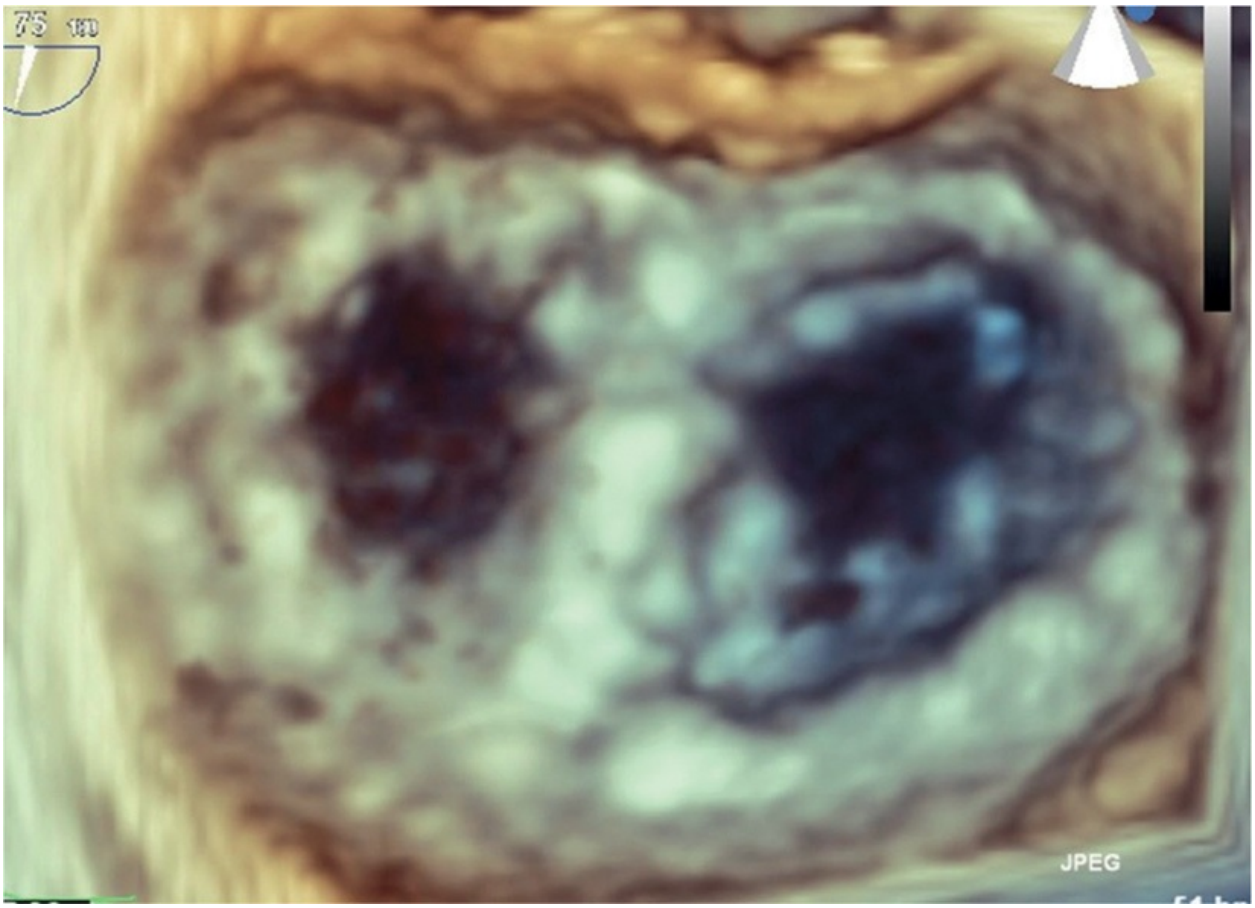

FIGURE 39.5 Three-dimensional echo of the mitral valve after percutaneous mitral valve repair with the MitraClip device. Intraoperative three-dimensional transesophageal echo of the mitral valve demonstrates the double orifice mitral valve resulting from successful percutaneous mitral valve repair with the MitraClip device.

The MitraClip is currently FDA approved in patients with severe symptomatic DMR who are deemed to have prohibitive risk to undergo mitral valve surgery. In the Endovascular Valve End-to-End Repair Study (EVEREST II), the MitraClip was compared to mitral valve surgery in 279 patients with a primary endpoint of death, mitral valve surgery, or 3+ or 4+ MR. All patients in that study were candidates for open heart surgery (inoperable patients were excluded) and most had DMR as opposed to FMR. The rate of the primary endpoint was 55% versus 73% ($P = 0.007$) at 12 months and 44% versus 64% ($P = 0.01$) in the MitraClip and surgery groups, respectively.[33,35] The difference in the primary endpoint was driven mainly by increased rates of mitral valve surgery in the MitraClip group, but mortality was comparable between arms and the rates of major adverse events were significantly lower in the MitraClip group at 12 months (15% vs 48%, $P < 0.001$). Importantly, the presence of the MitraClip did

not preclude future mitral valve surgery. The clip itself can be safely explanted during subsequent mitral valve surgery, and surgical mitral valve repair and replacement are options after MitraClip. Outcomes up to 4 years from the EVEREST II trial demonstrate equal survival in the MitraClip and surgery arms and equal rates of 3+ to 4+ MR in both arms.[36] Additionally, in the EVEREST II trial, successful MitraClip without significant residual MR was associated with improvements in quality of life and reductions in heart failure hospitalizations at 1-year follow-up in DMR patients.[37] Based on these data, the 2014 ACC/AHA guidelines give a class IIB recommendation that MitraClip may be considered in patients with severe symptomatic DMR who are not surgical candidates and have anatomy favorable for the MitraClip procedure.[11]

While the EVEREST II trial demonstrated the safety and efficacy of MitraClip in predominantly DMR patients with acceptable surgical risk, subsequent studies of the MitraClip in high-risk or inoperable patients including those with critical illness requiring inotrope therapy have demonstrated excellent procedural success rates, immediate hemodynamic improvements, and improvements in functional status.[25,38–43] Currently, the MitraClip is being compared to medical therapy in high-risk surgical patients with severe FMR and heart failure in both the Clinical Outcomes Assessment of the MitraClip Percutaneous Therapy for Extremely High Surgical-Risk Patients (COAPT) trial and the Randomized Study of the MitraClip Device of Heart Failure Patients with Clinically Significant Functional Mitral Regurgitation (RESHAPE-HF). As mentioned above, the role of mitral valve surgery is unclear in patients with severe FMR because there is no randomized controlled evidence of durable benefit from mitral valve surgery in these patients, and the ACC/AHA guidelines give only a class IIB recommendation that mitral valve surgery may be considered in this high-risk group.[11] The COAPT and RESHAPE-HF trials will offer important understanding of the potential benefit of mitral valve repair in high-risk surgical patients with heart failure and severe FMR.

Several other experimental percutaneous approaches to mitral valve repair are in development. Many of these other devices employ repair mechanisms distinct from the MitraClip system. For example, the Carillon device (Cardiac Dimensions, Kirkland, WA) uses an anchor mechanism placed in the coronary sinus to create an indirect percutaneous mitral valve annuloplasty while the Mitralign percutaneous annuloplasty system uses a retrograde approach across the aortic valve into the left ventricle to deliver an anchoring system directly into the mitral valve annulus from within the left ventricle. These and other devices

are currently being tested in clinical trials but have not been widely adopted in practice and remain beyond the scope of this chapter.[25,34,44]

TRANSCATHETER MITRAL VALVE REPLACEMENT

With the widespread adoption of TAVR over the past decade and its success in treating patients who were previously not candidates for AVR, there has been considerable interest in developing a transcatheter mitral valve replacement (TMVR) system. However, TMVR is far more technically challenging than TAVR for several reasons including higher-risk patient groups, larger and asymmetric valve annulus, complex subvalvular apparatus, and lack of annular calcium in many patients with severe MR that poses challenges for device anchoring. There are several TMVR devices currently in development, but these are only available in select centers on an experimental basis. Most devices were not attempted in humans until 2014 and the worldwide experience with these devices is very small to date.[25] While MitraClip and other transcatheter mitral valve repair devices can be successfully performed via a percutaneous approach, TMVR devices to date require a surgical approach with a transatrial or transapical exposure to the mitral valve. In highly selected cases of bioprosthetic mitral valve stenosis, there have been reports of placement of a TAVR device in the mitral position in a so-called valve-in-valve TMVR.[45] These valve-in-valve TMVRs have been performed with a percutaneous transseptal approach as well.[46]

TRANSCATHETER TRICUSPID VALVE INTERVENTION

Severe tricuspid regurgitation (TR) poses multiple therapeutic challenges. Most cases of severe TR are secondary to either primary right ventricular dysfunction or end-stage left-sided heart failure. Severe TR is a well-established independent risk factor for increased mortality, but the optimal treatment of severe TR remains a clinical conundrum. These patients are often quite ill and have manifestations of right-sided heart failure with peripheral edema, ascites, and congestive hepatopathy. Isolated surgical tricuspid valve repair or replacement is seldom performed due to very poor durability and outcomes in this population.[47]

There are several devices in development for transcatheter tricuspid valve

repair, but none of these is available outside of early clinical trials. A variety of mechanisms has been tested including annuloplasty systems like the aforementioned Mitralign device, direct anchor-based annuloplasty systems, and transvalvular spacing devices that anchor in the right ventricular apex. However, in-human experience with each of these devices is very small and no device appears to be close to widespread clinical use.[25,48]

Transcatheter tricuspid valve replacement has also been attempted, but most in-human experience with transcatheter tricuspid valve replacement involves valve-in-valve or valve-in-ring placement of a TAVR device or pulmonic valve device within a prior failed tricuspid bioprosthesis or tricuspid annuloplasty. Such valve-in-valve and valve-in-ring procedures are rare and only described in small case reports and series.[49–51] Transcatheter tricuspid valve replacement of a native tricuspid valve poses challenges given the ability of the tricuspid valve annulus to severely dilate under conditions of right ventricular failure. No such device is currently close to clinical use. Some centers have used "heterotropic" placement of a transcatheter valve (typically a TAVR device) in the superior and inferior vena cava to alleviate symptoms of severe TR as a palliative measure, but outcomes of this approach are limited to small observational series.[52,53]

TRANSCATHETER PULMONIC VALVE REPLACEMENT

Pulmonary valve disease is exceedingly rare in adult cardiology. Adult survivors of childhood congenital heart disease will occasionally present with pulmonic valve disease in adulthood. Those who have undergone a prior Ross procedure (replacement of the aortic valve with the patient's own pulmonary valve "autograft" and placement of a new pulmonary allograft valve) may present with a failing pulmonary bioprosthesis. Patients with repaired tetralogy of Fallot may present with stenosis or regurgitation of the reconstructed right ventricular outflow conduit. Infective endocarditis and rheumatic disease rarely affect the pulmonic valve. Other rare causes of pulmonary valve disease in adulthood include obstructive lesions due to cardiac masses or vegetation.[11]

In patients with a transpulmonary gradient > 50 mm Hg, balloon pulmonary valvuloplasty is indicated with serial balloon dilation of the pulmonic valve.[25] The maximum balloon to valve annulus ratio recommended is 1.4:1 to avoid subsequent pulmonic regurgitation. Unlike BAV, this procedure has durable efficacy with low rates of restenosis on long-term follow-up.[25,54] However, in

patients with stenotic pulmonary bioprostheses or prior conduits, pulmonic valve replacement is often required rather than balloon valvuloplasty because balloon valvuloplasty does not have durable efficacy in this setting as it does in native pulmonary valve stenosis. Cases of severe pulmonary regurgitation with right ventricular enlargement or dysfunction may also warrant pulmonary valve replacement.[25] Transcatheter pulmonary valve replacement can be performed safely and effectively with the balloon-expandable Melody pulmonary valve system or with an Edwards Sapien TAVR system.

FUTURE DIRECTION

Severe valvular heart disease is commonly encountered in the critical care setting, and the management of these patients often involves an interventional or surgical approach to achieve satisfactory long-term results. For over three decades, the only percutaneous option to treat valvular heart disease among inoperable patients was balloon valvuloplasty, but in modern practice the number of percutaneous therapies is rapidly expanding. Goals of the next generation of percutaneous devices include developing smaller profiles to expand treatment to more patients, and to reduce vascular and bleeding complications. Adjunctive therapies like embolic filter protection devices to mitigate the risk of stroke are also under ongoing clinical trial investigation. In the TAVR arena, novel devices are in development with anchoring mechanisms for patients with primary aortic regurgitation and little to no aortic annular calcium. Additionally, the adoption of TAVR in low- and intermediate-risk populations remains an area of active investigation and future promise. In the field of percutaneous mitral valve repair, the coming years will demonstrate whether this technology can improve outcomes among patients with congestive heart failure due to severe FMR. Moreover, the relatively young fields of tricuspid valve intervention and percutaneous mitral valve replacement promise substantial growth and maturation over the coming decade with several experimental devices in development in both these arenas.

Patient and Family Information: PERCUTANEOUS THERAPY FOR VALVULAR HEART DISEASE

INTRODUCTION

The heart is a highly complex organ involving multiple systems that work together, such as the coronary arteries that supply blood flow to the heart muscle, the electrical system that coordinates each heartbeat, and the heart muscle that pumps the blood through the body. The valves of the heart are like doors between the chambers of the heart. There are four heart valves (tricuspid, pulmonic, mitral, and aortic) with two primary roles: (1) to allow blood to pass from one chamber to the next at the right time during the heartbeat; and (2) to prevent blood from flowing backward within the heart and lungs. Valvular heart disease occurs when either of these two roles of the heart valve is compromised. A valve that does not allow blood to flow forward is called “stenotic” or narrowed, whereas a valve that allows excessive amounts of blood to flow backward is called “regurgitant” or leaky. Valves with severe stenosis or regurgitation (or both) cause heart failure due to weakening of the heart muscle and fluid buildup within the heart and lungs.

SIGNS, SYMPTOMS, AND EVALUATION

Valvular heart disease can present differently in different patients. Some patients remain asymptomatic despite severe valvular heart disease, while other patients may have symptoms of chest pain, shortness of breath, passing out, or even shock. The severity of symptoms depends on how long the valvular heart disease

has been present and how well the body is able to compensate. Your doctor may find a heart murmur, engorged neck veins, fluid in the lungs, or swelling in the abdomen or legs. However, it is important to realize that some patients will have very few physical signs and symptoms of valvular heart disease and, on the contrary, not all patients with a heart murmur have severe valvular heart disease. An echocardiogram, which is an ultrasound study of the heart, is needed to study the heart valves in detail. The echocardiogram provides information on the severity of valve stenosis and regurgitation as well as the overall heart size and muscle function. In many patients, an invasive echocardiogram in which the ultrasound probe is passed into the esophagus (transesophageal echocardiogram or TEE) is needed to adequately study the heart valves. Since the ultrasound probe can be placed in closer proximity to your heart with this method, the images obtained will better elucidate the functionality of your heart valves as if having a closer look.

MEDICAL TREATMENT

Some patients with valvular heart disease can be successfully treated with medications alone. The usual goal of medical treatment is to reduce fluid buildup with diuretics (“water pills”). However, medicines cannot reverse or cure valvular heart disease in most cases. Treatment of high blood pressure and other underlying heart conditions such as CAD and arrhythmias can also help the heart valve function and to reduce symptoms because the various systems of the heart all work in concert with each other. In patients with severe valvular heart disease who have symptoms despite medications, a procedure to correct the valve problem may be needed.

HEART SURGERY

A cardiac surgeon can repair or replace a diseased heart valve in patients who can safely undergo the operation without excessive risk. In the hands of an experienced cardiac surgeon, valve repair and replacement can be performed safely and with outstanding long-term improvements in symptoms. When valve replacement is performed, either a tissue valve or a mechanical valve may be selected on the basis of a discussion between the patient and surgeon after

weighing the pros and cons in each case. In some forms of valvular heart disease, heart surgery is a lifesaving procedure. However, in other patients, heart surgery carries a very high risk of complications such as major bleeding, stroke, heart attack, or death. Risk factors for heart surgery complications include weak heart function, advanced age, prior heart or chest surgery, prior chest radiation, obesity, and severe disease of other organs such as the lungs, kidney, or liver. For patients in whom heart surgery carries an unacceptable risk of a major complication, the only option may be a less invasive procedure.

PERCUTANEOUS INTERVENTION

In select patients, a cardiologist and cardiac surgeon can perform a percutaneous valve procedure. Percutaneous means that the procedure can be performed through the blood vessels by a small puncture made through the skin, so open heart surgery is not needed. Not everyone is a candidate for this type of procedure due to certain factors related to each patient's anatomy and the valve involved. Your doctor may perform testing including echocardiogram, CT scan, MRI, or heart catheterization to determine whether a percutaneous intervention will be possible. In most centers, a heart valve team including imaging cardiologists, interventional cardiologists, cardiac surgeons, nurses, and coordinators will review each case to determine whether a percutaneous heart valve procedure is possible. Currently, percutaneous interventions are commonly used for AVR and mitral valve repair. In select centers, other valve procedures such as pulmonic valve replacement, mitral valve replacement, tricuspid valve repair, and tricuspid valve replacement may be possible. Additionally, balloon valvuloplasty, which is a procedure in which a stenotic valve is opened with a balloon but the valve is not repaired or replaced, is widely available in many centers and has been used for over three decades. Percutaneous valve procedures usually have a lower risk of major complications compared with heart surgery, and may be a better option for patients who cannot undergo heart surgery due to the risk of the procedure.

WHAT TO EXPECT

Percutaneous valve procedures are typically performed in an operating room or a

cardiac catheterization suite. Some percutaneous valve procedures require general anesthesia while others can be performed safely with mild sedation. A TEE may be used during the procedure to help the physician performing the procedure visualize the valve in real time. Most, but not all, percutaneous valve procedures are performed by puncture of the artery and/or vein in the groin area. The doctor will place a sheath, which is a tube through which equipment can be passed, in the groin vessels using a needle and a thin wire as a guide. The sheath can range anywhere from 5 mm in diameter to almost 9 mm in diameter. Multiple sheaths may be used for one procedure. Some valve procedures require the placement of a temporary pacemaker during and/or immediately after the procedure. These procedures usually take 1 to 2 hours. Most patients who do require general anesthesia can have the endotracheal breathing tube removed at the end of the procedure. The puncture site in the leg is repaired with sutures and several hours of bedrest are often needed immediately following the procedure to prevent bleeding complications at the puncture site. A 3- to 5-day hospital stay is common after a percutaneous procedure and varies depending on each patient’s unique needs. After a percutaneous aortic valve replacement, some patients require placement of a permanent pacemaker. A few patients, especially elderly adults, may require a short stay in rehabilitation after a valve procedure, but most patients are discharged home directly. Serious procedural complications include heart attack, stroke, death, or need for an emergency surgery. Each of these complications arise in typically < 5% of cases. More common complications include bleeding or injury to a blood vessel that may require a surgical repair afterward.

Contemporary Surgical Approach to Valvular Disease

AORTIC VALVE SURGERY

PATHOPHYSIOLOGY OF AORTIC STENOSIS

Morphology

Calcium is deposited in the collagen framework of abnormal leaflets due to the shear stresses occurring with each cardiac contraction. Eventually, the aortic valve becomes a lumpy, rigid structure with a tiny orifice, with calcification extending down the membranous septum and over the ventricular surface of the anterior mitral valve leaflet. Approximately 1% to 2% of people have a congenitally bicuspid aortic valve (right and left cusp fusion is present in more than 80% of patients with bicuspid valves).[1] Shear stresses in bicuspid valves are greater and they tend to calcify decades earlier than trileaflet valves. Rheumatic disease causes fibrous leaflet thickening, rolled leaflet edges, and fusion of commissures, and eventually also results in accelerated calcific changes.

Structural and Functional Changes

The average decrease in the stenotic aortic valve is 0.1 cm^2/y. This occurs faster in degenerative and bicuspid stenosis than in rheumatic stenosis.[1] Major

hemodynamic compromise does not occur until the valve is reduced to less than half the normal aortic valve area of 3 to 4 cm^2; beyond this, left ventricular (LV) outlet obstruction rapidly increases.[2] Turbulent flow in the ascending aorta may cause poststenotic dilatation. The left ventricle hypertrophies in response to outlet obstruction. The number of myocytes is fixed: hypertrophy is an increase in myofibrils, causing existing myocytes to become thicker. Concentric hypertrophy occurs in response to pressure overload seen in aortic stenosis (AS); and eccentric hypertrophy occurs in response to volume overload, for example, aortic insufficiency (AI). Concentric hypertrophy maintains ventricular volume. There is also an increase in interstitial collagen, but not much fibrosis. Initially hypertrophy (increase in LV mass from 150 g to up to 300 g) allows generation of the high interventricular pressures required to maintain LV ejection fraction and cardiac output through the stenotic lesion, despite gradients > 100 mm Hg: this is compensated AS. Eventually, hypertrophy cannot compensate for increased wall stress, and the left ventricle thins, dilates, and ejection fraction falls: this is low-gradient low-ejection fraction (also known as low-gradient low-flow) AS.

Systolic Function

In compensated AS, ejection fraction is preserved. Decompensated AS (low gradient, low flow) occurs when systolic function declines as a result of chronic afterload mismatch. The transvalvular gradient falls because cardiac output decreases, even though the valve stenosis is unchanged or worse.[2,3]

Diastolic Function

Diastole has an energy-dependent and a passive component. The passive component depends on normal compliance: this is often reduced in AS. The time required for the energy-dependent phase is greater because of impaired myocardial relaxation and decreased chamber compliance. LV end diastolic pressure is increased, eventually reducing diastolic coronary flow. Adequate LV filling is very dependent on the “atrial kick” supplied by synchronized atrial contraction and controlled heart rate.

Patients may exhibit symptoms of diastolic failure with paroxysmal nocturnal dyspnea, orthopnea, and pulmonary edema even with normal ejection fraction, and decompensate if they go into atrial fibrillation. Diastolic dysfunction may take months to years to improve after surgery and may not improve if patients

are left with a significant gradient across the prosthetic valve.[2,3]

Coronary Blood Flow

In AS, the myocardial oxygen supply–demand mismatch causes angina even in patients with normal coronary arteries. This is due to increased muscle mass, which results in increased myocardial oxygen demand. This eventually outpaces compensatory increase in blood flow resulting in lower coronary blood flow per 100 g of myocardium. The increased LV end diastolic pressure reduces coronary perfusion during diastole. Increased systolic time reduces diastolic filling time. Additionally coronary vasodilatory reserve results in decreased coronary flow in exercise.

Clinical Findings in Aortic Stenosis

Patients may be asymptomatic. Most present with any of the triad of angina, exertional syncope, and dyspnea. There is a 5% incidence of sudden death. Symptom onset is closely related to survival. Clinical findings include a slow, rising, low-amplitude pulse, occasionally with a thrill at the carotids; a sustained apex beat; a soft first heart sound, sometimes preceded by fourth heart sound; a single heart sound if valve is calcified; an ejection systolic murmur radiating from the aortic area to the right carotid; and a soft early diastolic murmur due to AI while leaflets become immobile.

PATHOPHYSIOLOGY OF AORTIC INSUFFICIENCY

Morphology

Pathology of any of the components of the aortic root can prevent leaflet coaptation leading to AI. In developing countries, rheumatic disease causes leaflet thickening and shortening. The main cause of AI in developed countries is annular dilatation, for example, annuloaortic ectasia caused by cystic medial dilatation associated with connective tissue disorders such as Marfan disease, or type A aortic dissection. AI may also be caused by endocarditis resulting in leaflet destruction, and calcification resulting in leaflet mobility.

Structural and Functional Changes

Acute Aortic Insufficiency

Acute AI is most commonly caused by endocarditis, aortic dissection, and

trauma. Acute severe AI is usually a surgical emergency. This is because there is no time for any of the adaptive changes that characterize chronic AI to develop and the sudden volume overload results in pulmonary edema while the filling pressure increases in a noncompliant ventricle. Reduced coronary blood flow, low cardiac output, and hypoxia due to acute pulmonary results in end-organ ischemia.[2]

Chronic Aortic Insufficiency

Chronic AI is better tolerated than acute partly because of the following adaptive and maladaptive changes. AI leads to both volume overload, because of the regurgitant fraction, and pressure overload, because of the increased volume of blood ejected. Volume overload causes eccentric hypertrophy and LV dilatation. Pressure overload results in concentric hypertrophy: the same increase in myofibrils and interstitial collagen described in AS occurs in AI. Ventricular enlargement produces a larger total stroke volume (up to 10 L/min), all of which enters the aorta during systole: this is compensated AI and the resultant increase in pulse pressure causes systemic hypertension and a large increase in LV afterload. LV compliance decreases and diastolic function is compromised as hypertrophy progresses. Eventually LV end diastolic pressures and left atrial pressures begin to increase: pulmonary hypertension and congestive cardiac failure is a feature of decompensated AI as well as acute AI. Finally, as myocytes are stretched beyond their limit of effective contraction, LV systolic function decreases, and the rate of increased LV end systolic diameter accelerates to about 7 mm/y. Coronary perfusion may be reduced for the same reasons as in AS.

Clinical Findings in Aortic Regurgitation

Acute AI is characterized by cardiovascular collapse and the symptoms of pulmonary edema. Chronic AI is usually asymptomatic until LV function is significantly impaired. Symptoms eventually include angina (because of myocardial oxygen supply–demand mismatch caused by the combination of increased oxygen consumption due to ventricular hypertrophy and contractility, and decreased coronary reserve caused by the fall in diastolic pressure gradient between the aorta and left ventricle), effort dyspnea, and the symptoms of congestive cardiac failure. Fatigue may predominate.

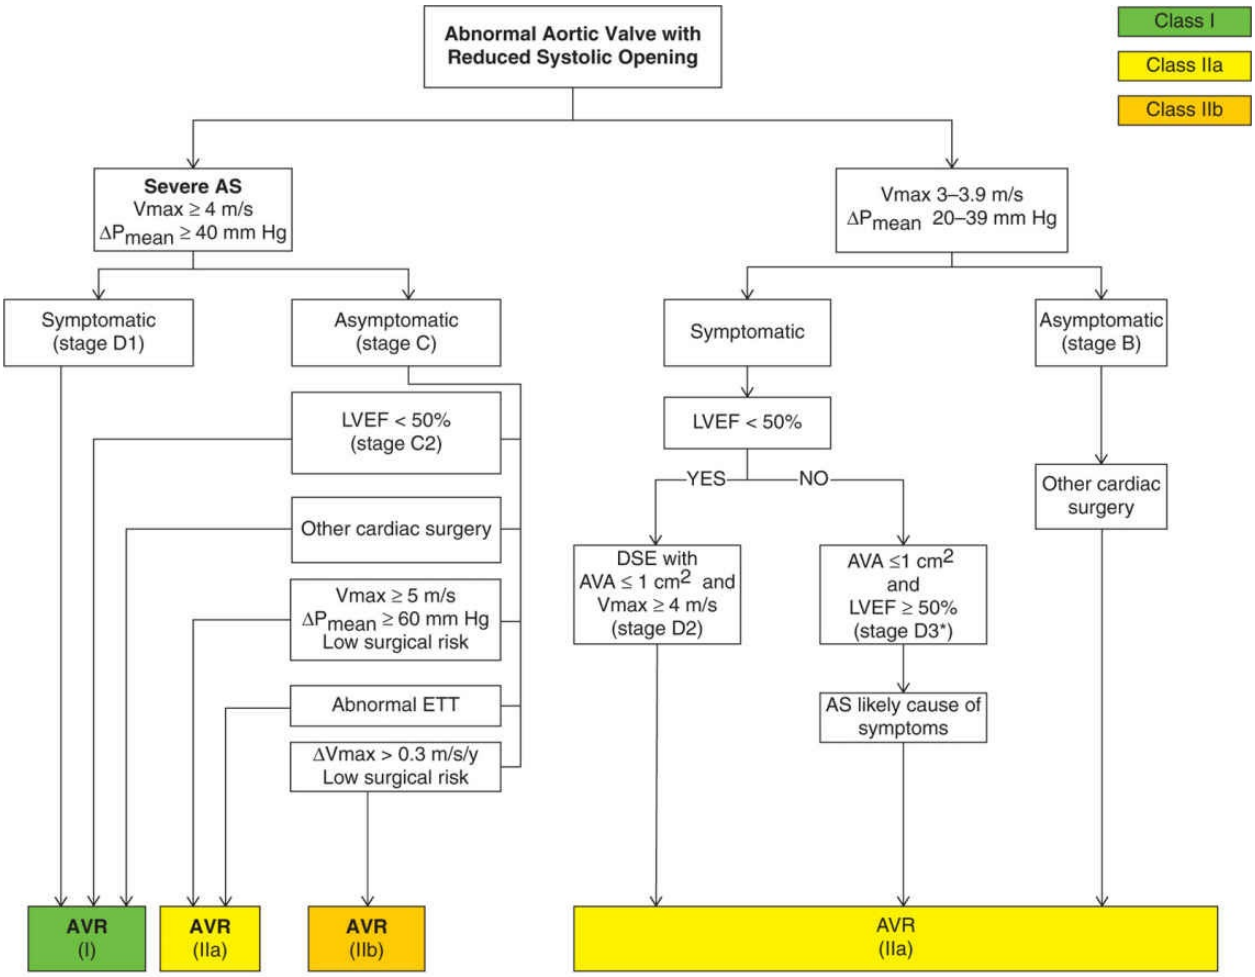
Clinical signs include a large-amplitude collapsing or “water-hammer” pulse

with a rapid upstroke; Quincke sign (capillary pulsation visible in the nail bed); Corrigan sign (visible pulsation in the neck); de Musset sign (head nodding as a result of arterial pulsation); Duroziez sign ("pistol-shot" femorals); a sustained, laterally displaced apex beat; a single second heart sound, with third heart sound; an early diastolic murmur maximal at lower left sternal edge radiating to the apex and axilla; an ejection systolic murmur may be present as well as a late diastolic murmur (Austin Flint) from fluttering of the anterior mitral leaflet as it is hit by the regurgitant jet.[2,3]

Indications for Aortic Valve Surgery

Severe AS may be defined as an aortic valve area < 1 cm^2. If the mean transvalvular gradient is over 40 mm Hg, then stenosis is severe, but severe AS may be present at lower gradients if the patient has poor LV function (see the above description of low-gradient low-flow AS).

The presence of symptoms or LV systolic dysfunction are both class I indications for aortic valve replacement in both AS and AI (**Figures 40.1 and 40.2**).



Arrow show the decision pathways that result in a recommendation for AVR. Periodic monitoring is indicated for all patients in whom AVR is not yet indicated, including those with asymptomatic AS (stage D or C) and those with low-gradients AS (stage D2 or D3) who do not meet the criteria for intervention.

*AVR should be considered with stage D3 As only if valve obstruction is the most likely cause of symptoms, stroke volume index <35 mL/m^2, indexed AVA is ≤0.6cm^2/m^2, and data are recorded when the patient is normotensive (systolic BP 140 mm Hg).

As indicates aortic stenosis; AVA; aortic valve area; AVR, aortic valve replacement by either surgical or transcatheter approach; BP, blood pressure; DSE, doubtamine stress echocardiography; ETT, exercise tredmill test; LVEF, left ventricular ejection fraction ΔP_{mean}, mean pressure gradient; and V_{max}, maximum velocity.

Indications for Aortic Valve Surgery

Class I indications for aortic valve replacement in AS[1]:

- Symptomatic severe AS (aortic valve area < 1.0 cm^2 or mean gradient > 40 mm Hg);
- Patients with moderate AS undergoing other cardiac surgery;
- Asymptomatic patients with severe AS and LV systolic dysfunction.

Class IIb indications for aortic valve replacement in AS:

- Asymptomatic AS and abnormal response to exercise (eg, hypotension,

symptoms), or aortic valve area < 0.6 cm^2/mean gradient > 60 mm Hg if low surgical risk, or calcification/coronary disease implying rapid progression risk.

Class I indications for aortic valve replacement in AI:

- Acute severe AI, symptomatic severe AI;
- Severe AI undergoing coronary artery bypass grafting or other valve surgery;
- Severe asymptomatic AI and EF <50%

Class IIa indications for aortic valve replacement in AI:

- Severe AI and LV end systolic diameter > 50 mm or LV end diastolic diameter > 65 mm

Class IIb indications for aortic valve replacement in AI:

- Severe AI with normal ejection fraction and LV end systolic diameter > 50 mm or LV end diastolic diameter > 65 mm and progressive dilatation or declining exercise tolerance;
- Indications for aortic valve replacement in endocarditis;
- Endocarditis and severe AI or AS resulting in heart failure, heart block, annular abscess, destructive penetrating lesion (class I); recurrent emboli and vegetation despite appropriate antibiotics, fungal or other virulent organism (class IIa), or large, mobile vegetation > 10 mm (class IIb).

Symptomatic Aortic Stenosis

The onset of symptoms in patients with AS is a poor prognostic sign. There is a 5% incidence of sudden death per year. Symptoms are most likely because it is as if the aortic valve area is <1 cm^2 or the transvalvular mean gradient is >40 mm Hg, and symptom onset in these patients mandates prompt aortic valve replacement in all except very high-risk cases.[2,3]

Low-Gradient Low-Ejection Fraction (Low-Flow) Aortic Stenosis

There are three main subgroups of symptomatic AS patients with transvalvular gradients of <40 mm Hg. Dobutamine infusion during echo or cardiac catheterization can help stratify patients. If cardiac output and transvalvular gradient increase in response to dobutamine, it suggests there is a true flow-

limiting lesion in the setting of reversible ventricular dysfunction: surgery would be beneficial although at higher risk than in patients with normal LV function. In the irreversibly damaged left ventricle, there is little or no increase in transvalvular flow in response to inotropes, and lack of contractile reserve: these patients present with high postoperative mortality and worse survival. Finally, in patients with severe cardiomyopathy due to nonvalvular cause, with only moderate or mild AS, the aortic valve area increases during dobutamine stress testing. These patients derive minimal benefit from surgery.[2]

Asymptomatic Aortic Stenosis

Most asymptomatic patients with severe AS have near-normal life expectancy without aortic valve replacement. Their 1% to 2% incidence of sudden death is less than the mortality of aortic valve replacement (which is approximately 2% overall in the United States), making it crucial to select only those patients at high risk of sudden death without surgery. Two techniques are employed: echocardiography and exercise testing. Asymptomatic patients with a peak transvalvular gradient > 64 mm Hg have an 80% chance of becoming symptomatic within 2 years (hence surgery in these patients has an ACC/AHA IIb indication if surgery is likely to be low risk). Exercise testing is safe in asymptomatic patients, and can identify the presence of exercise-induced hemodynamic compromise, which is an ACC/AHA IIb indication for aortic valve replacement. The natural history of AS in asymptomatic patients with a positive exercise test is probably very similar to that of patients with exertional symptoms.

Aortic Insufficiency

Acute severe AI is a surgical emergency because of the potentially immediately life-threatening sequelae of pulmonary edema and coronary ischemia described earlier. In infective endocarditis with lesser degrees of AI, the indications for early operation are annular abscess formation, new heart block, or evidence of heart failure. In patients who develop chronic severe AI, it may be 10 years before symptoms become severe because of the adaptive changes described earlier. The prognosis during this period is good: severe chronic AI with preserved ejection fraction has an 80% 5-year survival. Surgery should take place before permanent LV dysfunction ensues: so surgery is often indicated in asymptomatic patients. Progressive LV enlargement or decreasing ejection

fraction usually precedes the onset of symptoms and decompensation. Aortic valve replacement should therefore be carried out before the LV ejection fraction falls below 50%, the LV end systolic diameter increases to >55 mm, or the LV end diastolic diameter increases to >70 mm.

Special Considerations

Elderly and High-Risk Patients

The life expectancy of octogenarians without significant comorbidity can be more than 10 years. Aortic valve replacement in selected octogenarians has <3% operative mortality and results in improved quality and length of life in patients with symptomatic AS. These patients, and younger patients adjudicated high risk, are increasingly seen as candidates for transcatheter aortic valve replacement, which in the United States is approved for use in patients with a Society of Thoracic Surgeons predicted operative mortality score of >3% (intermediate and high risk), with severe trileaflet, calcific AS.

Patient Prosthesis Mismatch

The postoperative gradient across a prosthetic aortic valve depends on the valve size and cardiac output: it is higher in small valves, large patients, anemia, fluid overload, tachycardia, and hyperdynamic left ventricles (which is why β-blockers are sometimes used to address high postoperative transvalvular gradients). Postoperative gradients 20 to 30 mm Hg are very common particularly with bioprosthetic valves, and common practice is to try to minimize a postoperative gradient by implanting the largest prosthesis that will fit in the patient's aortic annulus (AA), and not implanting a prosthesis "too small" for the patient's size. How small is "too small" is quantified by Patient Prosthesis Mismatch (PPM), defined as Indexed Effective Orifice Area (IEOA) < 0.85 cm^2/m^2.[4–8] There are, however, no strong data to show difference in survival or symptoms according to whether patients have PPM because the data are dominated by observational studies that are prone to selection bias, primarily because PPM tends to occur in patients with other risk factors for worse outcomes (females, obese, older patients).

There are several options to avoid a high transvalvular gradient after aortic valve replacement in a patient at risk for this because of a small aortic root. The theoretical long-term benefits of minimizing the residual transaortic gradient must be weighed against the incremental operative risks posed to the patient:

occlusion of either coronary ostia or annular rupture due to placing an oversized prosthesis is associated with very high morbidity and mortality. Aortic root enlargement is associated with an incremental 2% to 3% risk of operative mortality in observational series, and national mortality for aortic root replacement is 7% to 10%, compared with 2% for aortic valve replacement.[9,10]

Planning before surgery may identify the potential problem in advance, allowing other modalities to be considered. For example, an annular diameter < 20 mm on preoperative echo is likely to take only a 19-mm valve. If the patient is very active or large, has diastolic dysfunction, or low-gradient low-ejection fraction AS, a 19-mm aortic valve is unlikely to be suitable. Options include transcatheter aortic valve replacement, which allows a prosthesis with a larger effective orifice area to be placed. Sutureless valves also appear to have better characteristics in this regard. Alternatively, mechanical valves have superior hemodynamics for given size, which requires a careful discussion before surgery with the patient given the need for lifelong anticoagulation and incremental risk of stroke and major bleeding events. Surgical approaches in increasing order of complexity and operative risks include stentless valves, aortic root enlargement, and aortic root replacement.

Valve Sparing Procedures

There are a large number of procedures described for patients with morphologically normal aortic valves, but with aortic regurgitation caused by pathology affecting the sinotubular junction (STJ) or the aortic annulus (AA). In patients with severe AI, a normal STJ, and normal AA, a Dacron tube graft approximately 10% smaller than the diameter of the AA is scalloped into tailored flaps that are used to recreate the sinuses of Valsalva. It is necessary to reimplant the coronary arteries. Alternatively, tailored flaps are omitted and the valve is simply resuspended within the Dacron tube, restoring valvular competency. In patients with a normal AA but dilated STJ, which occurs in patients with chronic hypertension, poststenotic dilatation and type A dissection, a simple interposition style graft can be placed, with or without a band of PTFE (Polytetrafluoroethylene) for additional support at the level of the STJ. It is not necessary to reimplant the coronaries. In patients where both AA and STJ are enlarged due to annuloaortic ectasia that can be caused by connective tissue disorders such as Marfan syndrome, AI can be treated by valve-sparing root remodeling. A number of modifications to procedures originally separately described by Magdi Yacoub and Tirone David exist. The main principles of

valve-sparing surgery in Marfan disease involve implanting a Dacron graft at the annulus. The sinus aorta is attached to the inside of the Dacron graft, with reimplantation of the coronary ostia.

Surgical Approaches

Transcatheter aortic valve replacement is described in Chapter 39, and is increasingly the procedure of choice for intermediate and high-risk patients.[11] Surgical aortic valve replacement is most commonly performed via a sternotomy or an upper hemisternotomy, which allows the incision to be 6 to 7 cm in length. Occasionally anatomy is amenable to a minithoracotomy approach, which allows a 6-to-7-cm incision via an intercostal space. The aim of smaller incisions is to limit the impact of surgery on postoperative respiratory function, pain control, bleeding and transfusion requirement, and to improve cosmesis. Cannulation for cardiopulmonary bypass is usually performed via the ascending aorta and right atrium; however femoral cannulation may be used to facilitate smaller incisions. Retrograde flow from femoral arterial cannulation is associated with higher rates of stroke in elderly patients and those with atheromatous vasculature.

Results of Aortic Valve Surgery

Early Mortality

In an analysis of 141,905 isolated valve procedures in a U.S. national database, unadjusted mortality was 1.4% for patients adjudicated “low risk” with a Society of Thoracic Surgeons predicted operative mortality score (STS-PROM) score of <4%; 5.24% in patients adjudicated intermediate risk (STS PROMO score 4% to 8%) and 11.2% in patients adjudicated high risk with an STS PROM score > 8%.[12] The biggest risk factors for operative mortality are emergency presentation, advanced age, multiple valve surgery, coronary artery disease, aortic root pathology, and endocarditis. Results have improved over recent decades despite sicker patient profiles. Most early deaths are related to cardiogenic shock, stroke, and hemorrhage. The higher mortality observed in patients undergoing bioprosthetic compared with mechanical aortic valve replacement is related to their higher preoperative comorbidity, including greater age.

Late Mortality

Overall survival (including hospital deaths) after aortic valve replacement is

approximately 75% at 5 years, 60% at 10 years, and 40% at 15 years, depending on the patient's age and comorbid conditions. Type of prosthesis (mechanical versus bioprosthetic valve) has not been shown to have an impact on survival. Although patients with bioprosthetic valves have significantly worse unadjusted survival curves than patients with mechanical valves, as with early mortality, this reflects the greater age and comorbidity of this group at baseline. Survival can be described in terms of hazard phases: the early, rapidly declining hazard phase (short-term survival) is dominated by perioperative mortality. It gives way to a phase about 6 months after operation (intermediate-term survival) where the death rate remains steady at approximately 2% per annum. This begins to rise steadily after 5 years (late-term survival). Other risk factors for late mortality include advanced age at operation (30-day mortality 1% in patients aged 40 to 50 years compared with >3% in patients aged > 80 years). Additional risk factors for operative mortality include worse New York Heart Association (NYHA) class, LV enlargement, atrial fibrillation, the number of previous aortic valve replacements, coexisting coronary artery disease, aneurysm, or LV structural abnormality.

Complications of Aortic Valve Replacement

The complications of cardiac surgery in general include reexploration for bleeding or tamponade (2%), perioperative myocardial infarction (1%), deep sternal wound infection (1%), prolonged mechanical ventilation (2%), and organ dysfunction (5%). Complications particularly associated with aortic valve replacement are as follows:

COMPLETE HEART BLOCK

Permanent pacemakers are inserted for permanent complete heart block in about 5% of aortic valve replacement patients. Complete heart block results from trauma to the bundle of His after extensive debridement of calcium from the junction of the right and noncoronary cusp. Heart block characteristically worsens over postoperative days 1 to 3, and sometimes settles as edema improves.[13], [14]

STROKE

The overall risk of stroke is about 2% for isolated aortic valve replacement, increasing to 3% in combined aortic valve replacement with concomitant coronary bypass surgery.[15] Stroke following aortic valve replacement shares

many of the same risk factors as in other cardiac surgery, including prior stroke, carotid artery disease, aortic atheroma or calcification, endocarditis, and atrial fibrillation. Removal of all calcific debris from the operative field and thorough de-airing help prevent perioperative stroke.

Prosthetic Endocarditis

Mechanical valves are at slightly higher risk of endocarditis up to 3 months after surgery, the risks even out by 5 years. Homografts were once assumed to carry a lower risk of early endocarditis, but this has not been supported by data. The cumulative risk of prosthetic valve endocarditis is about 1% at 1 year and 3% at 5 years post aortic valve replacement. Early endocarditis (within 3 months of surgery) is usually hospital acquired: organisms are commonly staphylococci and gram-negative bacilli. Late prosthetic endocarditis usually results from a transient streptococcal bacteremia. The mortality is up to 60%.

Thromboembolism

The rate of valve thromboembolism is roughly 1% to 2% per year: the rate in adequately anticoagulated mechanical valves is slightly higher than that in bioprosthetic valves, which is one of the strong rationales for bioprosthetic valves.[16–20] Valve thrombosis is a rare emergency: cardiovascular collapse, venous congestion, and systemic embolization are usually acute, but may be insidious in onset. The management is intravenous heparin. If the thrombus is greater than 5 mm, thrombolysis or reoperative bioprosthetic aortic valve replacement is indicated.

Paraprosthetic Leak

Major paraprosthetic regurgitation occurs in 5% to 10% of transcatheter aortic valve replacements. It is uncommon with surgical aortic valve replacement, and is caused most commonly by prosthetic endocarditis (late), and less commonly by technical errors in insertion (early). Patients present with hemolytic anemia, and if severe, congestive heart failure. The treatment is surgery. If the area of dehiscence is small and there is no evidence of sepsis, one or two interrupted sutures may suffice. Occasionally, paravalvular regurgitation is amenable to percutaneous closure with an Amplatzer-type device. Where this is not possible, redo aortic valve replacement is indicated.[21]

Prosthesis Failure

Failure of mechanical valves is almost exclusive to strut failure of a particular

Bjork-Shiley tilting disc valve, withdrawn in 1986. Bioprosthetic aortic valve failure is age dependent: rates of failure are <10% at 10 years in the over 70s age group, but closer to 30% in the 40-to-50-year age group. Degenerative failure in cryopreserved homograft aortic valve replacement is between 5% and 10% at 10 years.

Reoperation for Any Reason

The risk of reoperation is highest in the first 6 months following aortic valve replacement due to prosthetic endocarditis and paravalvular leak. It falls to about 1% a year where it remains for mechanical valves.[13,14] The risk also falls initially in bioprosthetic valves, but begins to rise rapidly after 10 to 12 years due to structural degeneration.[15]

Failure to Improve Symptoms and Left Ventricular Function

90% of patients are NYHA class I or II, 5 to 10 years following aortic valve replacement, depending on their other comorbidities, and baseline LV function. Completely normal LV mass is rarely achieved, but where the LV end diastolic pressure was low preoperatively, and the transvalvular gradient is minimal, LV mass eventually returns to near-normal values.

MITRAL VALVE SURGERY

PATHOPHYSIOLOGY OF MITRAL REGURGITATION

Morphology

The mitral valve consists of the mitral valve annulus, leaflets, chordae tendineae, papillary muscles, and the left ventricle wall. Disease involving any of these structures may result in reduced leaflet coaptation leading to mitral regurgitation, described using a functional classification, description of etiology, and segmental valve nomenclature. Leaflet dysfunction is commonly described using Carpentier's classification of leaflet motion as either type I, which is normal leaflet motion; type II, which is excessive leaflet motion or prolapse; type III, which is restricted leaflet motion; and further subdivided into type IIIa, which is restricted leaflet opening; and type IIIb, which is restricted leaflet closure.

The functional classification can be supplemented with a description of the lesion causing the functional problem. Common lesions are chordal elongation or rupture, leaflet perforation, annular dilatation, and papillary muscle

displacement or rupture. Finally, the etiology underlying the lesion is described: common etiologies of mitral regurgitation include degenerative disease (which covers a range of overlapping pathology resulting in mitral valve prolapse including myxomatous disease, fibroelastic deficiency, and Barlow disease), ischemic disease (which can result in acute and chronic changes causing regurgitation), rheumatic disease, endocarditis, and dilated cardiomyopathy.

Etiology

Degenerative mitral valve disease is one of the commonest causes of mitral regurgitation in developed countries with an incidence of 1% to 2%. Typically degenerative disease causes prolapse (type II mitral regurgitation) due to chordal elongation or rupture, most commonly of the P2 segment. Histology shows myxomatous degeneration. Degenerative mitral valve disease encompasses a spectrum from single segment prolapse in small valves (fibroelastic deficiency) to multisegment prolapse in giant valves (Barlow).

Ischemic mitral regurgitation is usually due to chronic LV dysfunction and posterior displacement of papillary muscle (type IIIb) with normal leaflets. Acute papillary muscle rupture is a rare cause of acute type II mitral regurgitation after myocardial infarction. Dilated cardiomyopathy causes type I MR due to annular dilatation.

Endocarditis causes type I mitral regurgitation due to leaflet perforation and destruction, which may be extensive and involve the mitral annulus. Rheumatic disease results in type IIIa MR with restricted leaflet opening due to calcification and commissural fusion.

Less common causes of mitral regurgitation include abnormal systolic anterior motion, which results in mitral valve regurgitation and elevated LV outflow tract gradients, congenital causes such as cleft mitral valve, and connective tissue disease such as Marfan disease.

Structural and Functional Changes in Mitral Regurgitation

Chronic Mitral Regurgitation

The pathophysiologic changes associated with mitral regurgitation commonly progress through one or more of three stages: acute mitral regurgitation, chronic compensated mitral regurgitation, and chronic decompensated mitral regurgitation. Acute mitral regurgitation results in LV volume overload at end diastole, that is, increased preload and decreased afterload due to the regurgitant

pathway into the left atrium. The combination of increased preload and reduced afterload means that a larger volume of blood is ejected from the left ventricle.

Because a large volume of ejected blood enters the left atrium rather than the aorta, forward stroke volume, and hence cardiac output decreases. The increased blood volume in the left atrium raises the pressure from a normal left atrial pressure of 10 mm Hg to up to 25 mm Hg. The increased preload leads to eccentric hypertrophy and LV dilatation, increasing total stroke volume and forward stroke volume to near normal levels. Left atrial enlargement accommodates volume overload at lower filling pressures (15 mm Hg), but predisposes to atrial fibrillation and mural thrombi.

Chronic decompensated mitral regurgitation exists when systolic dysfunction prevents effective ventricular contraction; stroke volume and cardiac output are reduced as blood flows into the low-resistance regurgitant pathway, and left atrial and pulmonary pressures rise as a result. Untreated decompensated mitral regurgitation rapidly progresses to pulmonary edema and congestive cardiac failure. Symptoms, LV dysfunction, left atrial dilatation, atrial fibrillation, and pulmonary hypertension, are all associated with decreased long-term survival in the setting of chronic MR.

Clinical Findings in Mitral Regurgitation

The interval from diagnosis of mitral regurgitation to the onset of symptoms varies by etiology (it may be months in fibroelastic deficiency to many years in rheumatic or Barlow disease). LV ejection fraction remains normal despite even severe LV dysfunction because 50% of stroke volume ejects into low-pressure left atrium. While most deaths are related to heart failure, the incidence of sudden death suggests ventricular arrhythmias are an important feature of the disease process. Signs include atrial fibrillation, prominent sustained apex beat, systolic thrill, right parasternal heave reflecting right ventricular hypertrophy due to pulmonary artery hypertension, quiet first heart sound, third heart sound audible, and loud pansystolic murmur loudest at apex radiating to axilla.

Acute Mitral Regurgitation

Acute severe mitral regurgitation may be caused by chordal rupture, ischemic heart disease, or infective endocarditis, and it is an indication for urgent surgery. A sudden volume overload is imposed on the left ventricle, increasing preload and resulting in a small increase in total stroke volume. Without the compensatory left atrial and LV dilatation seen in chronic severe mitral

regurgitation, however, forward stroke volume is reduced, and congestive heart failure or even cardiogenic shock may result. The patient with acute severe mitral regurgitation is always symptomatic.

PATHOPHYSIOLOGY OF MITRAL STENOSIS

Morphology

The commonest cause of mitral stenosis is rheumatic fever: the disease process causes leaflet thickening and calcification and commissural and chordal fusion. Isolated mitral stenosis occurs in 40% of all patients presenting with rheumatic heart disease, and 60% of patients with mitral stenosis give a history of rheumatic fever. The ratio of female to male patients with this pathology is 2:1. Congenital malformation of the mitral valve occurs rarely.[2,3]

Structural and Functional Changes

The cross-sectional area of the normal mitral valve is 4.0 to 5.0 cm^2. Narrowing of this area to <2.5 cm^2 means that a pressure gradient must be generated across the mitral valve in diastole in order to expel blood from the left atrium into the left ventricle. This results in elevation of left atrial and pulmonary venous pressures. Left atrial enlargement, atrial fibrillation, and thrombus formation result from chronic left atrial pressure overload. Pulmonary hypertension results from passive transmission of elevated left atrial pressures, pulmonary vasoconstriction, and irreversible pulmonary vasculature remodeling. Pulmonary edema occurs when pulmonary venous pressure is greater than plasma oncotic pressure. At rest, mitral stenosis is usually asymptomatic, but any increase in transmitral flow rates (eg, due to hyperdynamic circulation) or reduction in the diastolic filling period, such as tachycardia or atrial fibrillation, will result in an increase in the pressure gradient, causing dyspnea. Severe mitral stenosis may have a low gradient in patients with a low cardiac output.

Clinical Findings in Mitral Stenosis

The first symptoms of dyspnea in patients with mitral stenosis are usually precipitated by physical exertion including exercise, sex, emotional stress, infection, pregnancy, or rapid atrial fibrillation because of the increase in the pressure gradient across the mitral valve described earlier. Recurrent chest infections are characteristic. In advanced cases, hemoptysis may be caused by

chest infections, pulmonary infarction, acute pulmonary edema, and rupture of small pulmonary vessels. Systemic embolism is frequent, particularly in atrial fibrillation.

Signs on clinical examination include a decreased amplitude pulse, atrial fibrillation, “tapping” apex beat, left parasternal heave due to right ventricular hypertrophy, thrill due to palpable opening snap, loud first heart sound, an opening snap loudest at lower left sternal edge, and a presystolic murmur, with a delayed mid-diastolic murmur.[2]

Indications for Mitral Valve Surgery

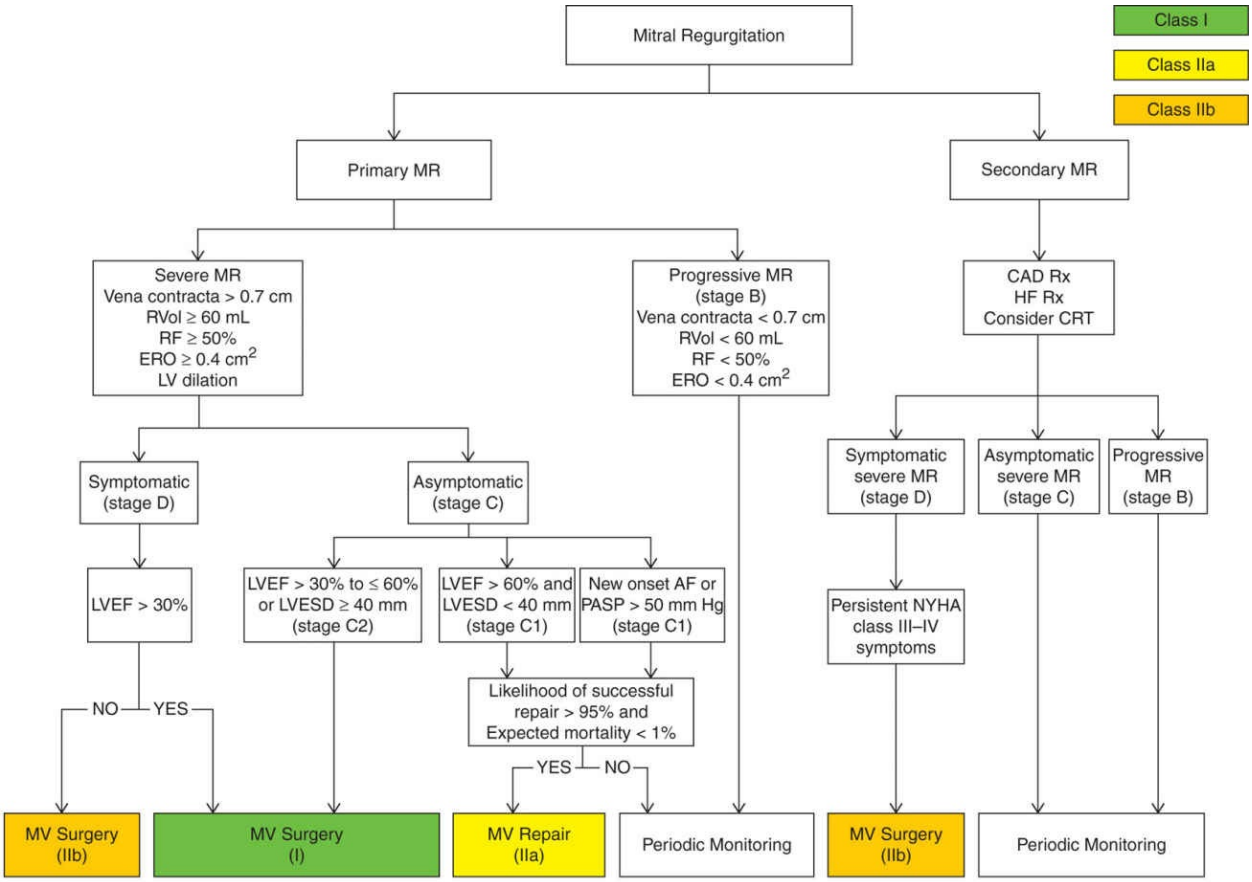
Chronic Mitral Regurgitation

The prognosis of chronic mitral regurgitation depends on both the etiology and severity of the lesion. In patients with severe symptomatic chronic mitral regurgitation of any etiology, the prognosis is poor. The average mortality rate is approximately 2% to 5% per year, and may be as high as 70% at 8 years. Patients with chronic mild to moderate mitral regurgitation are unlikely to require surgery, and therapy is aimed at treating the symptoms and preventing complications. American Heart Association (AHA) guidelines recommend that these patients are followed up on a yearly basis, with transthoracic echo if there are clinical grounds for suspecting a deterioration in LV or mitral valve function.[2,3]

In chronic ischemic mitral regurgitation, the valve itself is usually anatomically normal and the regurgitation is secondary to papillary muscle and LV dysfunction following infarction. The prognosis is poorer than in mitral regurgitation caused by nonischemic pathology. Coronary artery bypass may improve LV function and reduce mitral regurgitation. If LV dysfunction is very severe (LV end systolic diameter > 55 mm or LV ejection fraction < 30%), and repair/chordal preservation is unlikely, surgery does not extend life expectancy and is unlikely to provide symptomatic benefit.

Class I indications for mitral valve surgery therefore include chronic severe mitral regurgitation and NYHA class II to IV symptoms or mild to moderate LV dysfunction.[2,3] Additionally, class I indications include asymptomatic chronic severe mitral regurgitation with normal LV function if the likelihood of repair is more than 90%, or in the presence of new atrial fibrillation, pulmonary artery systolic pressures greater than 50 mm Hg at rest (or 60 mm Hg on exercise); or in the setting of NYHA III to IV symptoms with severe LV dysfunction if there

is a primary leaflet dysfunction (ie, not secondary or functional mitral regurgitation) and repair is likely. Class IIb indications for surgery include chronic severe mitral regurgitation due to severe LV dysfunction despite optimal medical therapy that may include biventricular pacing where appropriate (**Figures 40.3 and 40.4**).[2,3]



*Mitral valve repair is preferred over MVR when possible.

AF indicates atrial fibrillation; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; ERO, effective regurgitant orifice; HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; LVESD, left ventricular end-systolic dimension; MR, mitral regurgitation, MV, mitral valve; MVR, mitral valve replacement; NYHA, New York Hear Association; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume; and Rx, therapy.

Acute Mitral Regurgitation

Acute severe mitral regurgitation is a class I indication for urgent surgery. There is no scope for compensatory changes: cardiac output falls, left atrial pressures increase, and pulmonary edema and cardiogenic shock ensue.

Mitral Stenosis

It may be as long as 20 to 40 years between the occurrence of rheumatic fever and the onset of symptomatic mitral stenosis. Once symptoms develop, it may take up to 10 years before these become disabling. In the minimally symptomatic patient, 10-year survival is 80%, which drops to 10% to 15% once

symptoms become limiting. Once there is severe pulmonary hypertension, mean survival drops to <3 years. The mortality of untreated mitral stenosis is due to heart failure in 60% to 70%, systemic embolism in 20% to 30%, pulmonary embolism in 10%, and infection in 1% to 5% of patients. Patients with a mitral valve area of <1.5 cm^2 and NYHA functional class III to IV symptoms should be referred for surgery if balloon valvotomy is not possible. There is good evidence that patients with NYHA functional class I to II symptoms and a mitral valve area <1.0 cm^2, and severe pulmonary artery hypertension (systolic pulmonary artery pressure > 60 to 80 mm Hg) benefit from surgery.[2]

Surgical Approaches

Mitral valve repair and replacement is most commonly performed via a sternotomy, and right (and very occasionally left) thoracotomy approach is very feasible. As in aortic valve surgery, the aim of smaller incisions is to limit the impact of surgery on postoperative respiratory function, pain control, bleeding and transfusion requirement, and to improve cosmesis. Cannulation for cardiopulmonary bypass is usually performed via the ascending aorta and Bicavally (Superior and Inferior Vena Cava); however, femoral cannulation may be used to facilitate smaller incisions. Retrograde flow from femoral arterial cannulation is associated with higher rates of stroke in elderly patients and those with atheromatous vasculature.

Mitral Valve Repair

Planning Mitral Valve Repair

In degenerative valve disease, mitral valve repair is associated with better early and late survival, and freedom from complications of prosthetic valve including stroke, recurrence of mitral regurgitation, and reoperation compared with mitral valve replacement. Therefore, mitral valve repair is preferable to replacement in patients with degenerative valve disease, particularly in young patients and asymptomatic patients where the sequelae of valve replacement are more serious.[2,3]

Mitral valve repair is not as reproducible as mitral valve replacement because it requires additional technical expertise primarily because mitral valve morphology is highly variable, and repair complexity depends on valve morphology. Consequently, in order to maximize the likelihood of a competent and durable mitral repair, it is important to match surgeon expertise to repair

complexity. Lesions associated with a more straightforward repair include type II mitral regurgitation from isolated P2 prolapse from degenerative disease, and type IIIb P3 from ischemic disease.

Lesions associated with more complex repair include multisegment or bileaflet prolapse, in Barlow disease, type IIIa lesion from rheumatic disease, lesions related to infective endocarditis, such as leaflet perforation and annular abscess, cleft mitral valve, primary abnormal systolic anterior leaflet motion, and previous failed mitral repair. Patients with these lesions should be seen by a surgeon with specific expertise in mitral valve repair.

Special Considerations

Concomitant Tricuspid Annuloplasty

Functional tricuspid regurgitation commonly occurs secondary to mitral valve lesions causing pulmonary hypertension and right ventricular dilatation. When right ventricular dilatation develops, the tricuspid annulus dilates because it is not supported by a fibrous skeleton. This is most pronounced in the posterior and anterior part of the annulus because the septal annulus is relatively fixed. Leaflet coaptation is reduced leading to tricuspid regurgitation. Observational data suggest that in patients with more than 2+ tricuspid regurgitation, annular dilatation, or pulmonary artery hypertension, functional tricuspid regurgitation may not resolve with correction of the left-sided lesion, and should be repaired to avoid late severe tricuspid regurgitation, which develops in a minority of patients and is associated with high morbidity and operative mortality. Tricuspid repair can be easily accomplished using tricuspid ring annuloplasty without significant incremental morbidity.[22]

Concomitant Atrial Ablation and Left Atrial Appendage Closure

Atrial fibrillation may be addressed at the time of mitral valve surgery with concomitant ablation using a variety of energy sources: cryoablation is used most commonly. Full-thickness lesions are created around the pulmonary veins, and may include more complete left and right atrial lesions sets. The freedom from atrial fibrillation at 1 year using this technique is 60% to 70%. Cut-and-sew maze procedures, where the lesions are created by resecting and resuturing the left and right atrium, offer much greater freedom from atrial fibrillation but at the expense of increased morbidity, particularly related to bleeding risk, and are not widely performed. In patients with atrial fibrillation, it is possible to ligate

the left atrial appendage either from inside the left atrium, which affords a more complete and durable closure if performed as a double layer rather than a single purse-string, or from outside using sutures or clips, which is faster but may not occlude the base of the appendage as reliably as a hand-sewn closure. The rationale is to reduce the risk of thromboembolic stroke, but there are little data to support the efficacy of any of the techniques, with some data showing increased stroke risk if there is residual blood flow after attempted surgical closure.

Mitral Valvotomy

Open mitral valvotomy is a historic procedure that used to be performed for mitral stenosis (usually rheumatic), before the wide availability of percutaneous balloon mitral valvotomy. It was one of the first cardiac surgical procedures performed, and the basic principles of the operation remained unchanged for three decades until the advent of cardiopulmonary bypass enabled the surgeon to work on the mitral valve under direct vision, in a still, bloodless field. Percutaneous balloon mitral valvotomy is performed using a transvenous approach with a transseptal puncture. The initial results of percutaneous versus surgical valvotomy are comparable, and both interventions have low rates of restenosis providing good functional outcomes up to 3 years. At 3 years, however, valve areas in the balloon mitral valvuloplasty group are greater than in the surgical ones. Additionally, procedural mortality is less than that associated with mitral valve replacement. In view of this, as well as the lower cost and morbidity of the percutaneous approach, percutaneous approach is recommended in patients without any contraindications. Contraindications to percutaneous balloon valvotomy include > 2+ mitral regurgitation, left atrial thrombus, Wilkins score ≥ 8 (range 4 to 16), or Cormier group 3, severely decreased leaflet mobility, prominent leaflet or subvalvar thickening, calcification especially commissures, and severe concomitant coronary artery disease or AS requiring surgery.

Results of Mitral Valve Surgery

Early Mortality

The mortality of isolated mitral valve repair, with or without tricuspid repair, for degenerative disease in patients without pulmonary hypertension is <1%. Higher operative mortality (2% to 5%) is seen in patients with pulmonary hypertension,

LV dysfunction, advanced age, ischemic mitral regurgitation, active endocarditis, and mitral replacement.

Late Mortality

Successful repair for degenerative mitral regurgitation restores life expectancy to that of an age-matched normal population. Ischemic mitral regurgitation is associated with much poorer survival: one-third of patients are dead within 5 years despite successful repair. LV end diastolic dimension greater than 65 mm is associated with worse survival with <50% of patients alive at 5 years. Rheumatic patients are usually younger, and have good long-term survival with around 80% to 90% still alive 10 years after surgery.[13]

Complications

The complications of cardiac surgery in general include reexploration for bleeding or tamponade (2%), perioperative myocardial infarction (1%), deep sternal wound infection (1%), prolonged mechanical ventilation (2%), and organ dysfunction (5%). Complications particularly associated with mitral valve surgery are as follows:

FAILURE OF REPAIR

A patient leaving the operating room with greater than 1+ mitral regurgitation is described as having residual mitral regurgitation, whereas recurrent mitral regurgitation refers to patients who initially had no mitral regurgitation after surgery, but developed mitral regurgitation later. Residual mitral regurgitation is usually due to a technical issue, such as incorrect choice of ring, failure to close cleft, inadequate treatment of prolapse, or advanced disease due to an etiology not amenable to repair (rheumatic mitral disease). Recurrent mitral regurgitation may occur early, and is also usually related to a technical problem, such as dehiscence of leaflet suture line, failure of chordal reconstruction, or very occasionally endocarditis. Late recurrent mitral regurgitation is usually due to progression of underlying disease. The late failure rate for degenerative disease is around 1% to 2% per year, and much lower than the failure rate for rheumatic and ischemic repair, reflecting the more progressive nature of the latter two etiologies.

COMPLETE HEART BLOCK

Permanent pacemakers are inserted for permanent complete heart block in about

1% to 2% of mitral valve replacement patients. Complete heart block results from trauma to the bundle of His. Heart block characteristically worsens over postoperative days 1 to 3, and sometimes settles as edema improves.

STROKE

The overall risk of stroke is about 1% for isolated mitral valve replacement, increasing to 3% in mitral valve replacement combined with concomitant aortic valve replacement or coronary bypass surgery. Stroke following mitral valve replacement shares many of the same risk factors as in other cardiac surgery, including prior stroke, carotid artery disease, aortic atheroma or calcification, endocarditis, and atrial fibrillation. Removal of all calcific debris from the operative field, and thorough de-airing help prevent perioperative stroke.

PROSTHETIC ENDOCARDITIS

Mechanical valves are at slightly higher risk of endocarditis up to 3 months after surgery, the risks even out by 5 years. Homografts were once assumed to carry a lower risk of early endocarditis, but this has not been supported by data. The cumulative risk of prosthetic valve endocarditis is about 1% at 1 year and 3% at 5 years post mitral valve replacement. Early endocarditis (within 3 months of surgery) is usually hospital acquired: organisms are commonly staphylococci and gram-negative bacilli. Late prosthetic endocarditis usually results from a transient streptococcal bacteremia. The mortality is up to 60%.

THROMBOEMBOLISM

The rate of valve thromboembolism is higher than in aortic prostheses because flow velocity across the valve is slower. It is roughly 2% per year, with adequate anticoagulation of mechanical valves, and 1% per year with bioprosthetic valves, and may present as stroke or systemic embolization.[16] The mainstay of management is intravenous heparin. Valve thrombosis is rare, and presents with acute onset of extreme dyspnea and orthopnea, but may be insidious. Fluoroscopy or echo is used to visualize if one or both leaflets are not moving. Acute thrombosis can be treated with thrombolytic therapy, but usually this is a chronic process with acute exacerbation that requires replacement (normally with a bioprosthesis to avoid a repeat episode). The thrombus is usually very organized and may be superimposed on pannus. Surgical thrombectomy may be tempting but is often ineffective because it is impossible to clear pannus and thrombus easily from ventricular aspect of prosthesis.

Paraprosthetic Leak

Paraprosthetic leak is uncommon after mitral valve replacement: immediate or early paraprosthetic leaks may be due to needle holes (tiny, and disappear after protamine), incomplete decalcification of annulus, annular tear, or suture positioning. Late new paraprosthetic leaks are more likely due to endocarditis. Narrow, high-velocity jets are high risk for hemolytic anemia that may be disabling (requiring multiple transfusions). Broader jets may be hemodynamically significant especially if mitral regurgitation was not present preoperatively. The decision to treat depends on balancing disadvantages of fixing the paravalvular leak (eg, reclamping diseased aorta, additional ischemic time in sick heart, severe mitral annular calcification making any improvement unlikely, high-risk resternotomy) against the disadvantages of leaving it. Prosthetic valve endocarditis is a strong indication for surgery in this context. In the absence of endocarditis, paravalvular regurgitation may be amenable to percutaneous closure with an Amplatzer-type device. Where this is not possible, redo mitral valve replacement may be indicated.

Prosthesis Failure

In the mitral position, the lifetime risk of reoperation for bioprosthetic failure is around 45% for a 50-year-old, and this falls by just over 10% for every additional 5 years of age at the time of implantation. At 20 years after surgery, around 10% to 15% of patients with mechanical valves will have required reoperative valve replacement for infective endocarditis, pannus, or valve thrombosis.[22]

Reoperation for Any Reason

The risk of reoperation is highest in the first 6 months following mitral valve replacement due to prosthetic endocarditis and paravalvular leak. It falls to about 1% a year where it remains for mechanical valves. The risk also falls initially in bioprosthetic valves, but begins to rise rapidly after 10 to 12 years due to structural degeneration.[22]

Failure to Improve Symptoms and LV Function

90% of patients are NYHA class I or II, 5 to 10 years following mitral valve replacement, depending on their other comorbidities and baseline LV function. Completely normal LV mass is rarely achieved, but where the LV end diastolic pressure was low preoperatively, and the transvalvular gradient is minimal, LV mass eventually returns to near normal values.

Atrial Fibrillation

Around 10% to 20% of patients undergoing mitral surgery have a history of preoperative atrial fibrillation and the incidence of postoperative atrial fibrillation is around 40%. Atrial fibrillation is associated with thromboembolic complications including stroke, heart failure, and decreased survival; so aggressive treatment of patients with a history of preoperative atrial fibrillation with intraoperative ablation is recommended. These patients are routinely anticoagulated for 3 months after surgery, may be at increased risk for thrombus formation in the early postoperative period, and are often pacemaker dependent for several days after surgery.

TRCIUSPID VALVE SURGERY

PATHOPHYSIOLOGY

Morphology

Functional tricuspid regurgitation commonly occurs secondary to left-sided valve lesions causing pulmonary hypertension and right ventricular dilatation. When right ventricular dilatation develops, the tricuspid annulus dilates because it is not supported by a fibrous skeleton. This is most pronounced in the posterior and anterior part of the annulus, since the septal annulus is relatively fixed. Leaflet coaptation is reduced leading to tricuspid regurgitation. Observational data suggest that in patients with more than 2+ tricuspid regurgitation, annular dilatation, or pulmonary artery hypertension, functional tricuspid regurgitation may not resolve with correction of the left-sided lesion, and should be repaired to avoid late severe tricuspid regurgitation, which develops in a few patients and is associated with high morbidity and operative mortality.

Acute tricuspid valve endocarditis is usually associated with sepsis from long-term indwelling venous catheters or intravenous drug use. Common causative organisms are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Rheumatic tricuspid valve may result in annular dilatation and functional tricuspid regurgitation secondary to severe mitral stenosis. The tricuspid leaflets are often characterized by mild restriction and leaflet thickening.

Transvenous pacing wires can lead to leaflet perforation, or more commonly scarring, causing tricuspid regurgitation. Traumatic tricuspid valve rupture is a rare sequela of severe nonpenetrating chest injury. Carcinoid valve disease results in severe leaflet thickening and immobility, causing regurgitation and

stenosis.

Clinical Findings

The symptoms and natural history are determined by the dominant left-sided heart lesion. Tricuspid stenosis causes increased systemic venous pressure, resulting in hepatomegaly, ascites, and peripheral edema. A mid-diastolic murmur may be present. In tricuspid regurgitation, the progression is slower than mitral regurgitation, and many patients are symptom free for decades. The predominant clinical features are those of raised venous pressure. A pansystolic murmur may be present. Patients usually have moderate to severe right ventricular failure by the time they present for surgery, as well as severe pulmonary hypertension, and moderate to severe liver dysfunction, which is why isolated tricuspid valve surgery has such high mortality (approximately 10% to 15%) with low cardiac output, respiratory failure, and sepsis being the major problems postoperatively.

Indications for Tricuspid Valve Surgery

Class I indications for tricuspid repair include severe tricuspid regurgitation in patients having mitral valve surgery. Tricuspid repair for mild tricuspid regurgitation and pulmonary artery hypertension or tricuspid annular dilatation are class IIb indications for tricuspid repair in patients having mitral valve surgery. Severe symptomatic primary tricuspid regurgitation is a class IIa indication for isolated tricuspid valve surgery.[2,3,23]

Surgical Approach

The tricuspid valve is easily approached via either a sternotomy or a right thoracotomy. The most common procedure is tricuspid annuloplasty, which may be performed using a rigid or flexible ring, or a running stitch around the annulus known as a De Vega suture annuloplasty that is less durable. The tricuspid annulus tissue offers little support and sutures need to be placed and tied carefully to avoid tears, correcting tricuspid regurgitation by reducing the posterior and anterior annulus that are most prone to dilatation. The atrioventricular node is avoided, leaving the area at the apex of the triangle of Koch free of sutures. Tricuspid valve replacement is usually performed for failed repairs, and in operations for endocarditis or carcinoid tricuspid pathologies. A bioprosthetic replacement is usually preferred over a mechanical valve

replacement, which will preclude future placement of transvalvular catheters or wires. The valve and subvalvular apparatus is excised, and the valve is inserted using horizontal everting mattress sutures with pledgets on the atrial side.

SURGERY FOR INFECTIVE ENDOCARDITIS

DIAGNOSIS

The Duke diagnostic criteria are 95% specific, with a 92% negative predictive value.

Duke criteria for infective endocarditis establish a definite diagnosis with two major or one major and three minor or five minor criteria. Possible endocarditis is defined by the presence of one major and one minor, or three minor criteria. The major Duke criteria include positive blood cultures (*Streptococcus viridans*, *Streptococcus bovis*, HACEK, *Staphylococcus aureus*, enterococci with no other primary focus from two separate cultures or persistent positive cultures more than 12 hours apart or all of three or majority of four separate cultures positive drawn over the space of >1 hour), and echo evidence including an oscillating intracardiac mass in the absence of alternative explanation, abscess or new regurgitant lesion, or new partial dehiscence of prosthetic valve. The minor Duke criteria include predisposition, fever > 38°C, emboli, or blood culture and echo signs that do not fulfill the definition of major Duke criteria.[2,3,24–30]

INDICATIONS FOR SURGERY

Surgery is indicated for structural valve lesions with evidence of hemodynamic compromise or abscess formation. The optimal time to operate after embolic stroke is 7 to 14 days if possible, but it is often necessary to operate sooner because of the patient's hemodynamic state. An accurate assessment of neurologic function is necessary before proceeding with surgery.

Acute endocarditis with stenosis or regurgitation and congestive heart failure is a class I indication for urgent surgery. Other class I indications for surgical intervention include fungal endocarditis; endocarditis complicated by heart block, annular or aortic abscess, or fistulae between right or left atrium or ventricle and sinus of Valsalva, or mitral leaflet perforation in aortic valve endocarditis; prosthetic valve endocarditis and dehiscence; or worsening valve function, heart failure, or abscess. Native valve endocarditis and recurrent emboli and persistent vegetations despite appropriate antibiotics, and the

presence of prosthetic valve endocarditis and bacteremia despite appropriate antibiotics are class IIa indications for surgery. Finally, the presence of mobile vegetations > 10 mm in size are class IIb indications for surgery.[2,3]

Choosing the right time to operate can be difficult: the surgeon must define "appropriate antibiotics," and balance the need to optimize major comorbidity, often including acute embolic stroke, with the fact that these patients are liable to deteriorate irreversibly. In most cases, early surgical intervention is preferable to late: in case of preoperative embolic stroke, delay surgery for 5 to 10 days if possible; if the patient has evidence of a hemorrhagic stroke, then several weeks are usually needed to minimize the risk of additional intracerebral bleeding while on cardiopulmonary bypass or postoperatively.

SURGICAL APPROACHES

The goals of surgery are to remove infected tissue and drain abscesses, reverse hemodynamic abnormalities, and to restore cardiac and vascular architecture. Transesophageal echocardiography is critical in planning surgery that may involve drainage of abscesses, debridement of necrotic tissue, closure of acquired defects, such as ventricular septal defect, annular abscess, fistulae, and aneurysms, in addition to valve repair and replacement. The most common approach is median sternotomy, which allows assessment and treatment of all valves in the event of more extensive involvement than identified preoperatively.

Aortic valve endocarditis is not usually amenable to valve repair, and is treated with complete excision and debridement of all infected tissue, with valve replacement if extensive annular involvement is not there. Extensive destruction of the annulus and sinuses requires treatment with aortic root replacement. There is no good evidence that homograft valve replacement versus bioprosthetic or mechanical valve root replacement reduces the risk of recurrent infective endocarditis. Aortic valve abscesses are most common posterior to the membranous part of the interventricular septum, and under the left coronary ostia.

Mitral and tricuspid calve endocarditis can often be treated effectively with surgical repair after resection and debridement of all infected tissues. Mitral valve abscesses are most common in the P2 portion of the annulus. For small abscesses, evacuation and debridement is relatively straightforward, but in extensive root abscesses involving the atrioventricular and ventriculoarterial junction, debridement may cause dehiscence and abscesses around the mitral valve should also be debrided with great regard for atrioventricular discontinuity.

In prosthetic valve endocarditis, extra care must be taken to debride all prosthetic material. Small vegetations can be debrided and perforations in the mitral valve may be repaired with autologous pericardium.

COMBINED VALVULAR PROCEDURES

PATHOPHYSIOLOGY OF COMBINED VALVE DISEASE

Rheumatic valve disease, infective endocarditis, and connective tissue disease are the most common causes of disease requiring surgical intervention on two or more valves. The pathophysiology is dictated by the dominant lesion. Aortic and mitral regurgitation impose a large volume overload on the left ventricle, which undergoes marked hypertrophy and eventual dilatation. Aortic and mitral stenosis result in a small, hypertrophied, noncompliant left ventricle, usually with well-preserved LV function. In patients with mitral stenosis and aortic regurgitation, the mitral stenosis is usually dominant. Mitral stenosis restricts LV, blunting the effect of AI on LV volume. Even in severe AI, hyperdynamic circulation and dilated left ventricle are absent. In AS and mitral regurgitation, the AS worsens the degree of mitral regurgitation. The mitral regurgitation causes difficulty in assessing the severity of the AS because of reduced forward flow. Patients can decompensate rapidly. In mitral stenosis or regurgitation and tricuspid regurgitation, pulmonary hypertension is usually present.

INDICATIONS FOR SURGERY IN MODERATE VALVE DISEASE

Although the nondominant lesion may be mild at the time of operation, these lesions are progressive. Rheumatic AS that was mild at the time of operation on concomitant rheumatic mitral lesion progresses to moderate to severe in one-third of patients within 5 years. The progression of AI is much slower and better tolerated, although distorting the aortic annulus by mitral annuloplasty ring or replacement may cause 2+ AI to become severe. Regurgitant combined lesions tend to progress faster, and the prognosis in combined stenotic lesions is worse than in isolated stenotic lesions. The temptation to operate on multiple valves to avoid later surgery needs to be balanced against increased perioperative mortality and long-term morbidity of valve replacement. It is sometimes reasonable to inspect the valve in question at the time of surgery to make a final decision.

PROSTHETIC VALVES

TYPES OF VALVE PROSTHESIS

Valve prostheses are either mechanical or bioprosthetic ("tissue").[31] Tissue valves are mounted on a metal frame (stented), or supported by pig aorta and cloth (stentless). Stented valves are the most commonly used bioprosthesis, and are usually either porcine aortic valves or bovine pericardium. Homografts are human cadaveric aortic roots, complete with aortic valves in situ. A pulmonary autograft is the patient's own excised pulmonary valve used in the Ross procedure.

Mechanical Valves

Over 50 models of mechanical valves exist underlying the fact that no single design meets all the criteria of the perfect prosthesis. Bileaflet valves provide the best hemodynamic profile and lowest thromboembolic risk, and so are the most widely used today. Commonly inserted models include CarboMedics (radiopaque titanium ring with carbon discs) and St Jude Medical (pyrolytic carbon, radiolucent). Tilting disc (or monoleaflet) valves have been largely superseded by bileaflet valves with better hemodynamic profile. Tilting disc valves include Metronic-Hall A770 carbon-coated disc in sewing ring and Bjork-Shiley carbon-coated disc with titanium struts. Ball-in-cage valves were the first prostheses with long-term durability, but are no longer manufactured. They are associated with higher thromboembolic rates and are bulky prostheses with Starr-Edwards the best known model.

Bioprosthetic Valves

There is a similar variety of choices of tissue valves. Discovery of glutaraldehyde fixation in the 1960s by Alain Carpentier, followed by antimineralization led to second- and third-generation tissue valves with improved durability. There are two main types: stented and stentless.[30] Stented valves are the most commonly implanted, as they are technically easier to implant. Porcine stented valves are made of pig aortic valves, usually with the porcine noncoronary cusp (which is smaller in the pig) replaced with a coronary cusp to make the valve symmetrical. Examples include Carpentier-Edwards 2625, Hancock (Medtronic), and the Hancock II with an anticalcification agent added to the fixative. Bovine stented valves are made of bovine pericardium

(equine occasionally used), such as the Perimount (CE 2700/CE Magna). Stentless valves are porcine valves supported by porcine aorta. The lack of a stent means the valves have a better hemodynamic profile, but are technically trickier to implant. The most commonly used include the Freestyle, which may be implanted in the subcoronary position as a valve replacement, as an inclusion root cylinder, or as a full aortic root replacement, and hence “Freestyle.”

Homografts

Homografts are aortic roots removed from cadaveric human hearts and implanted as root replacements: the graft does not express major histocompatibility complex antigen as viable endothelial cells disappear within hours of implantation and so allograft rejection does not occur. Valves are removed from disease-free cadaveric hearts, unsuitable for transplantation, of donors aged 6 months to 55 years, up to 12 hours after death. The donor heart is procured using aseptic technique, preserved in cold Ringer lactate solution, and packaged in sterile plastic bag that is buried in slush. Homograft preparation takes place in a clean not aseptic environment. The homograft block consists of all tissue between the base of the left ventricle containing the anterior leaflet of the mitral valve and the aortic annulus, to the innominate artery. The coronary ostia are preserved with a small rim of coronary artery. The annulus is sized and the length of aorta recorded. There are three main techniques for preservation, which aim to prevent bacterial colonization and preserve fibroblasts and endothelial cells. Cryopreservation has largely superseded antibiotic preservation. Homovital preservation is a recent development. After harvest, the homograft block is stored in a culture medium that contains a low concentration of broad-spectrum antibiotics and stored at 4°C for 24 hours. The culture medium is changed and the tissue stored for a further 24 hours at 4°C. It can either be used at this time as a homovital graft or frozen in 10% fetal calf serum and 10% dimethylsulfoxide (DMSO) with controlled rate freezing (fall of 1°C/min to a target temperature of −40°C) to achieve cryopreservation.

Where root replacement is indicated, homografts are more pliable than Dacron composite valve replacements, may be more resistant to infection (although there are little data to support this), and so are favored in surgery for aortic valve endocarditis requiring root replacement where tissue is very friable and reinfection a significant risk. However, homografts are not as durable as mechanical valves, and may not be as durable as porcine or bovine valve replacement. Homograft aortic root replacement is a technically demanding

operation and the results are very dependent on the surgeon, given the additional technical complexity of positioning the homograft in the correct anatomic position, dissecting out the coronary ostia and reimplanting them, and additional suture lines, all of which carry an increased risk of postoperative bleeding and prolong the time for which the patient is on bypass. The national mortality for aortic root replacement is approximately 7%,[9] compared with approximately 1% to 2% for subcoronary aortic valve replacement. There is a theoretical risk of transmitted infections: tuberculosis was transmitted in several cases before preservation and procurement protocols changed. Homografts depend on donor organ supply, which is falling. Homograft tissue is variable in quality, depending on the age of the donor, as well as the skill of the harvester: both the homograft aorta and the valve leaflets may be perforated or buttonholed, and the tissue can be very friable.

Pulmonary Autograft

Using the patient's own pulmonary valve to replace the aortic valve is known as the Ross procedure, after Donald Ross, the British surgeon who pioneered its use. The pulmonary valve is replaced with a pulmonary homograft, which has a life expectancy of 15 to 20 years. The patient's own pulmonary valve in the aortic position has better life expectancy than an aortic bioprosthesis, is resistant to infection, does not warrant formal anticoagulation, and most importantly "grows" with the patient.

Indications for the Ross procedure are controversial because of the additional mortality and morbidity associated with the operation and variable data on the freedom from need for reoperation. The use of the Ross procedure is least controversial in very young patients who will not be well served by implanting small prosthetic valves. Use of the Ross procedure in older patients with a predicted life expectancy of greater than 30 years, and in whom an active lifestyle requires good hemodynamic function and contraindicates warfarin, is thought by some clinicians to be reasonable if the surgeon can offer operative mortality of <2%, that is, comparable to isolated aortic valve replacement.

Contraindications to the Ross procedure include Marfan and other connective tissue disorders. Rheumatic valve disease is a viewed by some as a contraindication.

The drawbacks are primarily related to the technical difficulty of both procedure and reoperation, and many more surgeons have been discouraged by the steep learning curve and abandoned the operation than have managed to

successfully adopt it as part of their repertoire. Mortality in one metaanalysis ranged from 1% to 7%. Reoperation for autograft dilatation is reduced by modifications where Teflon felt is used to buttress the proximal suture line.

CHOICE OF VALVE PROSTHESIS

There are no strong data showing major long-term survival difference between mechanical versus tissue valve in either aortic or mitral position.[15,22,23–36] In a patient aged over 65 years, a bioprosthetic valve will likely last the patient's lifetime, does not require long-term anticoagulation, and carries an approximate 1% annual risk of thromboembolic stroke; but valve failure becomes an increasing risk from 10 to 15 years depending on position and patient age. Mechanical valves last decades but approximately 15% will need explanting by 15 years because of endocarditis, pannus, or thrombosis; they require lifelong anticoagulation and have 3% to 4% annual risk of stroke or hemorrhage.

Bioprosthetic Valve Deterioration

Freedom from structural valve deterioration at 12 years in older patients is over 90% with third-generation tissue valves such as the Carpentier-Edwards pericardial valves in the aortic position.[22,37] Tissue valves last longer in the elderly because the hemodynamic demands on the valve are less: the chances of bioprosthetic aortic valve failure at 12 years is approximately 40% in patients aged 18 to 39 years, at least 30% in patients aged 40 to 49 years, and at least 10% in patients aged over 70 years. Lifetime risk of reoperation is similar for each age group. Tissue valves last less well in the mitral position compared with the aortic position, and redo mitral valve replacement is associated with higher risk of mortality than redo aortic valve replacement. Calcification of bioprostheses occurs in areas of greatest stress: the commissural regions of porcine valves or the zone of flexion in porcine and pericardial valves, and leads eventually to prosthesis failure. This may happen earlier in patients with renal failure, but the disadvantages of managing anticoagulation in these patients and their shorter life expectancy means bioprostheses remain a reasonable choice in these patients.

Hemodynamic Profile

In smaller sizes (eg, #19, #21), bioprostheses cause more flow obstruction than same-size mechanical valves. Stented bioprostheses are more obstructive than

stentless, which are more obstructive than mechanical.

Thromboembolic and Hemorrhagic Events

Without anticoagulation, life-threatening thrombosis and thromboembolic events are inevitable. Even in an optimally anticoagulated patient (INR 2.5 to 3), the incidence of major thromboembolic events including stroke and hemorrhage is still 2% to 4% per year (and this number is higher in multiple valves and older patients).[21,38–43] Bleeding problems (pericardial effusion, late tamponade) are more common postoperatively, and valve thrombosis is a later risk in patients not therapeutically anticoagulated.

CHOICE OF VALVE PROSTHESIS IN SPECIAL GROUPS

Younger Patients

National analyses show a trend toward implanting more tissue valves in younger patients. This may reflect the lack of evidence for a long-term survival difference between mechanical and biologic valves[23,24]; greater awareness of the lifetime risk of stroke and bleeding rate and the inconvenience of lifelong anticoagulation; better durability of tissue valves; the fall in the mortality of reoperative surgery; and the increasing feasibility of transcatheter valve-in-valve replacement.[44–55]

Pregnancy

Pregnant women have increased risk of mechanical valve-related thromboembolism: anticoagulation is vital.[43–45] Warfarin, a teratogen, is contraindicated in the first trimester, and low molecular weight heparin or unfractionated heparin should be administered instead, from initial attempts to conceive up until the beginning of the second trimester or delivery. Consequently, bioprosthetic valves may be a reasonable choice for women of childbearing age, even though they will eventually need reoperative valve surgery.

Endocarditis

There are no data to suggest that choice of valve replacement affects recurrence of endocarditis. Homografts have not been shown to give increased resistance to endocarditis, and they are less durable than porcine valves: their main advantage

is that they are more forgiving to implant in very friable tissue.

Atrial Fibrillation

Atrial fibrillation is no longer an indication to implant a mechanical valve: concomitant ablation means 60% of patients will be in sinus rhythm at 1 year, obviating the need for anticoagulation altogether if a bioprosthesis is implanted.

PERIOPERATIVE CARE

Preoperative Management

All patients undergoing cardiac surgery should undergo a careful history and physical examination to first confirm the indication for surgery, identify possibly contraindications to surgery, and conditions that may increase surgical risk. An accurate description of severity, duration, and nature of symptoms; a cardiovascular history including prior cardiovascular interventions, risk factors, and medications; and a comprehensive cardiovascular examination are mandatory. Assessment of respiratory, renal, and neurologic dysfunctions is indicated based on clinical history, examination, and risk factors. A recent change in symptoms or clinical examination may be an important finding that may change the timing or type of surgery.

All patients should have a recent echocardiogram clearly identifying the severity of the lesion as well as left and right ventricular function, the presence of pulmonary hypertension, and other valvular lesions. Cardiac catheterization should be performed in most patients; in young patients with no risk factors for coronary disease, a CT coronary angiogram may be sufficient to show anatomy. In patients with bicuspid valve disease, a CT scan is useful to evaluate the ascending aorta for aneurysm. Older patients, those with a history of mediastinal radiation, evidence of aortic calcification on imaging, any pulmonary history, and those patients undergoing reoperative cardiac surgery should undergo a CT scan of the chest without contrast. Lung function testing should be performed in patients with pulmonary disease or smoking history.

Antiplatelet agents and anticoagulation should be stopped several days before surgery, with appropriate bridging therapy if indicated. It is common practice to stop angiotensin converting enzyme inhibitors for 24 hours preoperatively to reduce the risk of postoperative vasoplegia. A complete blood count, coagulation profile, blood chemistry, liver function tests, and blood cross match are part of the standard panel of tests. All patients should have a 12-lead ECG and a chest

X-ray. The patients must not eat or drink for 8 hours before induction of anesthesia. In diabetic patients, an insulin sliding scale may be needed.

Postoperative Management

Most patients follow the expected postoperative course, but particular vigilance is required to prevent and recognize potentially life-threatening complications including hemorrhage, cardiac tamponade, respiratory and renal failure, stroke, and arrhythmias and conduction block, which can arise unexpectedly particularly during the first 48 to 72 hours after surgery. Urinary, respiratory, and sternal wound infections are more common after postoperative day 4.

Patients arrive on the intensive care unit ventilated with a central venous line, radial arterial line, Foley catheter, and sometimes a pulmonary artery catheter in place. A chest X-ray, 12-lead ECG, complete blood count, coagulation profile, blood chemistry, liver function tests, and arterial blood gas are performed on arrival. The chest X-ray is checked to review the position of the endotracheal tube, the pulmonary artery catheter, and the presence of hemothorax or pneumothoraxes. The ventilator settings are adjusted accordingly. Inotropic support may increase but more commonly decreases during the first 6 hours, and is weaned according to hemodynamic parameters such as cardiac index and mixed venous and blood pressure. Temporary epicardial pacing may be required and it is important to understand how the pacing wires and box work, particularly in an emergency. Most patients wean from the ventilator and are extubated within 6 hours. A spontaneous diuresis of at least 1 mL/kg/h is expected. Mediastinal drainage should decrease steadily and should not be greater than 150 mL/h. Insulin requirements often increase. Prophylactic antibiotics are continued. Aspirin is given 81 mg orally or via the nasogastric tube. Preoperative antianginals are discontinued.

On postoperative day 1, the large chest drains are removed after 3 hours of consecutive zero drainage and a post drain removal chest X-ray is taken and checked for pneumothoraxes. The central line and arterial line are removed. The patient is transferred to the stepdown unit, and helped to mobilize. Routine oral medication is commenced (usually aspirin 81 mg qd, furosemide 40 mg qd, preoperative statin, paracetamol 1 g qid, lactulose 10 mL bid, senna two tablets, and low-molecular-weight heparin such as enoxaparin 40 mg qd s/c). Patients who require formal anticoagulation are started on warfarin. Patients should be sitting out of bed, and start eating and drinking.

Over the next 2 to 5 days, the Foley and any remaining central venous, arterial

lines, and chest tubes are removed. The patient should complete a satisfactory stairs assessment with a physiotherapist. All blood results and imaging should be returning to normal values. Adequate pain control should be possible with regular Tylenol and occasional oral opiate analgesia. Pacing wires are removed if there is no conduction block or coagulopathy on postoperative day 4 to 6. Most valve patients should have a routine postoperative transthoracic echocardiogram. The patient should have passed stool before being discharged home.

Patient and Family Information for: CONTEMPORARY SURGICAL APPROACH TO VALVULAR DISEASE

WHAT THE PATIENT AND FAMILY NEED TO KNOW

The heart works by pumping blood though four one-way valves, and over time these valves may become too tight (stenosis) or leaky (regurgitation). This most commonly affects two valves on the left side of the heart—the aortic and mitral valves—and sometimes affects the first valve on the right side of the heart—the tricuspid valve. In all cases, this means that the heart has to work harder to accomplish its job of pumping 5 to 8 L of blood per minute around the body. If this happens slowly, then the heart can compensate by stretching and developing thicker muscle. But eventually the heart muscle reaches its limit, and heart failure can result. Before that, the effects of the extra work and compensation can be felt as chest pain, breathlessness, or dizziness with exercise. In advanced cases, fluids fill up in the lungs and patients may experience difficulty breathing even when lying down, and may have lower leg swelling.

Sometimes a murmur can be heard using a stethoscope, but usually the most accurate way to assess the problem is an echocardiogram, which is a type of ultrasound that measures the function and size of the chambers of the heart, and assesses the heart valves.

Mitral and tricuspid regurgitation can be repaired, which allows patients to keep their own valve tissue, with the advantage of not needing anticoagulation and less risk of needing repeat surgery in the future. Most stenotic valves cannot be repaired and need to be replaced: the options for replacement are either

mechanical valves or tissue valve (biologic). Mechanical valves are very durable, but need the recipient to take a blood thinner such as Coumadin for life. The risk of stroke and major bleeding is higher than with biologic valves, which do not need blood thinners. The disadvantage with tissue valves is that some patients will need repeat surgery as the valves eventually wear out over 10 to 15 years. For most people, a tissue valve is a good option.

Transcatheter aortic valve replacement is increasingly an option for treating aortic stenosis (AS), and for some people can replace a worn-out tissue valve. For most people, valve repair or replacement surgery is low risk, and the risk of major complications such as stroke is lower than the risk of dying or having a stroke if no treatment is carried out. Surgery usually takes 3 to 4 hours and is performed on the heart-lung machine, under a general anesthetic through a 2-to-5-inch incision usually in the front of the chest. Most patients are able to walk few days after surgery, and go home after 5 days.

The Care of the Adult Patient With Congenital Heart Disease in the Cardiac Care Unit

INTRODUCTION

Congenital heart disease (CHD) is the most common congenital lesion, estimated at 0.8% of newborns.[1–4] The medical and surgical revolution in the care of children with CHD over the recent decades has led to survival rates above 90% of children reaching adulthood. There are now more adults than children with CHD, with more than 1 million cases in the United States. Adults account for approximately 66% of the overall CHD population, and 60% of those with severe CHD.[5] A recent outcome study showed that survival of patients with adult congenital heart disease (ACHD) is increased when care is rendered in a center that has expertise in ACHD care.[6]

Care for the patient with ACHD in the cardiac care unit (CCU) is often challenging and requires meticulous investigation into the patient's past medical and surgical histories to understand complex pathophysiology. The patient and, commonly, the parents are an important source of information. One should enquire about the type of congenital defects and surgeries the patient underwent as well as the baseline vital signs, functional capacity, and known residual

lesions.

The physical examination may reveal and corroborate information. For example:

1. Left lateral thoracotomy scar may be a hint of a previous Blalock–Taussig (BT) shunt (communication between the subclavian and the pulmonary artery [PA] for lesions that obstruct pulmonary blood flow) or coarctation of the aorta (CoA) repair.
2. Blood pressure differences between the upper and lower extremities may suggest significant obstructive CoA.
3. Patients having Eisenmenger syndrome (ES) are cyanotic, have clubbing, an accentuated P2 component on cardiac auscultation, yet do not exhibit an impressive murmur of the original unrepaired shunt (eg, large ventricular septal defect [VSD]) because ventricular pressures have reached equilibrium.
4. Continuous murmur over the left upper chest with a wide pulse pressure may suggest a hemodynamically significant patent ductus arteriosus (PDA), aortic regurgitation (AR), or, in the relevant clinical setting, a sinus of Valsalva rupture.
5. Congenital pulmonary stenosis has a mid-systolic click on auscultation that decreases in intensity during inspiration (the only right-sided lesion that does not accentuate during inspiration).

To simplify the understanding of complex lesions and hemodynamics, the congenital clinical scenario could be deconstructed to basic components such as shunts and obstructive and regurgitant lesions. These are further incorporated to the common adult pathologies (eg, arrhythmia, heart failure [HF], ischemia, sepsis, hypovolemia, and pulmonary hypertension). A drawing of the heart with lesions may be useful.

Any evaluation of a change in the clinical status of a patient with ACHD warrants reevaluation of the anatomy using multimodality imaging (eg, transthoracic and transesophageal echocardiography [TTE, TEE], cardiac magnetic resonance imaging [MRI]) as well as a new hemodynamic assessment by a right-sided hemodynamic catheterization). Opacification of conduits, pathways, vascular structures, and baffles is often needed to further delineate the anatomy. In the setting of pulmonary hypertension, a vascular reactivity test with nitric oxide and oxygen may be useful to determine reversibility.

It is important to underscore the importance that ACHD cardiologists are to be

an integral part of the care team with congenital cases in the CCU. The ACHD team is a large collaboration between adult and pediatric clinical cardiologists, congenital imagers, and those in interventional cardiology, electrophysiology, intensive care, anesthesia, obstetrics, and genetics. Weekly complex case conferences with team members are encouraged.

The following sections detail specific congenital lesions followed by several fundamental topics.

SPECIFIC LESIONS

Shunt Lesions

In normal physiology, the pulmonary blood flow (Qp) and systemic blood flow (Qs) run in parallel and maintain an equivalent ratio of blood through both the circulations at any given time (Qp:Qs = 1:1). Any abnormal connection that allows oxygenated and deoxygenated blood to mix is called a shunt. Shunt calculations of Qp:Qs > 1 signify net left-to-right shunting, whereas Qp:Qs < 1 signifies net right-to-left shunting. Shunt lesions are further divided into pre-tricuspid lesion, such as atrial septal defects (ASDs) and partial anomalous pulmonary venous connection, and post-tricuspid lesions such as VSDs and PDAs. Pre-tricuspid lesions cause right-sided heart enlargement and post-tricuspid lesions cause left-sided heart enlargement. A Qp:Qs > 1.5 commonly denotes a significant shunt. The spectrum can vary from small ASDs or VSDs to near absence of delineation between the right and left heart, causing a single-ventricular mixing physiology. Commonly, shunt lesions with chamber enlargement are an indication for closure of the communication, unless there is evidence of irreversible pulmonary hypertension, which is the unfortunate sequela of chronic volume overload with or without pressure overload through the lung vasculature.[7]

CCU care of shunt lesions warrants delineation of the anatomy, shunt calculation (Qp/Qs, most accurate by cardiac magnetic resonance [MR] and cardiac catheterization), and assessment of the pulmonary pressures (by echocardiography and cardiac catheterization). The degree of shunting is influenced by the size of the shunt, compliance of the ventricles, and the downstream pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). Altering each of these components would change the degree of shunting.

We discuss the most common congenital shunt lesions including ASD, VSD,

and PDA.

Atrial Septal Defect

ASDs are among the most common CHDs encountered in adulthood (**Figure 41.1**).[8] ASDs typically cause left-to-right shunting and right-sided heart structure enlargement. The direction of the shunting occurs because of greater compliance of the right ventricle and thus lower right atrial pressure. The timing of the interatrial shunt is typically in late systole, early diastole, and during atrial systole. In situations where the right ventricular (RV) compliance is decreased and right atrial pressure is increased, ASDs may shunt right-to-left and cause cyanosis. Qp:Qs > 1.5 and an ASD larger than 1 cm are associated with a significant shunt. The clinical concern with ASDs is the development of RV enlargement and dysfunction due to volume overload, arrhythmias, paradoxic emboli, and the development of pulmonary hypertension. Although rare, the pulmonary vascular disease may progress to a fixed state that would cause the shunt to reverse and cause cyanosis, which is referred to as ES.

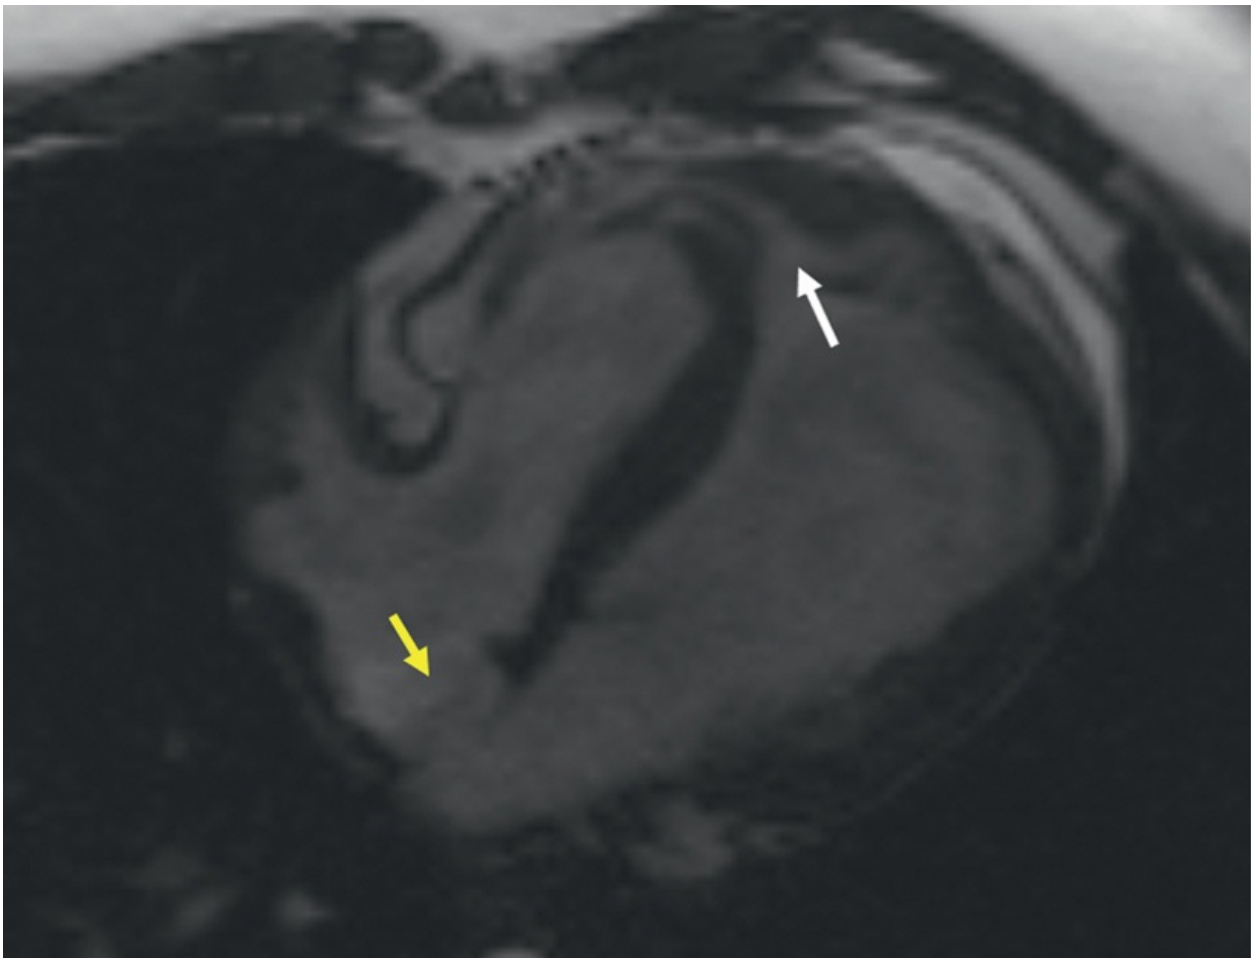

FIGURE 41.1 Shunts by CMR. Combination of a secundum atrial septal defect (*yellow arrow*) and an apical muscular ventricular septal defect (*white arrow*). The patient also has a relatively hypoplastic right ventricle compared to the left. CMR, cardiac magnetic resonance.

Clinically, the age and degree of symptoms vary according to the size of the shunt, direction of the shunt, and presence of other associated congenital malformations. The most common type of ASD is the secundum type, which is a deficiency of the septum primum, the major membrane forming the septum. The deficiency is located in the center of the interatrial septum. Other types include primum ASD, which is an inferior defect that is part of the endocardial cushions (junction between the atria and ventricles) and is associated with a cleft anterior mitral valve; sinus venosus defect is a deficiency in the tissue at the junction between the right atrium and the superior vena cava (SVC) or inferior vena cava (IVC) and is associated with anomalous pulmonary venous connections; and unroofed coronary sinus is a defect that opens between the coronary sinus (left-sided atrioventricular [AV] groove) into the left atrium and is associated with a persistent left SVC and could present with cyanosis.

Patients with ASDs commonly present by the fifth decade with exercise intolerance and/or arrhythmia. On physical examination, RV enlargement may cause an RV heave and on auscultation a wide and fixed splitting of S2 is characteristic of ASDs. Pulmonary hypertension will have a loud P2. Owing to the increased flow across the tricuspid valve (TV), a diastolic rumble that accentuates with inspiration may be heard. In primum ASD, which is associated with cleft mitral valve, murmur of mitral regurgitation can be appreciated. If a patient has ES, cyanosis and clubbing may also be present. Electrocardiogram (ECG) in secundum ASD shows right axis deviation, whereas in primum ASD it is left axis deviation; and the P waves in sinus venosus ASD are typically negative in the inferior leads. Otherwise, ECGs have rSr′ or rsR′ pattern due to RV hypertrophy, and the Crochetage pattern is a sensitive and specific sign of ASD described as a notch on the R wave in the inferior leads.

Echocardiogram is essential for diagnosis of an ASD and is helpful in identifying associated lesions. A TTE is also useful to evaluate the size and function of the right ventricle as well as direction of the shunt. Using Doppler echocardiography, pulmonary artery systolic pressure (PASP) and the ratio of Qp:Qs can also be estimated (however, these are not always accurate and are subject to errors). TTE is often adequate for diagnosis of secundum and primum ASDs. However, it is less sensitive for diagnosis of sinus venosus ASDs. Presence of right heart dilatation in the absence of an alternative etiology should always raise suspicion for an undiagnosed ASD on a TTE. TEE is typically needed for confirming diagnosis of sinus venosus ASD and unroofed coronary sinus. A TEE can identify anomalous pulmonary venous connection associated with sinus venosus ASD. A TEE is also helpful to evaluate the size of the ASD as well as to guide treatment options. Cardiac MRI is very useful for evaluating the degree of shunting (Qp:Qs), delineating the anatomy including identifying the pulmonary veins. In patients who cannot undergo a cardiac MRI, computed tomography (CT) may be considered. Lastly, once ASD repair is being considered, a cardiac catheterization is necessary to evaluate PA pressures as well as PVR and vascular reactivity because these factors impact the management of the ASD.

Indications for closure of ASDs are RV enlargement regardless of symptoms, paradoxic embolism, or orthodeoxiaplatypnea (dyspnea and cyanosis when sitting upright or standing). Secundum ASDs may be closed percutaneously with an ASD closure device, unless they are larger than 35 mm or have inadequate margins (<5 mm) and then surgical closure is warranted. Primum ASDs, sinus

venosus defects, and unroofed coronary sinus ASDs require surgical closure using a patch repair. Contraindications for ASD closure are evidence of irreversible pulmonary hypertension (ie, ES, PVR greater than two-thirds of SVR, or commonly PVR above 5 to 7 Woods units)

Patients with small, asymptomatic ASDs (typically <10 mm) with normal RV function and absence of pulmonary hypertension should be monitored.

Ventricular Septal Defect

VSDs are the most common CHD in children (**Figures 41.1** and **41.2**). VSDs are associated with left-sided heart enlargement and dysfunction and are more prone to cause pulmonary hypertension.[9]

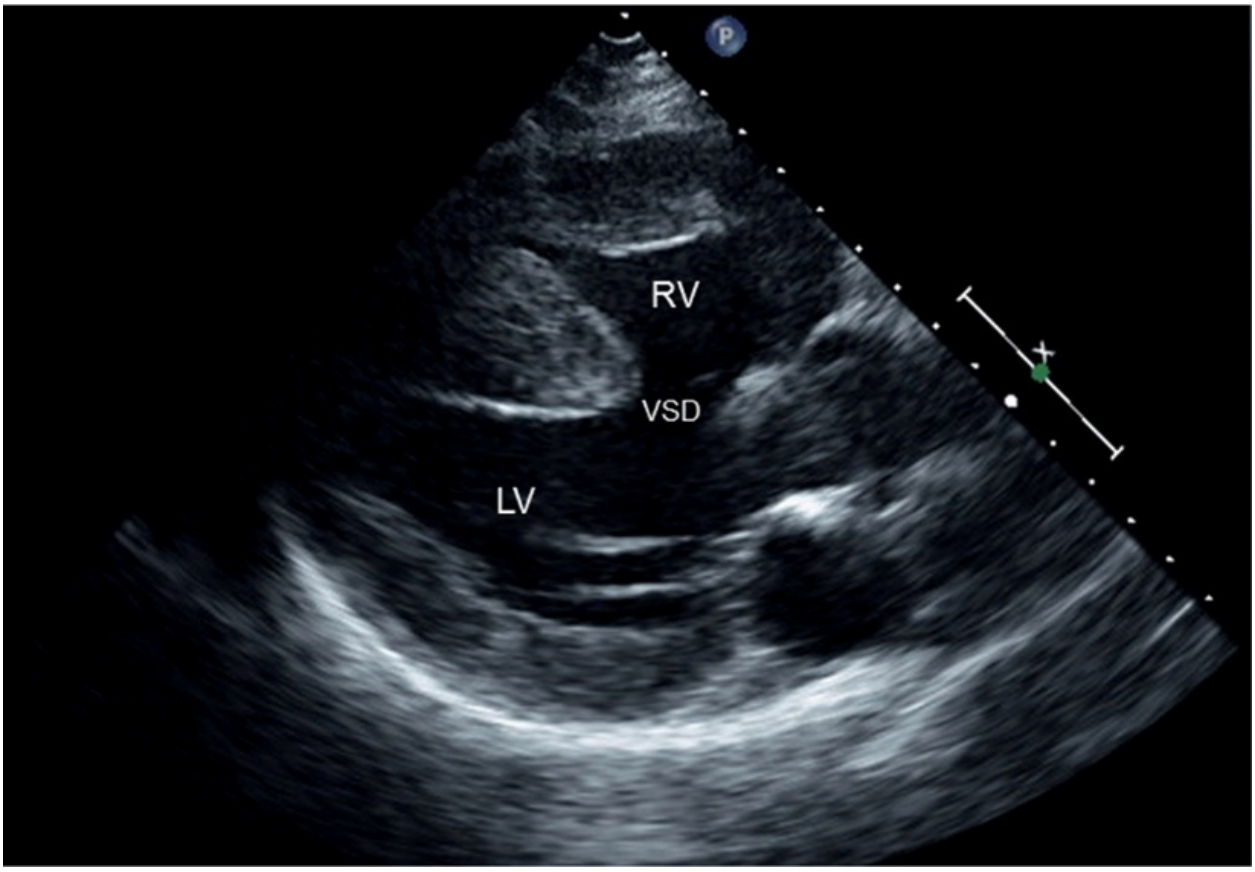

FIGURE 41.2 Large muscular VSD with Eisenmenger syndrome; transthoracic parasternal long-axis view echocardiography. The RV is severely hypertrophied. LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect.

The most common type is the membranous VSD, which is located next to the septal leaflet of the TV. Occasionally, it is associated within an aneurysm of the

TV-associated tissue and at times is occluded by the septal leaflet of the TV. Infundibular VSDs (also known as conal, supracristal, subpulmonary, subarterial, or doubly committed juxta-arterial) are common in the Asian population. These are typically located beneath the semilunar valves and are often associated with AR due to prolapse of the right coronary cusp of the aortic valve into the defect. Inlet VSD is a deficiency in the endocardial cushion (junction between the atria and ventricles) and is seen commonly in patients with trisomy 21. When associated with a primum ASD and a common AV valve, these constitute an atrioventricular canal defect (AVCD). Muscular VSDs (also called trabecular) are VSDs surrounded by muscle tissue and not infrequently are multiple. The types of VSDs that may close spontaneously in childhood (40% to 60% of VSDs) are the membranous and muscular types.

Clinically, the majority of patients in adulthood will not require any interventions, because isolated small VSDs remain asymptomatic. Moderate-sized VSDs already present with left-sided HF in childhood, and large VSDs present with HF in infancy or pulmonary hypertension in childhood. Interestingly, on physical examination the small VSDs present with a loud holosystolic murmur (large pressure gradient), whereas the large ones are minimally heard because there is equilibrium in pressure between the ventricles. As noted before, patients with ES would have cyanosis, clubbing, and signs of right-sided HF and an accentuated P2 on auscultation. Most patients with VSDs initially have relatively normal ECGs. Subsequently, as the left ventricle develops volume overload, signs of interventricular conduction delay and left ventricular (LV) enlargement may be noted. With the presence of Eisenmenger complex, signs of RV hypertrophy, right axis deviation may also be noted.

TTE is useful in visualizing the defect and assessing LV/RV size and function as well as pulmonary pressures. Cardiac MRI would provide supplemental visualization of the defect as well as more accurate shunt calculations. Cardiac catheterization is used to delineate anatomy and assess for pulmonary pressures as well as pulmonary vascular reactivity in the setting of pulmonary hypertension. A restrictive VSD is regarded as a small shunt with $Qp/Qs < 1.4$ and high-pressure gradients across the VSD. $Qp/Qs > 1.5$ denotes significant (moderate and above) shunt. LV enlargement with a $Qp/Qs \geq 2$ as well as symptoms or history of endocarditis without the presence of irreversible pulmonary hypertension are class I indications for VSD closure. Most VSDs require surgical patch repair; and if other concomitant lesions (such as aortic insufficiency) exist, they should be addressed as well. Percutaneous repair may

be considered for patients with an isolated uncomplicated muscular VSD and for membranous VSD bases on the anatomy. Asymptomatic patients with small VSDs can be followed up with serial imaging and follow-up. No endocarditis prophylaxis is warranted in patients with unrepaired VSDs.

Patients with ES are managed medically, which is discussed in a separate section.

Patent Ductus Arteriosus

PDA is a persistent communication between the aortic isthmus (junction between the aortic arch and descending aorta) and the main PA that causes a left-to-right shunt that may result in left-sided volume overload and pulmonary hypertension.[10] Usually, the ductus arteriosus, which is essential to the fetal circulation for blood flow from the heart to the lower part of the body, closes within 72 hours of birth. There is a female preponderance for PDA with a 2:1 ratio compared to male, and it is associated with congenital Rubella and birth at high altitudes as well as other congenital defects (ie, ASDs, VSDs, CoA). PDAs are primarily a clinical concern because of LV volume overload and dysfunction and a risk for endarteritis or endocarditis (commonly the pulmonary valve). The latter is estimated roughly as up to 1%/year.

The PDA shunt occurs continuously throughout the cardiac cycle in systole and diastole and sounds like “machinery” on auscultation. The direction of the shunt is from the aorta into the PA (left-to-right), and in the setting of a significant shunt, akin to AR, may cause a wide pulse pressure, low diastolic coronary filling pressures, and ischemia. With time, owing to the increased flow across the pulmonary bed, the PVR may rise, eventually leading to shunt reversal, right-to-left shunt, and Eisenmenger physiology. Because the shunt is connected between the PA and the aortic isthmus, the cyanosis only appears in the lower part of the body in the setting of ES, referred to as “differential cyanosis” (**Figure 41.3**).

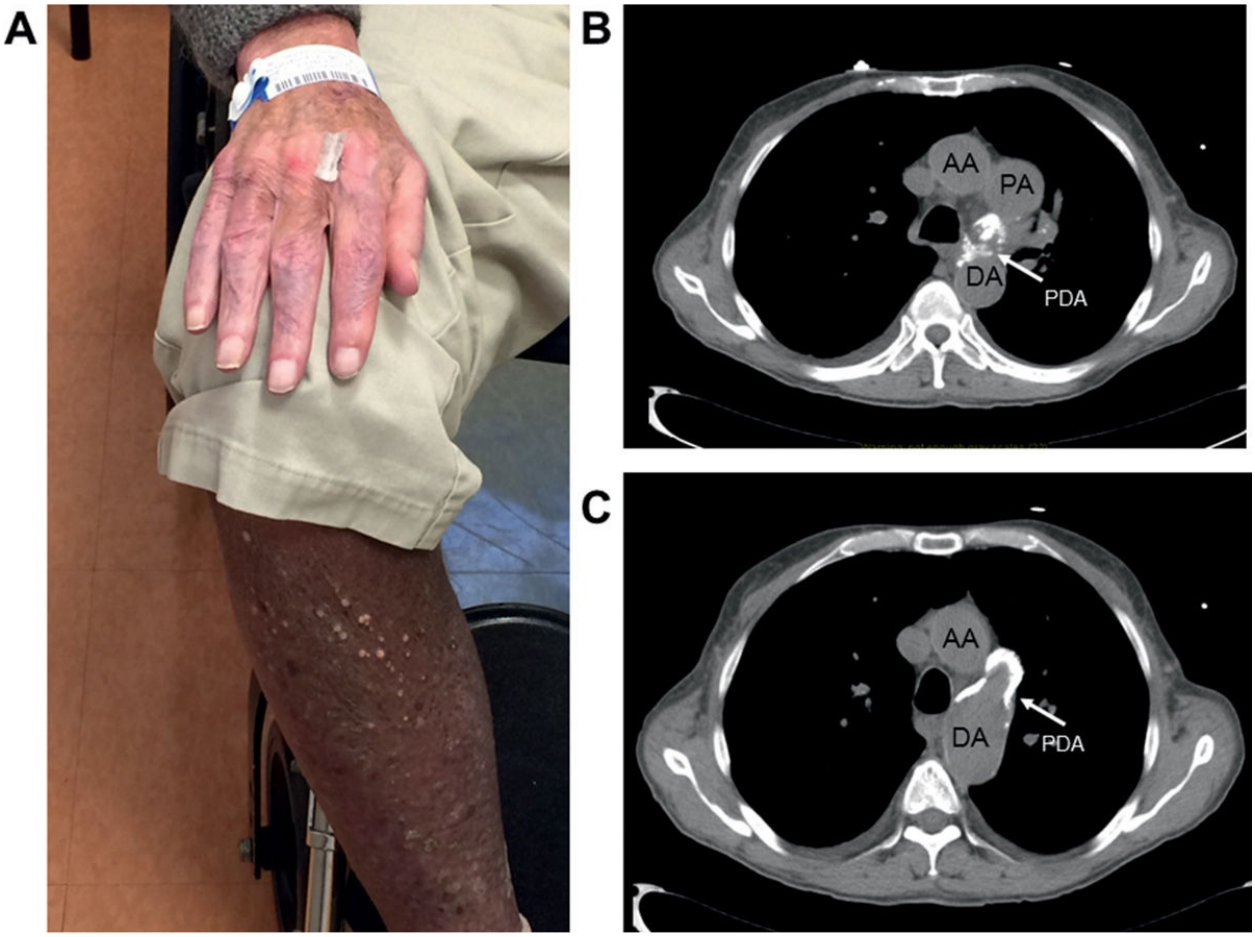

FIGURE 41.3 PDA complicated by Eisenmenger syndrome. A, "differential cyanosis," upper limbs proximal to the PDA are oxygenated and lower limbs beyond the PDA are deoxygenated, as pulmonary flow is shunting right-to-left through the PDA toward the lower body. B and C, two consecutive axial images of non–contrast-enhanced CT scan demonstrating a calcified large PDA *(arrow)* communicating between the DA and the PA. AA, ascending aorta; CT, computed tomography; DA, descending aorta; PA, pulmonary artery; PDA, patent ductus arteriosus.

The clinical presentation depends mainly on the size of the shunt and the presence of any concomitant lesions. Patients with small PDAs may remain asymptomatic and be incidentally diagnosed because of the presence of a murmur, whereas those with moderate-to-large PDAs typically present in early childhood and infancy, respectively, with signs of LV volume overload. Echocardiography is commonly the initial modality to make the diagnosis, and cardiac MR or CT angiography is supplemental for further delineation of the anatomy, Qp/Qs, and pulmonary pressure measurement in preparation for a catheter-based closure procedure.

Generally, any PDA that could be "heard" on auscultation during physical examination is designated for closure. According to guidelines, any PDA with

LV volume overload regardless of symptoms without irreversible pulmonary hypertension should be closed. Also, patients with a history of endocarditis should have their PDA closed. PDAs are occluded with coils or closure devices such as the Amplatzer ductal occluder.

BICUSPID AORTIC VALVE, COARCTATION, AND AORTOPATHIES

Bicuspid aortic valve (BAV) is a common congenital condition with an estimated incidence of 1% to 2% of the general population. The most common cusp fusion is between the right and left. Over time, BAVs can be either stenotic or regurgitant and may require aortic valve replacement in adulthood. BAV is associated with an aortopathy and increased frequency of ascending aortic aneurysms. Aortic root replacement is recommended when the aortic diameter exceeds 5.0 to 5.5 cm or if there is a rapid enlargement of the root (>5 mm/year).[11]

Frequently associated with BAV, CoA comprises a segmental narrowing of the aorta at the ligamentum arteriosum site adjacent to the left subclavian artery (**Figure 41.4**). Patients with significant CoA develop collateral vessels that mitigate the severity of the obstructive narrowing. More than half of patients with CoA have BAV, and about 10% of those with BAV, would be found to have CoA. Another association of CoA is Shone complex, which refers to multiple left heart obstructive lesions that include CoA, BAV, subaortic stenosis, parachute mitral valve, and supra-mitral valve ring.

FIGURE 41.4 Coarctation of the aorta by MR angiography. Three-dimensional reconstruction of the aorta demonstrating (*arrow*) a discrete coarctation of the aorta distal to the left subclavian artery and the area of the aortic isthmus. MR, magnetic resonance.

Patients with CoA commonly present with hypertension, exertional headaches, and leg claudication. CoA is an important diagnosis in the evaluation of systemic hypertension in the young. On physical examination, a significant CoA may cause an abnormally lower blood pressure measured in the lower limbs. However, a significant collateral network may mask these differences and a radial–femoral delay pulse check examination may be completely normal. In addition, carotid pulses may be hyperdynamic and a murmur or bruit may be present in the left interscapular area. Chest X-ray may show the “number 3” sign and rib notching. Patients with CoA are at risk for congestive HF, aortic rupture and dissection, endocarditis and endarteritis, intracerebral hemorrhage from associated brain aneurysms (5%), and myocardial infarction. Management of these patients includes consideration of percutaneous or surgical repair and medical therapy for hypertension. Blood pressure control in the setting of CoA may be challenging because excessive reduction of pressures beyond the coarctation may cause lower body hypotension, gut ischemia, and renal failure. By guidelines, intervention is recommended for patients who have a peak-to-peak gradient across the aortic narrowing as measured on cardiac catheterization greater than or equal to 20 mm Hg. Echocardiography measurements of the maximum instantaneous gradient across the area of coarctation commonly overestimate the peak-to-peak gradient measured in the catheterization laboratory. The mean gradient derived by TTE across the area of coarctation has been found to be more closely related to the peak-to-peak gradient. Cardiac MRI is very useful for delineation of the anatomy, collateral identification, and flow measurements in preparation for stent implantation, which is the preferred method of intervention in the adult patient. It should be noted that patients with CoA have accelerated atherosclerosis and ischemic heart disease, and these should be suspected in the relevant scenario.

TETRALOGY OF FALLOT

Tetralogy of Fallot (TOF) represents a spectrum of disease that is classically defined by four components: (1) subpulmonary infundibular/right ventricular outflow tract (RVOT) stenosis, (2) VSD (commonly membranous), (3) overriding aorta, and (4) RV hypertrophy. Frequently, these patients have small, stenotic pulmonary valves along with PA hypoplasia and stenosis, coronary anomalies, right aortic arch, as well as ASDs.

The embryonic pathophysiology is related to one single abnormal process—the anterior and cephalad deviation of the conal septum leading to right-sided obstruction with an aortic valve overriding the two ventricles. In the neonatal period, this disease causes lack of adequate pulmonary blood flow and cyanosis; and thus the initial treatment may include a shunt between the arterial and the pulmonary circulations (eg, BT shunt between the subclavian artery and the PA) followed by definite repair that includes surgical closure of the VSD and the relief of the RVOT obstruction, commonly using the transannular patch repair.

In the era of modern cardiac surgery, nearly all patients with TOF in the United States will have had reparative surgery early in life. Because the RVOT was resected and there is no functioning pulmonary valve, the major complication related to the TOF repair is chronic pulmonary regurgitation (PR) (**Figure 41.5**). Long-standing PR further begets RV dilatation and dysfunction, tricuspid regurgitation (TR), LV dysfunction related to RV/LV interactions (up to 30%) and tachyarrhythmias (intra-atrial reentrant tachycardia [IART], atrial fibrillation [AF], and VT). Other long-term complications include residual RVOT obstruction, residual VSD from a dehiscing patch, and patch-related TR. By clinical practice guidelines, pulmonary valve replacement (PVR) is warranted for severe PR in symptomatic patients with decreased exercise tolerance or clinical HF. In addition, it is generally agreed that PVR is also reasonable in asymptomatic patients with severe PR who exhibit moderate-to-severe RV enlargement (greater than indexed end-diastolic volume 150 cc/m^2, greater than indexed end-systolic volume of 80 cc/m^2) or dysfunction (right ventricular ejection fraction [RVEF] <47%), left ventricular dysfunction (left ventricular ejection fraction [LVEF] <55%), concomitant moderate and above TR, QRS >160 ms, severe AR, RVOT obstruction/aneurysm, or significant atrial or ventricular arrhythmias related to the right ventricle.[12] New native RVOT transcatheter pulmonary valves are in the investigational phase.

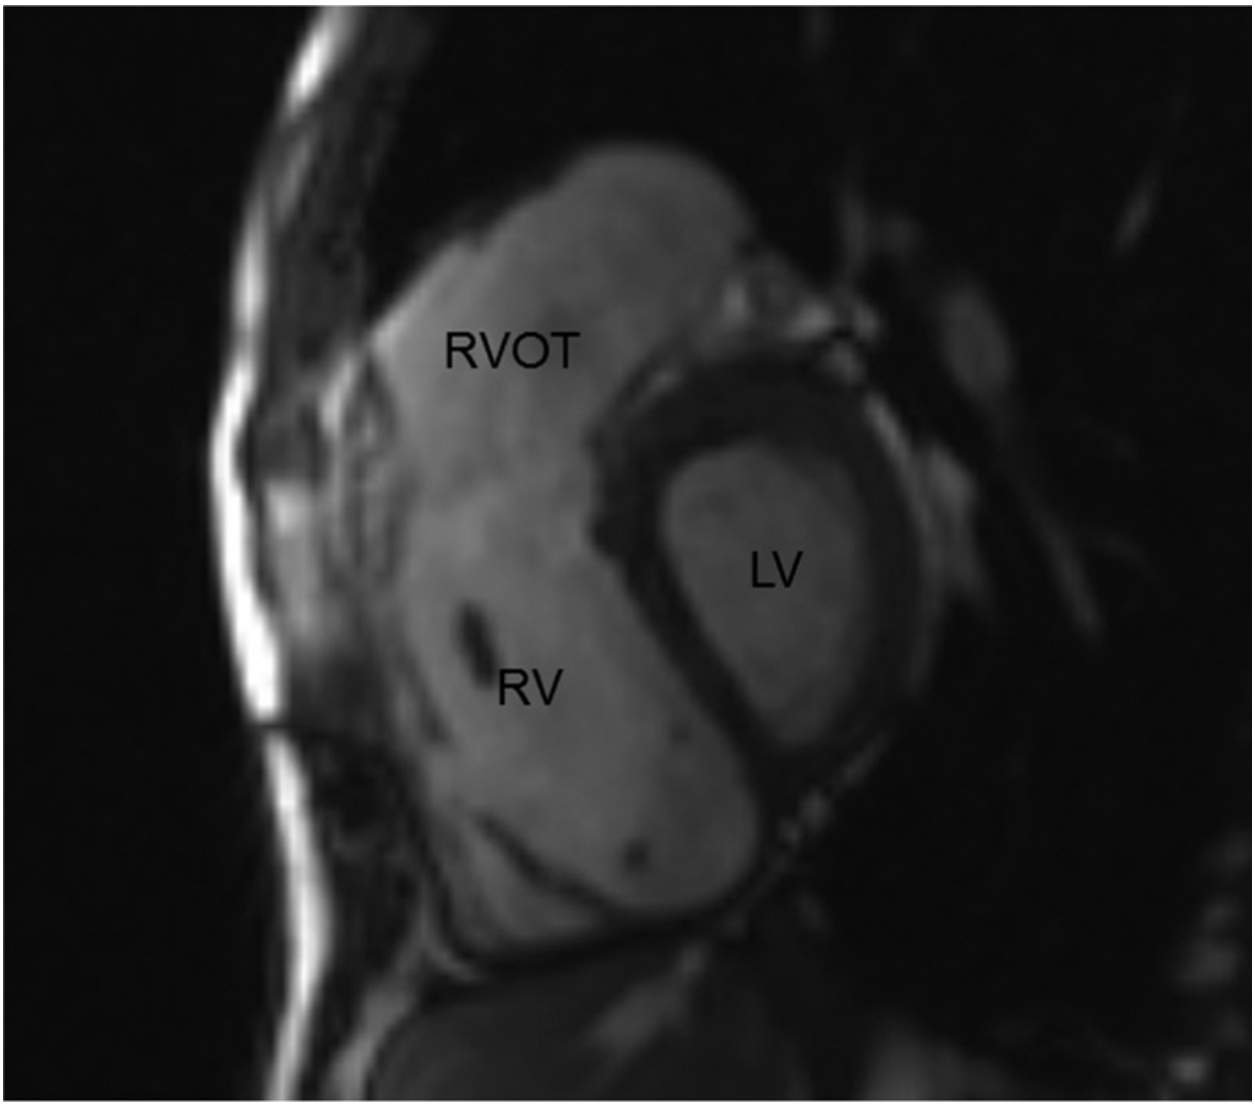

FIGURE 41.5 Repaired tetralogy of Fallot by CMR. Short-axis image demonstrating a severely dilated RV and an RVOT as well as free pulmonary regurgitation. There are no pulmonary valve leaflets identified. The septum is flat, suggesting RV volume overload compressing the LV. CMR, cardiac magnetic resonance; LV, left ventricle; RV, right ventricle; RVOT, right ventricular outflow tract.

Overall survival in repaired TOF is excellent, yet there is an increased risk of sudden cardiac death (SCD) later in life. Arrhythmias are related to surgical scar lines and dysfunctional right ventricle. SCD is estimated at 2% per decade in patients with repaired TOF, and overall arrhythmia frequency increases in the fifth decade. A QRS > 180 ms on ECG is a sensitive predictor of SCD in addition to morphologic findings such as RV hypertrophy and ventricular dysfunction. There is a direct relationship between the degree of RV enlargement/dysfunction and the degree of arrhythmias. Lastly, aortic root dilatation is also prevalent in patients with repaired TOF that could be explained

in part by the basic overriding aorta receiving an increased cardiac output and evidence of an intrinsic aortopathy.

Arrhythmia and HF related to RV and LV dysfunction are anticipated to be the diagnoses for admission to the CCU.

EBSTEIN ANOMALY OF THE TRICUSPID VALVE

Ebstein anomaly (EA) is a rare diagnosis and entails malformation of the TV in which there is failure of delamination (separation) of the septal and posterior tricuspid leaflets from the myocardium, causing the "functional" tricuspid annulus to be apically displaced[13] (**Figure 41.6**). The portion proximal to the annulus is dilated and the right ventricle proximal to the "functional" tricuspid annulus is similar in morphology to the atrium and thus is "atrialized." Because the posterior and septal TV leaflets are malformed, the anterior leaflet is often large and redundant; and, on physical examination, a systolic "snap" can be heard. This deformity leads to varying degrees of TR and rarely stenosis. EA is also associated with atrial communications (eg, patent foramen ovale [PFO], ASD), multiple accessory conduction pathways (ie, Wolf–Parkinson–White [WPW]), LV non-compaction, pulmonary valve abnormalities, PDA, and CoA. Clinical presentation varies and depends largely on the degree of malformation of the tricuspid leaflets, RV size and function, presence of associated cardiac lesions, and accessory pathways. For example, a first presentation to the CCU of a patient with EA may be collapse or SCD due to rapidly conducting AF in the setting of WPW. Others may present with exercise-induced cyanosis due to right-to-left shunting through an ASD or, more commonly, exercise intolerance due to RV dysfunction and severe TR. ECG shows "Himalayan" P waves, and the patient may have preexcitation with short PR interval and a very wide right bundle branch block. Echocardiographic diagnosis is based on apical displacement of the septal leaflet of the TV by more than 0.8 cm/m^2 from the true tricuspid annulus. TV repair of EA is surgically challenging and is warranted for decreased exercise tolerance, cyanosis, paradoxic embolism, and progressive RV enlargement and dysfunction. In the Cone procedure, the large anterior TV leaflet is manipulated to create a functional valve. If surgical repair is deemed impossible, a TV replacement is performed. In cases where the RV is considered too dysfunctional, a Glenn shunt (connection between the SVC and PA) may be performed to partially unload the right ventricle, that is, blood from

the upper part of the body would directly flow to the lungs bypassing the right ventricle. Lastly, accessory pathways should be ablated (see discussion in arrhythmia in adult congenital heart disease section).

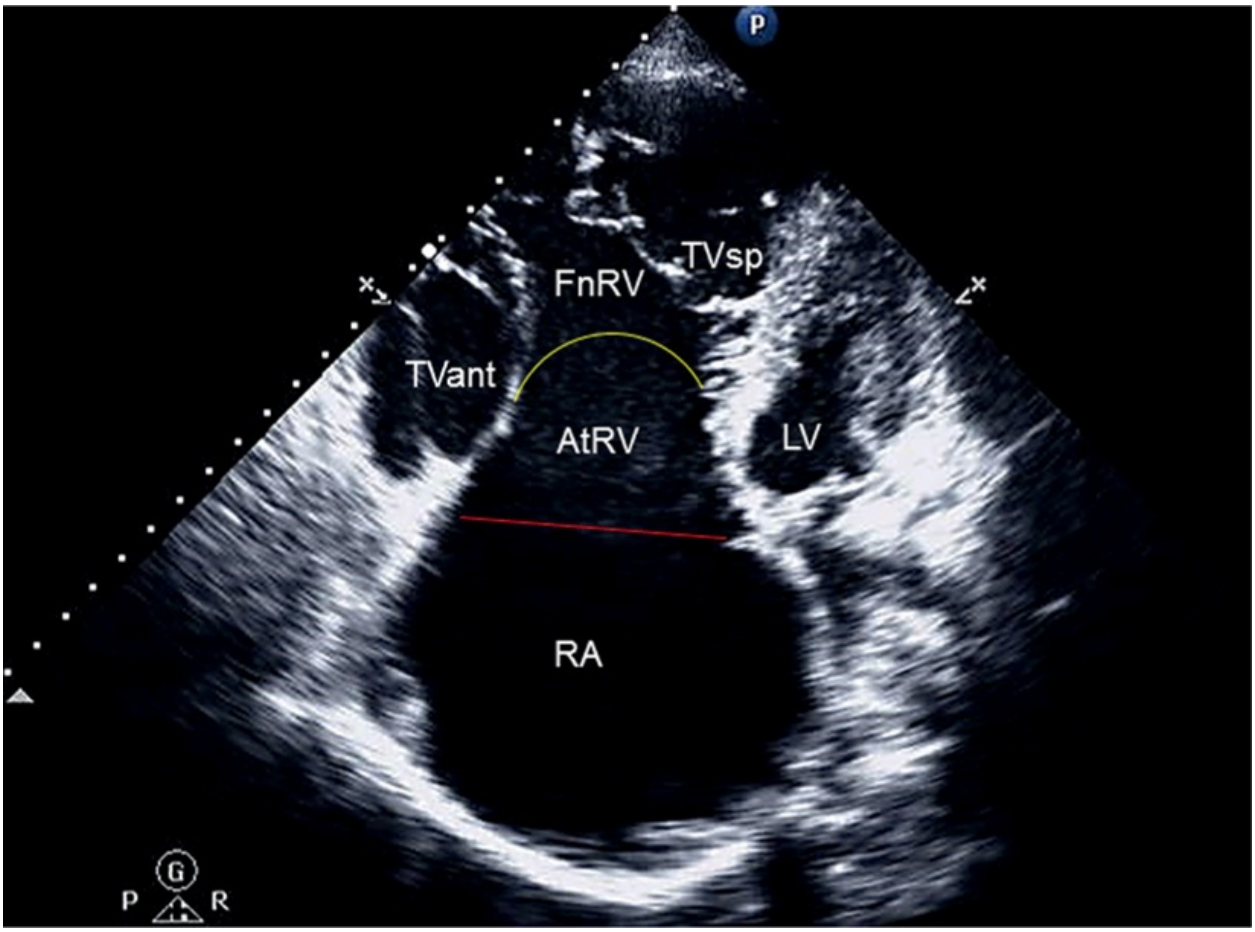

FIGURE 41.6 Transthoracic apical four-chamber view of Ebstein anomaly of the tricuspid valve demonstrating severe right ventricular dilatation, which is divided into a proximal atrialized portion (AtRV) and a distal function portion (FnRV) by the apicalized tricuspid annulus (curved yellow line). The apically displaced TVsp is diminutive in size and the TVant is large, redundant, and is connected to the anatomic tricuspid annulus (red line). The LV is small and compressed by the dilated right ventricle. Not seen in this figure, but the patient had severe tricuspid regurgitation. LV, left ventricle; AtRV, atrial right ventricle; FnRV, functional right ventricle; RA, right atrium; TVant, anterior leaflet of the tricuspid valve; TVsp, septal leaflet of the tricuspid valve.

PULMONARY ARTERIAL HYPERTENSION, CYANOSIS, AND EISENMENGER SYNDROME

Pulmonary arterial hypertension (PAH) occurs in approximately 5% to 10% of

ACHD. ES (**Figures 41.2 and 41.3**), which is the most extreme form of congenital PAH, is seen in about 1%.[14] The definition of PAH includes a mean PA pressure greater than or equal to 25 mm Hg with a normal capillary wedge pressure (<15 mm Hg). Congenital PAH is included in World Health Organization (WHO) group I category. ES typically occurs in patients with congenital defects that result in substantial unrestricted left-to-right shunting, most commonly VSD and AVCDs. Over time, the shunt causes detrimental hemodynamic effects with large increases in PVR (generally greater than 10 Wood units) that subsequently causes reversal or bidirectional flow across the existing shunt. Cyanosis and hemodynamic derangements depend on the degree of flow reversal across the shunt.

ES affects multiple organ systems because of the chronic cyanosis. The effects include secondary erythrocytosis with increased viscosity, iron deficiency anemia, thrombocytopenia, coagulopathy,[15] cerebral abscesses, microemboli, strokes, and renal dysfunction. Interestingly, the coronary arteries are ectatic with less atherosclerosis and calcifications.[16]

There are several unique management considerations for these patients including limitation of strenuous isometric exercise, dehydration, and chronic high altitude and warm environments. Active hydration is encouraged but may be challenging in the setting of chronic HF. Phlebotomy is offered for symptomatic patients with hyperviscosity symptoms such as severe headaches (commonly with hemoglobin >20 g%, hematocrit > 65%). Iron deficiency anemia is common and associated with increased frequency of strokes, yet careful correction is required because it increases the blood count further. Pregnancy is completely contraindicated because of the up to 50% maternal and fetal mortality, and termination of pregnancy should be counseled when possible.

Randomized controlled trials, the most notable being the BREATHE-5 (***B***osentan ***R***andomized Trial of ***E***ndothelin ***A***ntagonist ***THE***rapy-5), have demonstrated that patients with ES derive a clinical benefit from pulmonary vasodilator therapies (including prostanoids, endothelin receptor antagonists, and phosphodiesterase inhibitors). Although these patients are at an elevated risk of PA thromboembolism, the role of anticoagulation is not entirely clear because they are prone to bleeding such as hemoptysis. Oxygen supplementation has limited support but could be offered. Lastly, for those with advanced disease, heart–lung transplantation can be offered for selected patients on a case-by-case basis.

CCU care depends on the inciting pathology, yet general care of the patient

with ES includes intravenous (IV) filters, oxygen support as needed, maintenance of SVR (use of vasopressors as needed) and reduction of PVR (nitric oxide inhalation, IV prostacyclin therapy), and correction of arrhythmia and iron deficiency anemia. Decision making in regard to diuresis depends on the degree of HF in the setting of limiting hypovolemia and hyperviscosity.

TRANSPOSITION OF THE GREAT ARTERIES AND SYSTEMIC RIGHT VENTRICLE

In d-transposition of the great arteries (d-TGA), the aorta originates from the right ventricle and the PA from the left ventricle.[17] The aorta is usually situated anteriorly and to the right of the PA. The immediate palliation at birth is the creation of an ASD with a balloon because the two parallel circulations are not compatible with life. The original surgical correction for d-TGA was the atrial switch operation (ie, Mustard or Senning procedures) in which the systemic venous circulation was baffled to the LV and the pulmonary venous circulation to the RV (**Figure 41.7**). Long-term complications include baffle obstruction (commonly at the SVC junction), baffle leak with paradoxic emboli, systemic RV dysfunction, TR, and tachyarrhythmia (mostly atrial that may degenerate to ventricular). CCU evaluation of the d-TGA post atrial switch should include imaging of the baffles for obstruction/leakage, correction of arrhythmia, and HF support. Baffle leaks and obstructions could be treated with stenting.

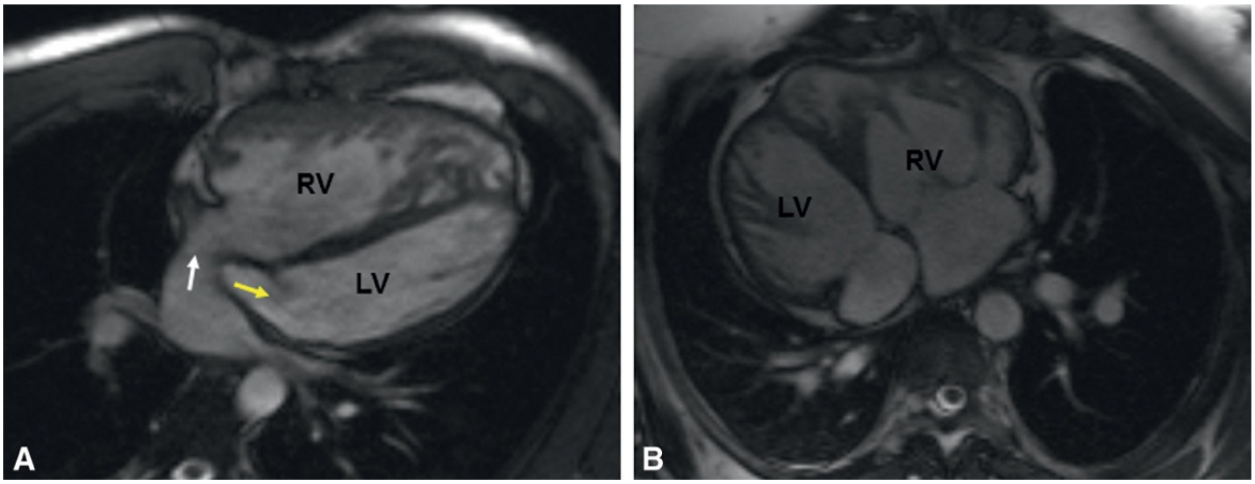

FIGURE 41.7 Transposition of the great arteries (TGA) with systemic right ventricles by CMR. A, d-TGA post atrial switch operation; white arrow denotes the pulmonary venous baffle and the yellow arrow denotes

the systemic venous baffle. B, Dextrocardia with congenitally corrected TGA (cc-TGA or levo-TGA [L-TGA]). CMR, cardiac magnetic resonance; LV, left ventricle; RV, right ventricle.

For the past 25 years, the arterial switch operation (ASO) or Jatene procedure has been the standard surgical approach to treatment of d-TGA. This procedure restores normal anatomy, yet has its own set of complications including coronary obstruction, aortic dilatation, and supra-pulmonary stenosis. A d-TGA post ASO should always raise suspicion of ischemia. Of note, the patient may have damaged cardiac innervation and not have classic complaint of angina.

In congenitally corrected transposition of the great arteries (cc-TGA or levo transposition of the great arteries [L-TGA]), the ventricles are inverted, and the morphologic right ventricle is situated on the left side and is connected to the aorta (so-called “double discordance”—AV and ventriculoarterial). The aorta is anterior and to the left of the PA. Long-term complications include TR (in 90%, the TV is abnormal), heart block (1% to 2%/year), outflow tract obstructions, and systemic RV dysfunction. Common surgeries for cc-TGA are TV repair, and at present children undergo double-switch operation with a simultaneous arterial switch and atrial switch for complete anatomic repair.

To reiterate, both d-TGA post atrial switch and cc-TGA share the same pathology of a systemic right ventricle (**Figure 41.7**). The systemic right ventricle, acting as the main pumping chamber to the aorta, is subjected to both increased pressure and volume load and thus develops HF. Interestingly, the TR seen in cc-TGA is primarily related to an abnormal TV and thus has the benefit of being corrected/replaced before worsening the systemic RV function (per guideline before RVEF of 40%); whereas in d-TGA post atrial switch, the TR seen is functional and related to systemic RV dilatation and dysfunction. Also, because the right coronary artery is still the main coronary providing blood to the chamber, ischemia may develop because of supply–demand mismatch. Potentially advanced HF therapies may be offered in the setting of intractable systemic HF (see Heart Failure in adult congenital heart disease section).

SINGLE VENTRICLE AND FONTAN PALLIATION

Single ventricle anatomy is one of the more challenging and complex ACHD pathologies (**Figure 41.8**). The term encompasses several different conditions including tricuspid atresia, mitral atresia, double-inlet left ventricle, and hypoplastic right or left ventricle. In caring for the patient with ACHD having

single ventricle anatomy, it is important to note that most of these patients have had several staged procedures early in life culminating in the Fontan operation.[18] Broadly, the Fontan operation is a palliative procedure in which systemic venous return is routed directly to the pulmonary arterial circulation. The systemic venous circulation flows passively into the lungs, now propelled by the negative intrathoracic pressure, skeletal muscles, and gravity of the blood from the upper part of the body. The hemodynamic consequence of the Fontan circulation is chronically elevated systemic venous pressures that eventually cause chronic liver congestion, ascites, leg varices, and promote lymphatic congestion that may cause protein-losing enteropathy (PLE)[19] and plastic bronchitis. Current Fontan surgery includes a total cavopulmonary connection that consists of an extracardiac conduit or lateral tunnel baffle (within the right atrium) connecting to the PA from the IVC and a Glenn shunt connecting the SVC to the PA from above. An older version of the Fontan palliation consisted of atriopulmonary connection (right atrium connected to the PA) that resulted in an extremely large right atrium that promoted arrhythmia and clot formation.

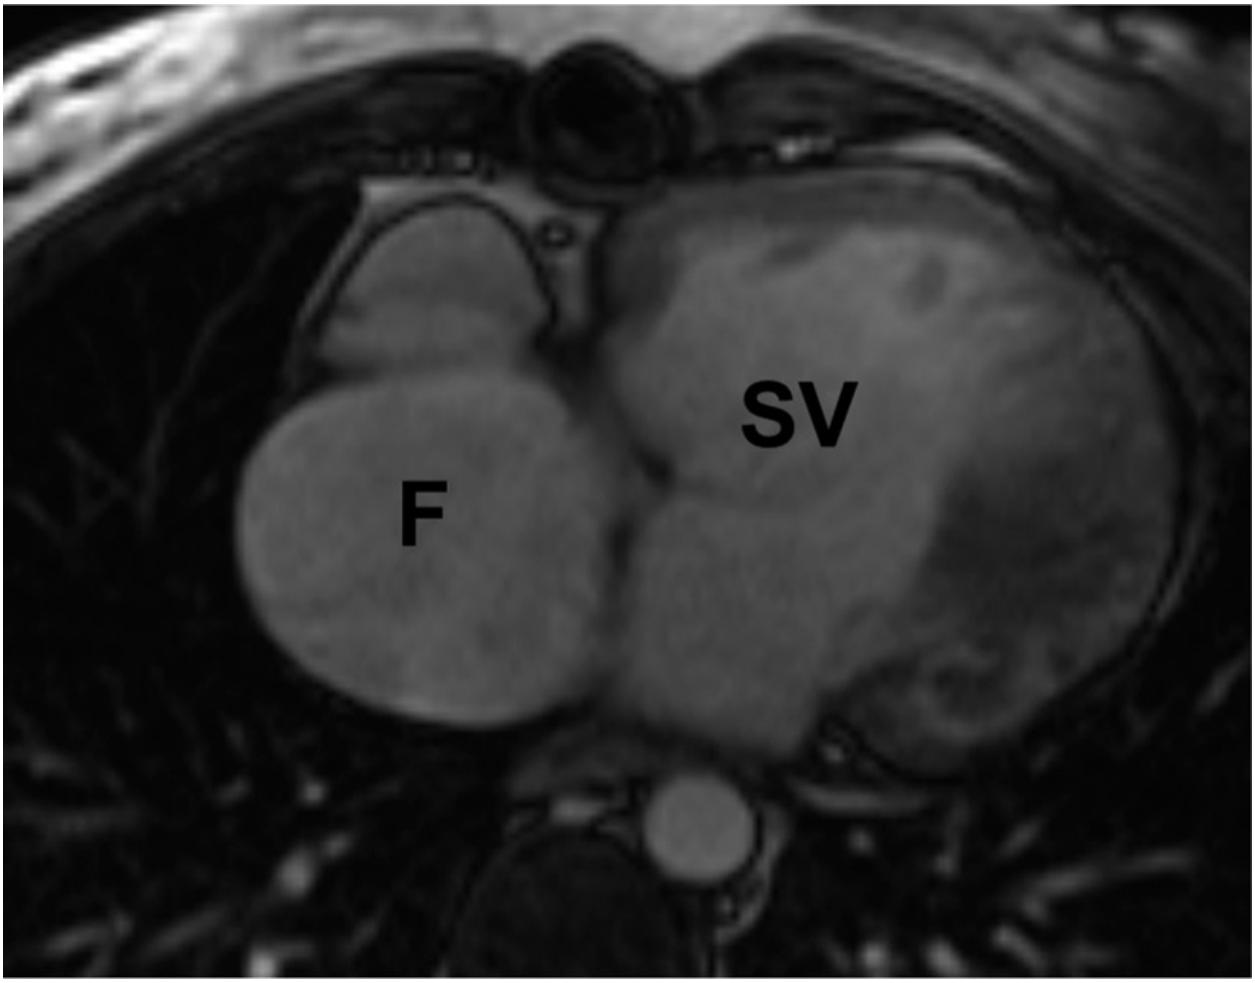

FIGURE 41.8 Fontan circulation by CMR. Baseline anatomy is double-inlet left ventricle with an atriopulmonary Fontan circulation. CMR, cardiac magnetic resonance; F, Fontan; SV, single ventricle.

The patients should be followed up closely by an ACHD specialist, particularly as several characteristic long-term issues arise including atrial arrhythmias, right atrial thrombus often necessitating systemic anticoagulation, single ventricular dysfunction, systemic AV valve regurgitation, cyanosis (due to veno-veno collaterals, pulmonary arteriovenous malformations, residual shunts, open fenestration, lung disease), hepatic congestion with deterioration of liver function from fibrosis to frank cirrhosis,[20–22] PLE, and plastic bronchitis. Although the 10-year survival after a Fontan is estimated to be 90%, many of these patients do require reoperation in adulthood and the long-term survival is protracted with SCD, thromboembolism, and HF being the most common causes of death.

CCU care for the patient with a Fontan circulation requires a thorough understanding of the limitation of having a passive pulmonary circulation. Any

increase in left atrial pressure (eg, LV dysfunction, AV valve regurgitation, LV outflow tract obstruction) or increase in PVR (eg, pulmonary baffle obstruction, pulmonary hypertension, pneumonia, pneumothorax, and obstructive sleep apnea) may hinder the passive flow and decrease the cardiac output. Arrhythmia is commonly supraventricular and not tolerated well, and therefore cardioversion is commonly the initial step in the treatment. A common caveat is that in such patients, a heart rate of 120 beats/min is commonly atrial flutter (IART). Furthermore, volume management is challenging because HF, cirrhosis, lymphatic obstruction, and chronic hypoalbuminemia contribute to chronic anasarca. End-stage patients require increasing dosages of diuretics and repeated paracentesis. Patients with atriopulmonary Fontan, which is the older version of the connection, may be offered a "Fontan conversion" in which the connection would be changed to an extracardiac version with plication of the right atrium and placement of a pacing system. The conversion reduces the frequency of arrhythmia and increases the efficiency of the circuit.

GENERAL TOPICS OF DIAGNOSIS AND MANAGEMENT IN ADULT CONGENITAL HEART DISEASE

ARRHYTHMIA IN ADULT CONGENITAL HEART DISEASE

Cardiac arrhythmias are a leading cause of morbidity and mortality in the ACHD population. The burden of arrhythmias increases with age, number of cardiac surgeries, and the complexity of the congenital lesion.[23,24]

Atrial Arrhythmias

The most common atrial arrhythmia in the ACHD population is IART. It may originate within the natural conduction channels (ie, the cavotricuspid isthmus) or iatrogenic conduction channels (suture lines or patches). IART commonly occurs in patients who have undergone surgical atrial manipulation (eg, atrial switch operations or Fontan procedure). Electrocardiographically, it will appear similar to atrial flutter, yet usually slower in rate (250 to 400 ms) and frequently conduct 2:1 to 1:1. Like in AF, these patients are at risk of thromboembolic complications. Hemodynamically unstable patients should be cardioverted emergently. Antiarrhythmic drugs may be considered for rate or rhythm control but have low efficacy. Therefore, these are typically treated with catheter ablation. The success of ablation procedures ranges from 55% to 90% depending

on the anatomy of the burden of fibrosis in the atrium. These arrhythmias may recur post ablation; and in select patients, surgical (intraoperative) ablation may be indicated.

AF is also a commonly encountered arrhythmia in ACHD and its frequency increases with age. Because AF arises from the left atrium, lesions affecting the left-sided structures are associated with AF; for example, mitral valve deformities and single ventricle or aortic stenosis. It should be noted that often times AF may occur in association with sinus node dysfunction with a slow ventricular response. Treatment strategies include class III antiarrhythmics and may warrant catheter or surgical pulmonary vein isolation. Anticoagulation should be prescribed in accordance with the AF guidelines to prevent thromboembolic complications.

Accessory pathways predispose patients with ACHD to tachyarrhythmias, and some may be life-threatening. WPW syndrome is commonly associated with EA (found in about 20% of patients), and congenitally corrected TGA with an Ebstenoid malformation of the left-sided TV. The location of the multiple accessory pathways is usually in the vicinity of the tricuspid annulus. The treatment typically includes catheter ablation of the pathway; however, it is often challenging because of the altered anatomy and the presence of multiple pathways.

Ventricular Tachycardias and Sudden Cardiac Death

The overall incidence of SCD in patients with ACHD is about 1% per decade but may be higher in more complex lesions and typically increases with age. The highest risk lesions include repaired TOF, EA, and congenital aortic stenosis. As in patients with HF, systemic ventricle dysfunction is the major risk factor for SCD. Any hemodynamic compromise or stress on the ventricles can increase the risk of malignant arrhythmias. In TOF, the risk of SCD is approximately 2% until adolescence, but acutely rises to 6% to 10% per decade in adulthood. RV enlargement and longer duration of the QRS width have also been correlated with SCD. Holter monitor and in select patients electrophysiologic (EP) study may be performed for risk stratification. Evidence of non-sustained ventricular tachycardia (VT) on Holter or inducible VT on EP study has been shown to predict risk of SCD in patients with TOF. In patients with congenital aortic stenosis or CoA, the risk of SCD directly correlates with the severity of the gradient across these lesions. VTs should be managed similarly to the general population, whereby hemodynamically unstable patients warrant emergent

defibrillation. Implantable cardioverter defibrillators (ICDs) are indicated for prevention of SCD. The indication for ICD implantation in patients with ACHD is largely similar to the general adult population. ICD implantation can often be challenging and have higher risk because of the distorted anatomy and prior surgeries. At times, epicardial ICDs may be implanted if venous access cannot be obtained. In select patients, subcutaneous ICDs are implanted. Patients with monomorphic VT can also be considered for VT ablations. Cardiac resynchronization therapy (CRT) is a primarily effective therapy for restoring electromechanical synchrony in the morphologic left ventricle. Owing to the altered anatomy, CRT is less effective in patients with ACHD with systemic right ventricles or single ventricles.[25]

Bradyarrhythmias

Sinus node dysfunction is common as a result of direct injury after a surgery. Rarely is the sinus node congenitally absent. Sinus node dysfunction is commonly seen after atrial switch operations (ie, Mustard and Senning) for d-TGA or after a Fontan operation. The bradycardia may predispose patients to higher incidence of atrial tachyarrhythmias. Because the AV node is embryologically a part of the AV canal, congenital anomalies including AV canal defects can lead to AV block. cc- TGA is also a common congenital cause of complete heart block as the AV node has an aberrant location. Similar to sinus node dysfunction, AV block can also occur post surgically (eg, post VSD or TOF repair). Treatment inevitably includes a pacemaker implantation. However, it should be noted that transvenous pacemaker implantation in the patient with ACHD is often challenging and requires thoughtful planning based on the anatomy, presence of intracardiac shunts, and patency of the venous system. Transvenous pacemakers are contraindicated in patients with atrial or ventricular shunts because of the risk of thromboembolism. In such cases, epicardial lead placement may be considered; however, this requires surgical access and is technically a more arduous procedure.

HEART FAILURE IN ADULT CONGENITAL HEART DISEASE

HF portends worse prognosis and increased mortality in patients with ACHD and is a major mode of death.[26,27] Of note, patients with ACHD may present with atypical symptoms compared to the general population; hence, a high index of suspicion must be maintained for the diagnosis. More commonly, patients

with ACHD develop heart failure with reduced ejection fraction (HFrEF), which can be due to pressure or volume overload, valvular dysfunction, alteration in the myocardial architecture (eg, non-compaction), ischemia, or arrhythmias.[28] However, heart failure with preserved ejection fraction (HFpEF) is probably under-recognized and has been implicated in patients with obstructive physiology (eg, Shone complex) or restrictive physiology. Presenting symptoms vary according to the affected ventricle. Involvement of the systemic ventricle regardless of morphology typically leads to symptoms of pulmonary congestion including shortness of breath, orthopnea, paroxysmal nocturnal dyspnea, wheezing, and reduced exercise tolerance. If the sub-pulmonic ventricle is involved, the symptoms are typically that of "right-sided HF," which include fatigue, weight gain, increased abdominal girth, and bloating. A combination of the symptoms will occur in patients with biventricular failure. Patients with shunts may present with worsening cyanosis and, frequently, the first presentation is new onset of arrhythmia.

During the diagnostic investigation, laboratory testing, imaging, and, frequently, a new hemodynamic study (ie, right heart catheterization) is performed. Imaging is important to assess ventricular and valve function as well as conduit/baffle/pathway patency and functionality. Commonly, an echocardiogram is initially performed and cardiac MRI or CT (for pacemaker-dependent patients) is added for supplementation of data. Cardiopulmonary exercise test is helpful to determine the exercise capacity and the peak oxygen consumption (VO_2). Lower VO_2 values predict higher mortality and can help guide the need for advanced HF therapies, commonly peak VO_2 less than 14 cc/kg/min.[29]

When patients with ACHD have IV access, air filters should be placed on IV tubing to prevent paradoxic embolization of air and thrombus, because many patients will have residual shunts. In addition, establishment of arterial and central venous access can be difficult because the vascular anatomy may be altered and the patients frequently have occlusion of multiple arteries and central veins due to prior procedures. In patients with Glenn shunts (ie, communication between the SVC and PA), namely, most patients with Fontan circulation, the tracing in a central line represents the pulmonary pressures and not the right atrium.

B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) are helpful for management and prognostication. BNP levels correlate with the functional class and degree of shunt severity. However, in asymptomatic

patients, there is no significant correlation between the degree of hypoxia and BNP levels. High BNP levels typically reflect elevated cardiac filling pressure, worsening valvular function, and chamber enlargement. In TOF patients, studies have found a correlation between BNP levels and the degree of RV dilatation as well as the severity of PR. In addition, the BNP levels decrease after pulmonary valve replacement. Rather than the absolute BNP value, the trend in BNP may be more helpful in evaluation of patients with HF. In addition, presence of anemia, liver/renal dysfunction, and hyponatremia portend a worse prognosis.

Limited data exists regarding the medical and surgical management of HF in patients with ACHD. However, understanding the underlying pathophysiology is key to tailoring the management in this patient population. For example, vasodilator therapy for HFrEF of the LV in a patient with right-to-left shunt will cause increase in shunt flow and should be used cautiously.

Medical management of HFrEF of the morphologic left ventricle is similar to the general management of HF, which includes diuretics, β-blockers, angiotensin-converting enzyme inhibitors/angiotensin receptor blockers, and mineralocorticoid receptor antagonists. For HFrEF of a systemic RV (eg, cc-TGA, d-TGA post atrial switch) data are extremely limited. Symptomatic patients with signs of congestion may be treated similar to LV failure with diuretics, β-blockers, and neurohormonal blockade. However, in asymptomatic patients, the utility of β-blockers and neurohormonal blockade is not known and cannot be routinely recommended. In addition, in patients with d-TGA post atrial switch, venodilators that reduce preload may impair ventricular filling and cardiac output, and β-blockers should be used cautiously because sinus node dysfunction is common. Morphologic right ventricle in the subpulmonary position (normal anatomy) is commonly managed with diuretics, possibly digoxin, and in the setting of pulmonary hypertension with pulmonary vasodilators (ie, phosphodiesterase inhibitors, endothelin antagonists, or prostacyclins). Single ventricle post Fontan operation patients with HFrEF are commonly treated with diuretics and standard HF therapy as well as advanced PH therapies when applicable, yet data are scarce. In regard to HFpEF management, no medications have been found to improve survival in this group of patients with HF. For symptomatic relief of volume overload, diuretics should be used.

In critically sick patients with acute HF, extracorporeal membrane oxygenation and ventricular assist devices (VADs), right or left sided, may be considered. A VAD also has a role in bridge to transplant in patients with

advanced HF. A thorough evaluation of the vascular anatomy and patency should be conducted before deployment of these therapies.

Ultimately, patients with irreversible and medically refractory HF should undergo evaluation for heart transplant. A very detailed workup is performed to evaluate candidacy for heart transplant. Irreversible pulmonary hypertension should be ruled out before transplant to ensure favorable outcomes, or the patient should be considered for a heart–lung transplant.

Lastly, cardiopulmonary rehabilitation is recommended because limited data have demonstrated improved quality of life measures and safety.

PREGNANCY IN ADULT CONGENITAL HEART DISEASE

Medical care for these patients begins in the preconception period with careful planning that takes into account anticipated hemodynamic shifts and possible complications throughout pregnancy and labor orchestrated by a multidisciplinary team.[30] Although a detailed discussion of management strategies for specific congenital disorders is beyond the scope of this chapter, it is important to note that the normal hemodynamic changes in pregnancy may unmask previously undiagnosed CHD or exacerbate residual lesions. Several disease conditions have been designated as contraindicated to undergo pregnancy (according to the modified WHO classification), including PAH, severe systemic dysfunction (LVEF < 30%, NYHA class III to IV), severe mitral stenosis, severe symptomatic aortic stenosis, Marfan syndrome with dilated aorta >4.5 cm, BAV with aortic dilatation >5 cm, and severe CoA. As a general rule, with the increased blood volume and decreased SVR, regurgitant lesions tend to be tolerated (eg, PR in TOF, TR in EA), moderate and above stenotic lesions may become symptomatic and hemodynamically significant (eg, aortic stenosis), aortic dimensions enlarge (patients with connective tissue disease are most susceptible), systemic ventricular dysfunction may worsen, and the frequency of arrhythmia may increase. Fetal ultrasound is recommended at 18 weeks of gestation owing to the increased likelihood of CHD in the offspring of a patient with ACHD (from 0.8% in the general population to 3% to 6%) as well as genetic evaluation.

INFECTIVE ENDOCARDITIS IN ADULT CONGENITAL HEART DISEASE

Patients with ACHD have inherently the highest risk of contracting infective

endocarditis (IE) among the different cardiovascular populations owing to the abundant use of prosthetic material and the presence of shunts within their hearts.[31] In the CCU setting, any patient with ACHD who presents with clinical sepsis should immediately raise suspicion of IE, especially if the patient has had a recent dental procedure. Vegetations tend to develop on prosthetic material or in areas of turbulent flow that damage the endothelium (eg, septal leaflet of the TV from a membranous VSD jet or the pulmonary valve from a PDA jet). Treatment considerations are the same as those for the general population. Right-sided lesions such as pulmonary or TV endocarditis are usually well tolerated and the risk of systemic embolization depends on the presence of a concomitant shunt. Long-term follow-up of prosthetic conduits or graft endocarditis may be performed by serial positron emission tomography-fluorodeoxyglucose studies and inflammatory markers.

Primary prevention according to guidelines[32] currently recommends antibiotic prophylaxis for IE before dental procedures for ACHD with history of IE; prosthetic valves; uncorrected/palliated cyanotic CHD (including with shunts/conduits); completely repaired CHD (surgically or with a device) for the first 6 months and repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch/device that inhibits endothelization. In addition, the ACHD guidelines recommend IE prophylaxis before vaginal delivery in patients with prosthetic valves.[1]

COMORBID CONDITIONS

Noncardiac comorbidities are common in patients with ACHD. Renal dysfunction is present in up to 50% of young patients with ACHD, with up to 10% having moderate-to-severe dysfunction with a glomerular filtration rate <60 mL/min.[33] Similarly, restrictive lung disease is prevalent and results from prior sternotomies and thoracotomies, diaphragm dysfunction, parenchymal lung disease from perioperative insults, and cardiomegaly. These patients may also develop plastic bronchitis.[34] Patients with ACHD having chronic elevation in central venous pressure, such as patients with Fontan physiology or RV dysfunction, may have hepatic dysfunction and cirrhosis that may lead to abnormalities in coagulation, as well as to portal hypertension and esophageal varices.[20] Fontan patients are also at risk for the development of PLE.[19] In patients with cyanosis, hematologic abnormalities are common and include iron deficiency despite erythrocytosis, thrombocytopenia, platelet dysfunction, and

factor deficiencies.[15] Longitudinal studies of the neurocognitive development of patients with CHD have also revealed that neurodevelopmental and behavioral abnormalities are common in this population, as are abnormalities on brain MRI.[35] Presence of noncardiac abnormalities may significantly impact overall outcomes in patients with ACHD.

CONCLUSION

The majority of patients with CHD are reaching adulthood and require a new knowledge base and management considerations by the treating cardiologist. ACHD specialists are a valuable resource for the care of these fascinating and complicated patients.

INTENSIVE CRITICAL CARE

Mechanical Ventilation in the Cardiac Care Unit

MECHANICAL VENTILATION

Mechanical ventilation is a life support method by which a device supports the partial or total transport of oxygen and carbon dioxide between the environment and the pulmonary capillary bed. Mechanical ventilation itself is not a treatment modality, but rather a supportive measure. The physiologic and clinical objectives are to restore homeostasis and support respiration as the underlying pathology is being treated (**Table 42.1**).

TABLE 42.1 Objectives of Mechanical Ventilation

- Improve pulmonary gas exchange by supporting alveolar ventilation and arterial oxygenation
  - Improve hypoxemia
  - Improve acute respiratory acidosis
- Decrease the metabolic cost of breathing by unloading the muscles of respiration
  - Ease respiratory distress and respiratory muscle fatigue
- Reduce systemic or myocardial oxygen consumption
- Prevent or improve atelectasis
- Reduce the risk of ventilator-associated lung injury

The causes of respiratory failure may be divided into hypoxemic and hypercapneic (**Table 42.2**). The majority of patients being admitted to a cardiac

care unit with respiratory failure falls into the category of hypoxemic respiratory failure due to cardiogenic pulmonary edema. Cardiogenic pulmonary edema causes decreased lung compliance, ventilation-perfusion mismatching, and diffusion impairment. Hypoxemia of mild-to-moderate severity can often be managed by the administration of oxygen through delivery systems ranging from nasal cannula to facemasks. However, it can be increasingly difficult to maintain adequate oxygenation and oxygen delivery with more severe hypoxemia, and these patients may require positive-pressure ventilation (PPV).

TABLE 42.2 Causes of Respiratory Failure

Hypercapnic respiratory failure

- Increased respiratory workload due to
  - Airway resistance (asthma, airway obstruction)
  - Elastic workload (pulmonary fibrosis, pneumonia, congestive heart failure)
  - Severe metabolic acidosis
  - Carbon dioxide production
  - Copious secretions in the airways
- Diminished central respiratory drive due to
  - Sedative or analgesic medications
  - Central nervous system injury
- Diminished respiratory muscle function due to
  - Mechanical disadvantage from
    - Chest wall deformities
    - Dynamic hyperinflation (COPD)
  - Respiratory muscle weakness from
    - Electrolyte abnormalities

Hypoxemic respiratory failure

- Ventilation-perfusion mismatching
- Right-to-left shunt
- Alveolar hypoventilation
- Diffusion impairment
- Reduced inspired oxygen concentration

COPD, chronic obstructive pulmonary disease.

Physiologic derangements and clinical findings will determine the need for mechanical ventilation, which should be considered early in the course and not be delayed until the need becomes emergent. Patients suffering from cardiogenic shock will have an increased respiratory workload and reduced cardiac output delivered to the muscles of respiration. They are often described as “tiring out” or developing respiratory muscle fatigue and may show physical examination findings such as nasal flaring, use of accessory muscles of respiration (sternocleidomastoids or intercostals), paradoxic or asynchronous movements of

the rib cage and abdomen, and an increased pulsus paradoxus. If the mechanical workload progressively increases, the breathing demand at some point will exceed the respiratory pump capabilities. The patient will be unable to sustain adequate levels of ventilation to effectively eliminate carbon dioxide, and progressive hypercapnia will ensue. A substantial proportion of patients who require mechanical ventilation have relatively normal arterial blood gases, but show the other signs of respiratory failure mentioned. Therefore, the decision to place a patient on mechanical ventilation should not be determined by abnormalities of the arterial blood gas.

Increased respiratory work may markedly raise the oxygen cost of breathing, so that the respiratory muscles disproportionally consume oxygen at the expense of aerobic metabolism of other vital organs such as the heart, brain, and kidneys. Under these circumstances, mechanical ventilation decreases the work of breathing, decreases the oxygen cost of breathing, and redistributes oxygen delivery to the respiratory system and thereby improving oxygen delivery to other bodily organs.

If the underlying pathology is readily reversible and the clinician believes there is time, a trial of oxygen or noninvasive support can be initiated. However, those patients who are post cardiac arrest, are undergoing therapeutic hypothermia, experiencing ongoing cardiac ischemia, demonstrating cardiac or airway instability, exhibiting altered mental status, or having copious secretions are not candidates for noninvasive ventilation (NIV) and they require endotracheal intubation with PPV.

Working closely with the respiratory therapist is essential in decision making and implementation of respiratory support for critically ill patients.

HIGH-FLOW NASAL CANNULA

High-flow nasal cannula (HFNC) is emerging as a new mode of oxygen support for patients with acute hypoxemic respiratory failure with mild-to-moderate work of breathing.[1] Traditional nasal cannulas or masks can deliver flows up to 15 L/min. HFNC is a new form of oxygen support in which oxygen is delivered at very high flow (**Figure 42.1**). Humidified air is delivered at flows up to 60 L/min. In states of high patient workload, room air is entrained and there is dilution of the administered oxygen. With HFNC, the flow rate matches the patient's inspiratory flow and so there is less dilution of the administered oxygen. With HFNC, there is a small amount of positive pressure generated and an increase in lung volume. Compared with conventional oxygen therapy,

patients demonstrate a decrease in respiratory rate and greater synchrony. HFNC may be better tolerated than conventional oxygen or NIV.

FIGURE 42.1 High-flow nasal cannula.

Thus, HNFC may be effective in patients in the CCU with hypoxemia who are

able to sustain the work of breathing.

NONINVASIVE VENTILATION

NIV refers to a method of delivering ventilatory assistance through the use of a mask interface rather than through an invasive interface, such as an endotracheal tube (ETT) or tracheostomy. NIV may provide respiratory support to selected patients while avoiding complications of invasive mechanical ventilation.[2] Cardiogenic pulmonary edema and chronic obstructive pulmonary disease (COPD) exacerbation are two acute disorders for which NIV has proved beneficial.[2]

NIV reduces respiratory muscle work and facilitates a slower and deeper pattern of breathing, thus improving minute ventilation and alveolar ventilation. NIV has been shown to improve gas exchange, normalize arterial carbon dioxide, increase arterial oxygen, increase pH, increase tidal volume, and decrease respiratory muscle work in acute and chronic respiratory failure. Its use can also stabilize certain metabolic parameters such as heart rate, respiratory rate, and blood pressure.

The modes that are most commonly used in the critical care setting are PPV modes of continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BPAP).

In acute cardiogenic pulmonary edema, both CPAP and BPAP have been shown to reduce the work of breathing and intubation rates.[3,4] CPAP has been shown to improve oxygenation, reduce respiratory rate, and reduce the rate of intubation compared to standard oxygen therapy. BPAP similarly has demonstrated lower intubation and complication rates compared to standard oxygen therapy. Although a trial comparing standard oxygen therapy with NIV (CPAP or BPAP) found no significant difference in 7- or 30-day mortality between either of the two groups, the NIV group did achieve more rapid improvement in respiratory distress and metabolic disturbances than did oxygen therapy alone.[5]

For patients with acute cardiogenic pulmonary edema who are hemodynamically stable and meet criteria for NIV, we recommend BPAP as the initial ventilatory mode.

PATIENT SELECTION

Successful application of NIV may obviate the need for endotracheal intubation in select patients. A trial of NIV is therefore worthwhile in most patients who do not require emergent intubation, assuming that they have no contraindications. Potential indicators of success with NIV use are listed in **Table 42.3**. The clinician must exclude patients in whom the use of NIV would be unsafe. Patients who are at risk of imminent respiratory or cardiac arrest or who have already sustained arrest should be promptly intubated. Patients with unstable conditions such as shock, myocardial ischemia, or life-threatening cardiac arrhythmias should not be managed with NIV. Patients who are comatose, agitated, or uncooperative also cannot undergo NIV. Patients being considered for NIV should be able to manage their secretions, and those with copious amounts should be considered for intubation. Facial surgery, trauma, or deformities that may prevent adequate fitting of the mask interface, and patients with gastric distension and vomiting are relative contraindications.

TABLE 42.3 Potential Indicators of Success with Noninvasive Ventilation

- Younger patient
- Lower severity of illness (APACHE score)
- Ability to cooperate, coordinate breathing with ventilator, less air leaking
- Moderate degree of hypercapnia ($Paco_2$ > 45 mm Hg, <92 mm Hg)
- Moderate degree of acidemia (pH > 7.1, <7.35)
- Improved gas exchange, heart rate, and respiratory rate within 2 h

INITIATION AND SETTINGS

Once the patient has been selected to receive a trial of NIV, it should be initiated as soon as possible. Any delay may result in further deterioration of the patient's condition and increase the likelihood of failure. The oronasal mask should be selected for most patients (**Figure 42.2**). This mask is secured to the patient's face by the use of adjustable Velcro straps. Parameters that need to be set with the BPAP mode of ventilation include inspiratory positive airway pressure (IPAP), expiratory positive airway pressure (EPAP), fraction of inspired oxygen (FIO_2), and a backup respiratory rate.

FIGURE 42.2 Oronasal noninvasive ventilation mask.

IPAP is used synonymously with the term *pressure support* and EPAP is regarded as *positive end-expiratory pressure (PEEP)*. Therefore, an IPAP of 15 cm water and an EPAP of 5 cm water are equivalent to a pressure support of 10 cm water and a PEEP of 5 cm water. The initial target IPAP and EPAP should be selected on the basis of bedside observation and determined primarily by patient tolerance. A minimum IPAP of 10 cm water and EPAP of 5 cm water is usually

appropriate, because giving the patient higher initial pressures may result in intolerance and early failure. The tidal volume delivered with this mode depends on the difference between IPAP and EPAP. For example, the tidal volume will be greater using an IPAP of 15 cm water and an EPAP of 5 cm water (difference of 10 cm water), than an IPAP of 10 cm water and EPAP 5 cm water (difference of 5 cm water). The goal tidal volume to be delivered in most patients is usually 6 to 8 mL/kg predicted body weight.

The BPAP machine is a pressure-limited device that supports a spontaneous mode of ventilation. That is, the breath will be delivered only if there is a recognized patient effort. If the physician wishes to add a mandatory minimum machine-directed breath, he can set a backup rate of 10 to 12 breaths/min. However, these forced breaths are commonly not synchronized with the patient's effort.

A practical approach is to set the initial F_{IO_2} to 100%. Arterial blood gas analysis should then be performed after 1 to 2 hours of initiation of BPAP, and the F_{IO_2} can be titrated down if the Pa_{O_2} is at an acceptable level. It is then reasonable to further titrate down the F_{IO_2} in small decrements based on the patient's oxygen saturation on pulse oximetry (usually to a goal greater than or equal to 90%). **Table 42.4** shows a protocol to guide the initiation of NIV. Adjustment of IPAP and EPAP may be necessary to achieve optimal tidal volumes and tolerance of NIV.

TABLE 42.4 Protocol for Initiation of NIV

1. Appropriately monitored location, with monitoring of pulse oximetry and vital signs
2. Patient in bed or chair at >30° angle
3. Connect all tubing, turn on ventilator, and select and fit mask interface
4. Start with low pressure with backup rate; 8 to 12 cm water IPAP; 3 to 5 cm water EPAP; back up rate of 12 breaths/min
5. Gradually increase IPAP (by 2 cm increments up to 10 to 20 cm water) as tolerated to achieve alleviation of dyspnea, decreased respiratory rate, increased tidal volume, and good patient–ventilator synchrony
6. Provide F_{IO_2} supplementation as needed to keep oxygen saturation >90%
7. Check for air leaks and readjust straps if needed
8. Monitor initial blood gas (1 to 2 h after initiation) and then as needed
9. Encouragement, reassurance, and frequent checks and adjustments as needed

EPAP, expiratory positive airway pressure; IPAP, inspiratory positive airway pressure; NIV, noninvasive ventilation.

MONITORING AND TROUBLESHOOTING

Patients who are started on NIV for acute respiratory failure should be monitored

in the same way as patients who are mechanically ventilated through an ETT. Patients should be observed closely for the first 2 hours after initiation to troubleshoot, provide reassurance, and monitor for deterioration. If there is no stabilization or improvement over this time, NIV should be considered a failure and the patient should be promptly intubated. If the patient is clearly failing immediately after initiation, the clinician should not wait but should proceed to intubation. Clinical signs of failure include worsening gas exchange, worsening encephalopathy or agitation, inability to clear secretions, inability to tolerate any of the mask interfaces, persistent signs and symptoms of respiratory fatigue, and hemodynamic instability. Reductions in respiratory rate and accessory muscle use, coupled with improvement in thoracoabdominal synchrony and gas exchange, suggest a favorable response and good prognosis if seen within 2 hours.

Many patients do not tolerate BPAP, and this is usually due to patient–ventilator asynchrony (when the phases of inspiration and expiration do not match that of the patient). Waveform displays of breath-by-breath delivered flow, volume, and pressure are available on most intensive care unit (ICU) ventilators (**Figure 42.3**). If the alarms for these parameters are triggered (ie, low tidal volume or pressures), this is most likely due to a mask leak. Patients can often be satisfactorily ventilated despite such leakage because most pressure-limited ventilators are able to compensate for leaks by sustaining airflow to maintain mask pressure. If the leak is large enough to interfere with ventilatory support, readjusting the position of the mask on the face with tightening of the Velcro straps may help. Also, the mask size itself may have to be changed to ensure a proper fit. Air leaks may also be present if ventilator tubing becomes disconnected from the ventilator or facemask, or if nebulization ports remain open to the atmosphere.

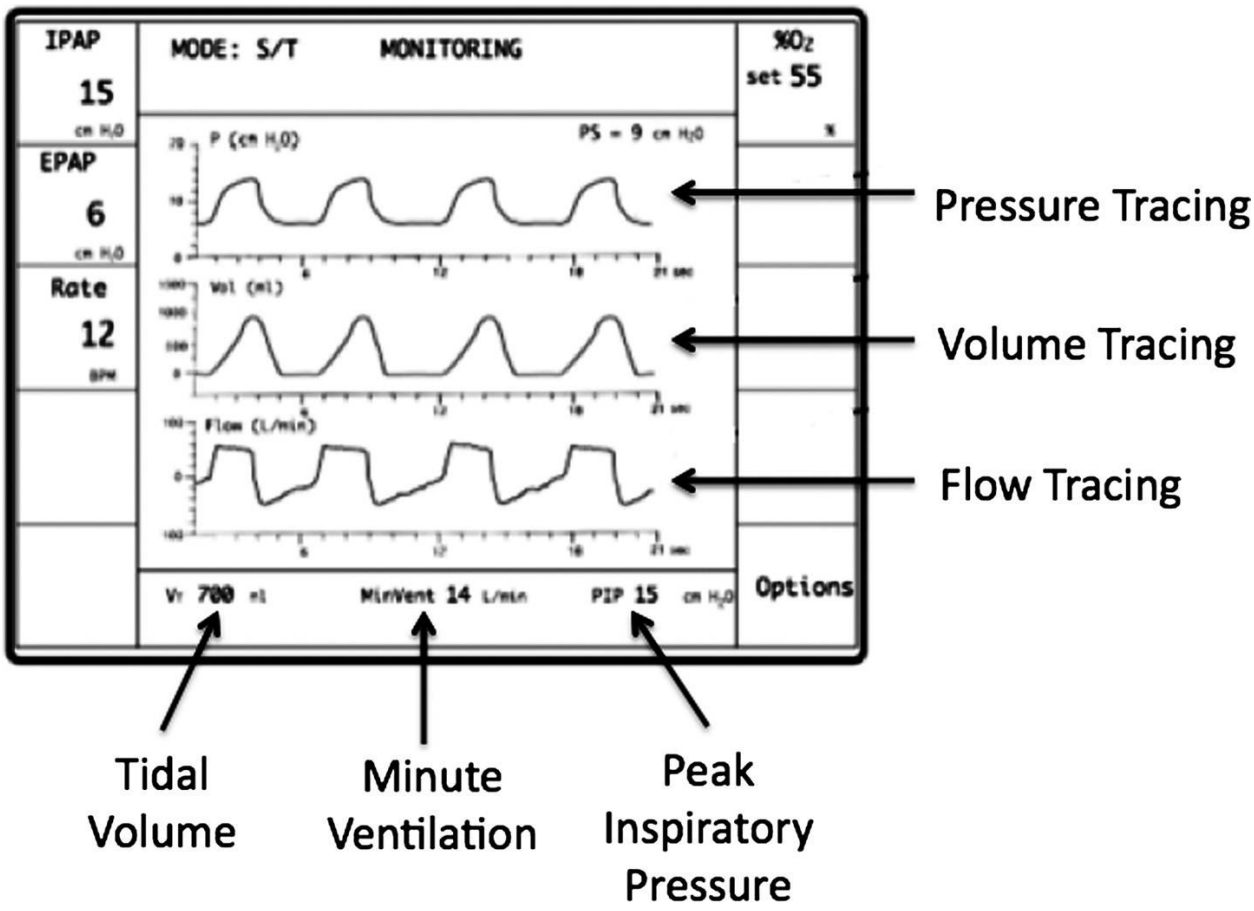

FIGURE 42.3 Waveform display in NIV. EPAP, expiratory positive airway pressure; IPAP, inspiratory positive airway pressure; NIV, noninvasive ventilation; PIP, peak inspiratory pressure. (Philips Respironics BiPAP Vision, Respironics Inc., Murrysville, PA.)

Some of the other problems that may be encountered with NIV are nasal congestion or dryness, nasal bridge redness or ulceration produced by excessive mask tension, irritation of the eyes causing conjunctivitis, and gastric insufflation leading to distension. Major complications such as aspiration, hypotension, and pneumothorax are seldom seen, and these events can be prevented by carefully selecting patients for NIV.

Patients With Do Not Intubate Order

NIV is frequently used in patients who have a directive for no intubation but have a potentially reversible cause of respiratory failure such as cardiogenic pulmonary edema. These patients may be good candidates for NIV because their short-term prognosis may be significantly improved. In contrast, NIV is also initiated in patients with advanced-stage diseases who have poor prognosis. It is

a life support measure and its use should be guided by the goals of care, because it may still offer benefits in alleviating respiratory distress or suffering. More information regarding this topic can be found in the chapter on *End-of-Life Care in the CCU*.

INVASIVE MECHANICAL VENTILATION

Invasive mechanical ventilation is usually initiated in the CCU for patients with acute respiratory failure, cardiogenic shock, and cardiac arrest. If a patient with pulmonary edema has a contraindication to or fails NIV, he/she should be promptly intubated.

UNDERSTANDING THE MECHANICAL VENTILATOR

The mechanical ventilator gives the patient each breath based on the settings selected by the clinician.[6] Understanding a few basic terms is helpful. The term *cycling or control* refers to the way the ventilator determines that the inspired breath is complete and signals to stop inspiration. This can be sensed either by volume (inspiration stops once the target volume is delivered), pressure (inspiration stops once the target pressure is reached), flow (when flow decreases to a given level, inspiration is terminated), or time (inspiration stops after a preset time interval). The term *limit* refers to a factor that limits the rate at which gas flows into the lungs and causes inspiration to end before cycling is complete. A limit can be pressure, volume, or flow. *Triggering* is the signal that opens the inspiratory valve, allowing air to flow into the patient. To initiate a breath, the ventilator must recognize that a set value has been reached. The trigger can be set to time, volume, pressure, or flow.

Breath types can be classified in several different ways. If the patient determines the beginning, duration, and end of a breath, the breath is termed *spontaneous*. If the ventilator controls for any of these aspects, the breath is considered to be either *assisted* or *mandatory (controlled)*.

Tidal volume (V_T) is the amount of air delivered with each breath. The normal V_T in a 70-kg person is roughly 500 mL. *Minute ventilation (MV_E)* is the product of tidal volume and the respiratory rate, and is the amount of air inhaled or exhaled in 1 minute. The normal MV_E is 5 to 8 L/min. *Fraction of inspired oxygen (Fio_2)* is the percentage of oxygen in the inspired air, and can range from

21% (room air) to 100%. *PEEP* is the pressure set on the ventilator to prevent expiratory alveolar collapse.

The selection of ventilator mode for a critically ill patient is generally based on the experience of the clinician and institutional preference. PPV can be either volume controlled or pressure controlled.[6] In *volume control (volume preset* or *volume cycled)* ventilation, the machine delivers a preset volume determined by the physician and, within limits, delivers that volume irrespective of the pressure generated within the system. The amount of pressure necessary to deliver this volume can fluctuate based on the resistance and compliance of the patient and ventilator circuit. If the tidal volume is set at 500 mL, the ventilator will continue to deliver gas until it reaches this goal. Upon completion of the inspired volume, the ventilator will open a valve allowing the patient to passively exhale.

In *pressure control (pressure preset* or *pressure cycled)* ventilation, the ventilator applies a predefined pressure target set by the physician. The ventilator will flow gas into the patient until this set pressure is reached. Upon reaching the preset pressure, the ventilator allows for passive exhalation. The resulting tidal volume will vary according to airway resistance and lung compliance.

The mode is also classified on the basis of how the breath is initiated—whether by the ventilator, the patient, or both. In *controlled mechanical ventilation (CMV)*, the MV_E is determined entirely by the set respiratory rate and the set control (volume or pressure control). The patient does not initiate additional MV_E above that set by the ventilator (ie, there is no ventilator triggering by the patient). For example, in volume-controlled CMV, if the set respiratory rate is 12 breaths/min and the preset tidal volume is 500 mL, the patient will be guaranteed an MV_E of 6 L/min (no lower and no higher). Patients are unable to alter their MV_E if the clinical situation changes such as hypoxemia or worsening acidosis, and acid–base maintenance is solely the responsibility of the physician. If placed on this mode, patients who are awake or spontaneously triggering may generate asynchronous respiratory efforts that may contribute to increased work of breathing, patient discomfort, and worsening gas exchange.

During assist-control (AC) *AC ventilation,* the physician determines the minimum MV_E by setting the respiratory rate and control (volume or pressure control). The patient can increase his own MV_E by triggering additional breaths (by flow or pressure) above the set respiratory rate. Each time the patient triggers, the ventilator will generate a fully supported breath according to the

volume or pressure preset. For example, in volume-controlled AC, if the respiratory rate is set to 12 breaths/min and the tidal volume to 500 mL, the minimum MV_E will be 6 L/min. If the patient triggers an additional 8 breaths/min, the MV_E then becomes 10 L/min. This mode is the most commonly used mode of ventilation in ICUs and is best suited for those who are awake or still have spontaneous respiratory efforts, and can even be used in those who do not generate any respiratory efforts.

Pressure-regulated volume control (PRVC) is a dual-control mode available on many ventilators. Its basic features are similar to those of AC ventilation, with the main difference being that the ventilator is able to auto-regulate the inspiratory time and flow to deliver the preset tidal volume at the lowest possible plateau airway pressure.

Pressure support ventilation (PSV) differs from the other modes of mechanical ventilation discussed in that it is a flow-cycled mode and is intended to support spontaneous respiratory efforts. The ventilator delivers inspiratory pressure until the inspiratory flow decreases to a predetermined percentage of its peak value (usually 25%). In this mode, the physician sets the pressure support level, PEEP, and FIO_2. The patient must trigger each breath because there is no set respiratory rate. Work of breathing is inversely proportional to pressure support level and inspiratory flow rate. Tidal volumes are therefore determined by a combination of PSV settings, the patient's effort, and underlying pulmonary mechanics. An adequate MV_E cannot be guaranteed and it cannot be used in patients who are heavily sedated, paralyzed, or who cannot generate spontaneous efforts.

CPAP is a mode of support that is also applied to spontaneously breathing patients. During the respiratory cycle, a constant pressure is applied to the airway throughout inspiration *and* expiration. The ventilator does not cycle during CPAP, and all breaths must be initiated by the patient. CPAP is commonly combined with PSV or may be used alone in patients weaning from mechanical ventilation.

Additional modes of ventilation (such as airway pressure release ventilation) are used mainly for patients with acute respiratory distress syndrome (ARDS) and are beyond the scope of this discussion.

ENDOTRACHEAL INTUBATION

Endotracheal intubation should only be performed by an experienced clinician or anesthesiologist. Patients are often intubated using an induction agent (ie,

propofol, etomidate) and in some instances undergo rapid sequence intubation with the addition of neuromuscular blocking agents. A specific neuromuscular blocking agent, succinylcholine, may cause a sudden release of potassium into the bloodstream and should be avoided in patients with renal failure or hyperkalemia because it may lead to sudden cardiac arrest. Induction agents have a common problem of causing peripheral vasodilation. This effect may become even more pronounced if there is significant dehydration, hypovolemia, or underlying acidosis. Critically ill patients in a state of compensated shock maintain their circulation by vasoconstriction and tachycardia. The use of a vasodilating induction agent can blunt this response and reduce systemic blood pressure by reducing peripheral vascular resistance.

When positive pressure is applied to the airway, there is an increase in intrathoracic pressure and a decrease in venous return to the heart causing reductions in ventricular filling pressures, stroke volume, and cardiac output. The effects of initiating PPV on blood pressure and cardiac output can usually be treated with the administration of saline boluses. Intravenous fluid preparations should always be prepared for the intubation process in anticipation of such adverse effects. If the effects of vasodilation caused by induction agents cannot be reversed with saline infusion, the temporary use of vasoconstrictor agents (ie, phenylephrine, norepinephrine) may be required. Complications of intubation include local trauma and aspiration of gastric contents.

Once the ETT is advanced through the vocal cords, the tube is secured and the cuff is inflated. Placement is clinically confirmed by the symmetric rise and fall of the chest wall, the presence of bilateral breath sounds, and end-tidal carbon dioxide measurement during manual ventilation. If placement is adequate and oxygen saturation is sufficient, the patient can then be attached to the mechanical ventilator. ETT cuff inflation pressure should not exceed 30 cm water to avoid complications such as tracheal rupture, pressure necrosis, or tracheo-innominate artery erosion and fistula. A chest radiograph should be obtained to ensure ideal location of the tip of the ETT, which should be between 3 and 5 cm above the carina.

PHYSIOLOGIC AND PATHOPHYSIOLOGIC CONSEQUENCES OF POSITIVE-PRESSURE VENTILATION

PPV can produce complex interactions in the patient's cardiopulmonary state.[7] PPV results in an increased mean intrathoracic pressure; the clinical effect on cardiac output is variable and depends on the patient's intravascular volume

status/ventricular filling pressures, underlying left ventricular compliance, and ejection fraction.

Increases in intrathoracic pressure can decrease venous return to the right heart. The amount of venous return is determined by the pressure gradient from the extrathoracic veins to the right atrium. The intrathoracic and right atrial pressures increase during PPV, which reduces the gradient for venous return. This effect may be overexaggerated by increases in PEEP or in those with intravascular volume depletion. Right ventricular output can also be reduced by increased alveolar inflation and compression of the pulmonary vascular bed, resulting in increased pulmonary artery pressures and pulmonary vascular resistance. In addition, left ventricular output may be compromised from shifting of the interventricular septum toward the left ventricle leading to impaired diastolic filling.

In contrast to these adverse effects, PPV can be beneficial in patients with left ventricular failure and pulmonary edema.[7] Transmyocardial pressures can be reduced by increases in intrathoracic pressure, resulting in a decreased left ventricular afterload and overall improved left ventricular performance. This effect is most likely to be seen when filling pressures are high and ventricular performance is poor.

Measurements of pressure, airflow, and volume can reveal basic physiologic properties of the respiratory system (**Figure 42.4**). *Peak inspiratory pressure (PIP)* is the maximal airway pressure recorded in the patient–ventilator circuit. It represents the total pressure needed to overcome resistance related to the ventilator tubing, ETT, and patient airways in addition to the elastic recoil of the lungs and chest wall.

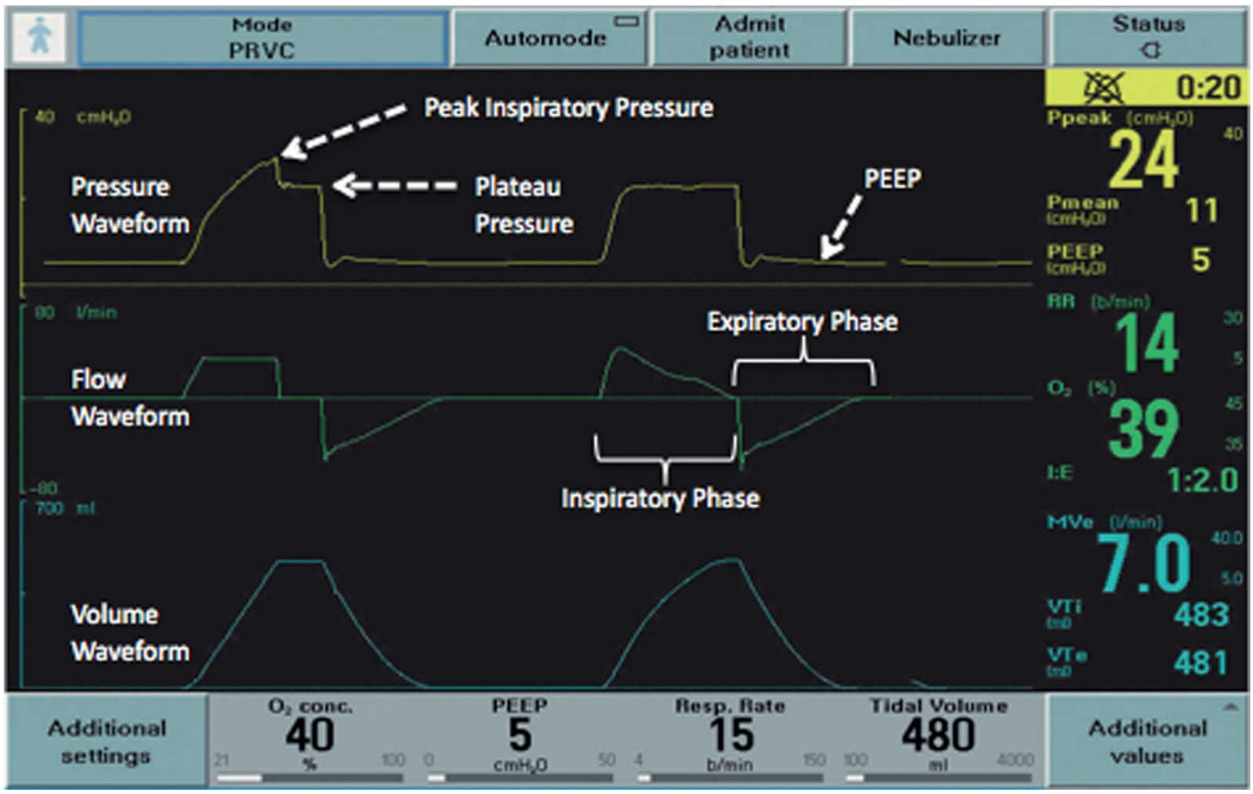

FIGURE 42.4 Waveform and pressure analysis on the invasive mechanical ventilator. PEEP, positive end-expiratory pressure; PRVC, pressure-regulated volume control. (SERVO-i, Maquet, Tastatt, Germany.)

The end-inspiratory pressure is measured by applying an inspiratory pause at the end of passive inflation; this will result in an immediate drop in airway opening pressure to a lower initial value, followed by a gradual decrement until a *plateau airway pressure* is reached. Because plateau pressure is measured when there is no airflow, it reflects the static compliance of the respiratory system. Increases in plateau pressures can be seen in patients with decreased lung compliance (ie, ARDS, congestive heart failure, multilobar pneumonia, severe atelectasis) or decreased chest wall compliance (ie, morbid obesity, kyphoscoliosis, abdominal distension, tension pneumothorax) (**Table 42.5**).

TABLE 42.5 Causes of Respiratory Distress in the Patient on Mechanical Ventilation

Ventilator issues
• Inadequate minute ventilation (tidal volume or respiratory rate), F_{IO_2}, inspiratory flow rate, PEEP, or trigger sensitivity
• Ventilator circuit leak
• Ventilator malfunction
Increased peak inspiratory pressures with unchanged plateau pressures

- Endotracheal tube problems
  Examples: patient biting, increased resistance in tubes by heat and moisture exchange, obstruction by secretions, blood, or foreign object
- Bronchospasm (asthma or COPD)
- Obstruction of lower airways (secretions, blood, or foreign object)
- Aspiration of oropharyngeal or gastric contents

Increased peak inspiratory pressures with increased plateau pressures
- Pneumonia
- Atelectasis
- ARDS and pulmonary edema
- Migration of ETT into a mainstem bronchus
- Pneumothorax
- Abdominal distension

Extrapulmonary issues
- Delirium, anxiety, or pain
- Acute neurologic event
- Sepsis

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; ETT, endotracheal tube; PEEP, positive end-expiratory pressure.

Normally, a transpulmonary pressure of 35 cm water would inflate the lungs to near-total lung capacity. In patients with acute lung injury (ALI) or pulmonary edema, total lung capacity may be reduced because of alveolar collapse. Therefore, V_T delivered with each assisted breath may result in heterogeneous ventilation and over-distension of the more compliant regions of the lungs, and subsequent increased plateau/alveolar pressures. This may cause *volutrauma* to the alveoli as a result of the shear mechanical forces applied to the alveoli because they are repeatedly opened and closed. This damage is termed *ventilator-associated lung injury* and is often indistinguishable from other causes of ALI clinically and radiographically. Primary interventions to reduce this injury include preventing alveolar over-distension through the use of smaller V_T (6 mL/kg of predicted body weight) and keeping plateau pressures to a goal of less than 30 cm water.[8]

Pneumothorax, subcutaneous emphysema, pneumomediastinum, and other forms of extra-alveolar air are generally referred to as *barotrauma*. Barotrauma is usually the result of disruption of the pulmonary parenchyma and alveolar rupture from elevated airway pressures or volumes.

Extrinsic PEEP is generally added to prevent alveolar collapse, and increasing levels may be required depending on the clinical situation. In the setting of respiratory failure from ARDS or congestive heart failure, decreased lung compliance may lead to significant alveolar collapse and refractory hypoxemia

due to increased shunt fraction. In these settings, extrinsic PEEP has been used to prevent alveolar collapse, recruit alveoli, and improve oxygenation.

Intrinsic PEEP ($PEEP_i$*, auto-PEEP,* or *breath stacking)* is present when alveolar pressure exceeds atmospheric pressure at the end of expiration in the absence of a set ventilator PEEP level. When inspiration is initiated before expiratory flow from the preceding breath has ceased, air trapping will occur. Auto-PEEP can develop for numerous reasons including high minute volume (due to high V_T, respiratory rate, or high trigger sensitivity), prolonged inspiratory times (leading to obligatory decrease in expiratory time), and expiratory flow resistance or limitations (due to small-bore ETT or obstructive airways disease). Consequentially, it may potentiate the aforementioned hemodynamic effects of PPV by further increasing intrathoracic pressure. Auto-PEEP will also increase the risk of pulmonary barotrauma and the work of breathing by making it more difficult for the patient to trigger a ventilator-assisted breath. Treatment for auto-PEEP involves adjusting ventilator settings (decreasing inspiratory time, increasing inspiratory flow rate, decreased V_T, decreasing respiratory rate, decreasing trigger sensitivity), maintaining adequate anxiolysis and analgesia to reduce ventilatory demand, and reducing expiratory flow resistance (suctioning, bronchodilators).

Although supplemental oxygen is necessary and valuable in many clinical situations, inappropriate or excessive therapy can be detrimental. The effects of normobaric hyperoxia on the respiratory system have been extensively studied, showing effects ranging from mild tracheobronchitis to diffuse alveolar damage or ARDS. Hyperoxia appears to produce cellular injury through increased production of reactive oxygen species, which can ultimately result in cell death.[9] In general, attempts are made to decrease the FIO_2 to less than 60% to a goal Pao_2 of 60 to 65 mm Hg or Spo_2 greater than or equal to 90% as soon as patients are able to tolerate it. Optimal selection of PEEP may also help decrease oxygen requirements.

SETTINGS FOR MECHANICAL VENTILATION IN THE CCU

This section covers the basic initial settings for the volume-controlled AC mode. The settings that need to be considered with this mode include the V_T, respiratory rate, extrinsic PEEP, and FIO_2.

In principle, the ventilatory management of patients with cardiogenic shock

and pulmonary edema is similar to that of patients with noncardiogenic pulmonary edema (ARDS). In addition, patients in the CCU, especially those following cardiac arrest, may suffer ARDS due to aspiration at the time of the cardiac arrest. Many of the recommendations regarding ventilatory strategies for these groups of patients are based on avoiding the pulmonary complications of alveolar over-distension. These strategies are called *lung protective strategies*. Owing to the overwhelming evidence that inflating the lungs to near-total lung capacity or above can damage normal lung units in patients with ARDS and worsen mortality, the current recommendations for ARDS are to set the tidal volume to 6 mL/kg of predicted body weight.[8] It is reasonable to use V_T of 6 to 8 mL/kg predicted body weight in patients ventilated for reasons other than ARDS. Predicted body weight is based on height and gender, and so the height should be measured in all ventilated patients to set the proper tidal volume.

PEEP can potentially improve oxygenation by recruiting collapsed and flooded alveoli for gas exchange, diminishing intrapulmonary shunting of blood, improving ventilation-perfusion mismatching, and also redistributing intra-alveolar edema.

Initial Settings

Tidal volume V_T: 6 to 8 mL/kg predicted body weight.

Respiratory rate: at least 12/min. Higher rates may be required, for example, in patients with severe underlying acidosis or patients being ventilated for ARDS.

F_{IO_2}: set to 100% after intubation. The lowest possible F_{IO_2} necessary to meet oxygenation goals should be used. Arterial blood gas analysis should then be performed after 1 hour to ensure adequate oxygenation. F_{IO_2} should then be rapidly titrated down (by 10% to 20% every 30 minutes) to a goal Pa_{O_2} of 60 to 65 mm Hg or Sp_{O_2} greater than or equal to 90% to avoid complications of high inspired oxygen concentration.

PEEP: A typical initial PEEP of 5 cm of water is often applied to prevent atelectasis. Higher levels of PEEP may be required to recruit alveoli and improve gas exchange; however, attention must be paid to airway pressures to avoid complications of alveolar over-distension. PEEP above 20 cm water should rarely be used.

MONITORING PATIENTS ON INVASIVE MECHANICAL VENTILATION

Patient–ventilator asynchrony is commonly manifested as respiratory distress with “bucking” or “fighting” the ventilator. This happens when the phases of the breath delivered by the ventilator do not match that of the patient. Clinical signs include anxiety, agitation, tachypnea, tachycardia, use of accessory muscles of respiration, and uncoordinated thoracic wall and abdominal movements. Asynchrony can lead to dyspnea and increased work of breathing. Bedside observation and examination of ventilator waveforms can help detect the presence and identify the cause of asynchronous ventilation.

Asynchrony or respiratory distress may signify a life-threatening complication, and so rapid assessment is required. In addition to clinical examination, the clinician must monitor ventilator parameters such as tidal volume, respiratory rate, peak inspiratory pressure, plateau airway pressure, and auto-PEEP values. It should be noted that patient–ventilator asynchrony need not be present for possible pulmonary complications associated with mechanical ventilation to arise. In addition, extrapulmonary processes such as fever, pain, delirium, and anxiety may also increase respiratory drive and lead to patient–ventilator asynchrony. **Figure 42.5** offers an algorithmic approach to the mechanically ventilated patient in respiratory distress.

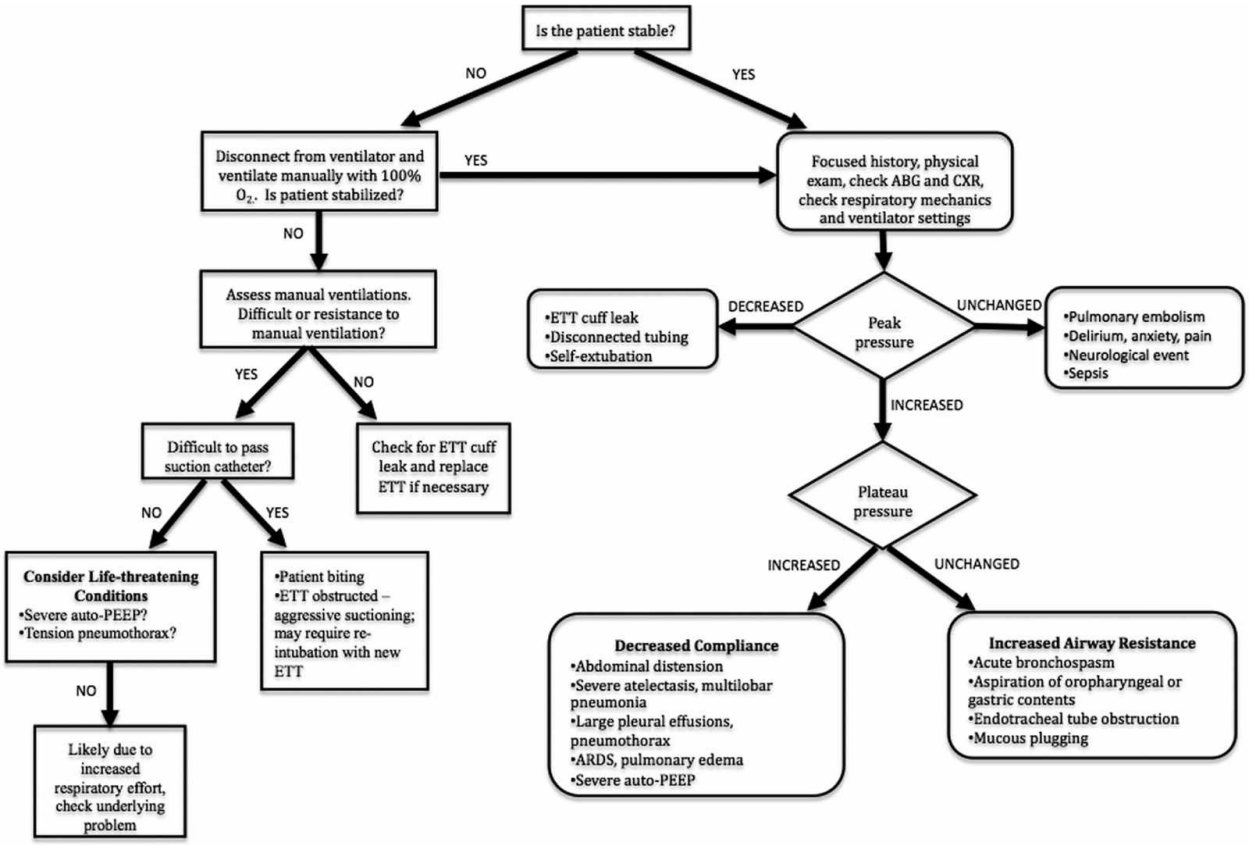

FIGURE 42.5 Approach to the mechanically ventilated patient in respiratory distress. ABG, arterial blood gas; ARDS, acute respiratory distress syndrome; CXR, chest X-ray; ETT, endotracheal tube; PEEP, positive end-expiratory pressure.

Chest radiographs should be followed to ensure proper positioning of the ETT (optimal 3 to 5 cm above the carina), because cephalad or caudad migration is very common.

Arterial blood gas analysis is usually performed at the initiation of mechanical ventilation and then periodically based on the disease process and ventilator changes. Acid–base disturbances may require adjustments of minute ventilation, because they can lead to significant and potentially life-threatening cellular dysfunction or hemodynamic consequences. F_{IO_2} will be adjusted to assure adequate oxygenation and avoid potential oxygen toxicity.

SEDATION IN THE MECHANICALLY VENTILATED PATIENT

The majority of mechanically ventilated patients will require sedation and/or analgesia to facilitate ventilator synchrony, and alleviate pain and discomfort from critical care procedures and treatments.[10] A number of different agents can

be used alone or in combination to achieve consistent sedation, anxiolysis, and analgesia. Common medication classes include benzodiazepines, opioid analgesics, and neuroleptic agents. A neuroleptic agent may be used if medication for delirium is indicated. Each class differs in the amount of anxiolysis, analgesia, amnesia, and hypnosis provided. Elimination half-life, volume of distribution, and drug clearance may be significantly altered in critically ill patients. No single agent is sufficiently superior to other agents to recommend its standard use in all patients. Selection must therefore be individualized according to the patient's distress, physiologic parameters, expected duration of therapy, and potential interactions with other medications. Careful attention should also be paid to the possible development of adverse reactions. Brief descriptions regarding drug classes, effects, and pharmacokinetics are presented in **Table 42.6**.

TABLE 42.6 Characteristics of Sedative Medications Commonly Used in the ICU Setting

DRUG	ONSET	DURATION	EFFECTS
Opioids • Morphine • Fentanyl	5–10 min <0.5 min	4 h 30–60 min	Potent sedative/analgesic effects, without causing anxiolysis, hypnosis, or amnesia
Benzodiazepines • Lorazepam • Midazolam • Diazepam	5–20 min 1–5 min 1 min	6–8 h 30 min 20–60 min	Sedative anxiolytic, hypnotic, and amnesic effects without analgesic effects
Neuroleptic • Haloperidol	30–60 min	0.5–6 h	Potent sedative anxiolytic with minimal hypnotic and amnesic effects; no analgesia provided
Anesthetic–sedative • Propofol	<1 min	3–10 min	Potent sedative hypnotic, with minimal amnesic effects; anxiolysis seen at low doses; no analgesia provided
Central α_2 agonist • Dexmedetomidine	5–10 min	1–2 h	Sedative sympatholytic with moderate anxiolysis and analgesia; no hypnosis or amnesia; no significant effect on respiratory drive

ICU, intensive care unit.

A goal depth of sedation should be determined before initiating sedative–

analgesic regimens and the goal should be individualized on the basis of the clinical situation.[10] Patients expected to have a shorter duration of mechanical ventilation may require lighter sedation or no sedation at all. On the other hand, patients being mechanically ventilated for severe hypoxemia or ARDS may require deeper sedation. The goal depth of sedation should be frequently assessed and titrated using validated and reliable scales for mechanically ventilated patients (eg, Richmond Agitation-Sedation Scale).

VENTILATOR-ASSOCIATED COMPLICATIONS

Critically ill patients requiring mechanical ventilation are at risk for clinically important upper gastrointestinal hemorrhage due to stress ulceration.[11] Histamine-2 receptor antagonists and proton pump inhibitors reduce the frequency of overt upper gastrointestinal hemorrhage in patients in the ICU when compared to no prophylaxis.

A ventilator-associated pneumonia (VAP) may complicate the course of patients requiring mechanical ventilation. The Centers for Disease Control has introduced the surveillance definition of a ventilator-associated event as worsening oxygenation for 2 days following a period of stability. On the basis of current definitions, a VAP requires sustained worsening oxygenation, along with fever, leukocytosis, need for antibiotics, purulent endotracheal secretions, and growth of a pathogenic organism. The most common cause of VAP is aerodigestive tract colonization, followed by aspiration of contaminated secretions into the lower airways. Proper specimens should be collected before beginning empiric antibiotic coverage. Steps to reduce the risk and prevent development of VAP should be employed routinely in mechanically ventilated patients.[12] These include semi-recumbent positioning, oral care, and compliance with strict hand washing and other infection control protocols.

WEANING AND EXTUBATION

Weaning refers to the process of liberating the patient from the mechanical ventilator. The use of weaning protocols, generally involving respiratory therapists and nurses, has been shown to reduce the duration of mechanical ventilation.[13] Readiness testing refers to the use of objective clinical criteria to determine whether a patient is ready to begin weaning. The reason for the patient’s respiratory failure should have been identified and the patient should have shown a favorable response to the treatment. Chest radiograph should

demonstrate improvement in pulmonary edema. Oxygenation should be satisfactory: Spo_2 greater than or equal to 90% while receiving less than or equal to 50% FIO_2 and PEEP less than or equal to 5 cm water. Patients should be hemodynamically stable with minimal or no need for vasopressor support, and without myocardial ischemia or unstable cardiac arrhythmias. Sedative drugs should be discontinued, and the patient should be awake and alert, or easily arousable, and be able to manage secretions. In addition, significant fluid, electrolyte, and metabolic disorders should be corrected before weaning attempts.

A once-daily spontaneous breathing trial should be initiated when the patient meets readiness criteria. A weaning trial can be performed using a T-piece or PSV.

A T-piece trial involves removing the ventilator with the ETT in situ connected to oxygen and monitoring spontaneous respirations. In a PSV trial, a pressure support level of approximately 5 cm water is added to the CPAP mode. We prefer using the PSV approach over the T-piece because PSV provides reassurance of ventilator alarm features and backup ventilatory assistance in case of apnea, extreme tachypnea, or inadequate minute ventilation. In addition, PSV overcomes the increased work of breathing from resistance of the ETT that may be seen with T-piece trials. A successful weaning trial meets the criteria outlined in **Table 42.7**. If the patient meets all of the weaning criteria, the patient may be extubated. If the patient fails to meet all of the criteria, ventilatory support should be resumed and another weaning trial should be attempted the following day. In the case of cardiogenic pulmonary edema, the administration of diuretics before extubation may be beneficial even if the patient is not in overt heart failure, because the cardiovascular effects of PPV discussed earlier will be reversed once positive pressure is removed.

TABLE 42.7 Criteria for a Successful Ventilator Weaning Trial

- Pressure support ≤ 8 cm water (ideally <5 cm water)
- PEEP ≤ 5 cm water
- Spo_2 > 92% while breathing ≤ 50% FIO_2
- Respiratory rate < 35 breaths/min
- Heart rate < 140 beats/min
- Systolic blood pressure <180 mm Hg but >90 mm Hg
- No diaphoresis or signs of respiratory fatigue
- Tolerated for at least 30 min to 2 h

PEEP, positive end-expiratory pressure.

For extubation, the patient should be placed in the upright position and the oropharynx and trachea via the ETT should be suctioned to remove secretions. The ETT cuff is then deflated and the ETT is removed. Immediately after removal, any secretions that are coughed up and present in the oropharynx should be promptly suctioned and supplemental oxygen should be provided. Physical examination including auscultation of the lungs to confirm bilateral air entry and the upper airway to exclude the presence of inspiratory stridor (which would suggest laryngeal edema) should be performed.

Respiratory distress following extubation may be due to airway disease, recurrent pulmonary edema, secretions, or laryngeal edema. In many cases, early and aggressive management with suctioning, bronchodilator therapy, diuresis, or NIV can prevent re-intubation. If laryngeal edema is present, the administration of intravenous glucocorticoids and inhaled racemic epinephrine may lessen the need for re-intubation. In patients with respiratory distress following extubation, NIV may prevent re-intubation if applied early.[14] If the patient fails a trial of NIV or meets any of the contraindications to the use of NIV discussed earlier in this chapter, he/she should be promptly re-intubated followed by a thorough evaluation and treatment of the cause of the post-extubation respiratory failure.

CONCLUSION

Mechanical ventilation provides life-saving support in the CCU. Clinicians must closely attend to the goals, ventilator settings, and patient–ventilator monitoring to utilize mechanical ventilation to the greatest benefit and prevent complications. Understanding and utilizing sedation goals and daily weaning assessments will assure that patients are promptly liberated from mechanical ventilation.

Patient and Family Information For: MECHANICAL VENTILATION

A mechanical ventilator is a machine that helps patients breathe when they are not able to breathe enough on their own. It is commonly referred to as a *breathing machine or respirator*. Most patients who require help breathing with mechanical ventilators are cared for in the ICU or cardiac care unit. Many people think of mechanical ventilators as a way to treat breathing-related issues. However, patients are placed on ventilators to support their breathing function while giving time for treatments to improve their condition. Being on a respirator means the patient is critically ill—it is life support.

There is always a team taking care of the patient, including the physician, nurse and respiratory therapist.

WHY MECHANICAL VENTILATORS ARE USED

Mechanical ventilators help support the patient by pushing breaths with oxygen into the lungs, as well as removing carbon dioxide from the lungs. There are some patients who are in an ICU in whom breathing is difficult—they may feel short of breath and tired from the work that their breathing requires. This is called *respiratory failure* and is often due to the cardiac disease where poor pumping leads to fluid buildup in the lungs. Some patients also have pneumonia, COPD, or asthma, or too much mucus present in the windpipe or airways; and these conditions make it even more difficult to breathe. Mechanical ventilators can help ease the work of breathing for these people and prevent their condition from getting worse. If a patient does not get help early enough, the condition can worsen very quickly and ultimately cause the heart and lungs to stop.

Other patients may not be breathing at all because they are in a coma, have

brain damage or injury, very weak muscles, or because they suffered a cardiac arrest. In this case, a ventilator must be used to breathe for the patient.

HOW MECHANICAL VENTILATORS WORK

There are two basic types of ventilators that are available. The first is called a *noninvasive ventilator* or *BiPAP machine*. This device pushes air into the lungs through tubing that is connected to the patient by way of a mask, which covers the nose and mouth. It can help improve oxygen levels in the blood and lessen the amount of work that the muscles need to do to in order for the patient to breathe. Patients can sometimes still speak to their family and friends while on this machine, and some may also be able to eat provided it is safe to do so. This type of ventilator is commonly used in the cardiac care unit for patients suffering from shortness of breath due to heart failure.

Patients on BiPAP have to be monitored very closely. Even with the help of this device, some patients will continue to have a great deal of trouble breathing. If the patient has not improved within a few hours of this device being started, then this machine is not successful and the patient will need a second type of machine, called the *invasive mechanical ventilator*. Also, not all patients are good candidates for BiPAP and we may decide that it is more harmful than beneficial to use it.

The invasive mechanical ventilator is connected to the patient through a tube (called an ETT) that is placed in the mouth or nose and down into the windpipe. The process of placing the tube into the patient's windpipe is called *intubation*. The device blows air into the lungs and it can help a person by doing all of the breathing for them or just assisting their breaths. The difference between BiPAP and the invasive ventilator is that with the invasive ventilator the doctors have more control over a person's breathing and are able to completely rest the muscles used for breathing.

HOW PATIENTS FEEL WHILE ON INVASIVE MECHANICAL VENTILATORS

The ventilators themselves do not cause pain, but most people who require invasive ventilators do not like the feeling of having a tube in their mouth or

nose. They cannot talk because the tube passes through the voice box into the windpipe. They also cannot eat when the tube is in place, and so they need a temporary feeding tube from the mouth to the stomach until the breathing tube is removed. Some people will feel some discomfort as air from the machine is being pushed into the lungs and they will try to breathe out while the machine is trying to push air in. This is called *fighting* against the ventilator and makes it more difficult for the ventilator to help. In addition, people undergo many diagnostic tests and therapies that can cause physical discomfort or pain. For these reasons, patients are often given medications such as sedatives or painkillers to make them feel more comfortable.

HOW PATIENTS ARE MONITORED

Anyone on a ventilator will be hooked up to a monitor that measures heart rate, breathing rate, blood pressure, and oxygen levels at regular intervals. Other tests that may be done routinely include chest X-rays and blood tests that will measure the amount of acid, oxygen, and carbon dioxide in the blood. The doctors, nurses, and respiratory therapists use this information to gauge how well the patient is doing and to see if any adjustments need to be made to the ventilator.

RISKS OF MECHANICAL VENTILATION

Some risks of mechanical ventilation do exist. However, if the doctors feel that the patient needs to be on a ventilator, the benefits of placing the patient on one are always greater than these potential risks.

When a person is first placed on a respirator, he/she may experience a drop in blood pressure. This can usually be reversed with the use of intravenous fluids, but some patients may temporarily require medications to keep their blood pressure normal.

Sometimes, a part of the lung that is weak can become too inflated with air and start to leak. This leaked air collects in an empty space between the lungs and the chest wall. Because there is a limited amount of space in the chest, the leaked air starts to take up more space and the lung begins to collapse. This is called a *pneumothorax*. This air needs to be removed as soon as possible because

it can result in life-threatening complications. It is drained by a *chest tube*, which is likely to remain until the patient no longer requires the ventilator.

The pressure from the ventilator to put air into the lungs can also damage the lungs. Doctors try to keep this risk to a minimum using the lowest amount of pressure that is needed. In addition, very high levels of oxygen may be harmful to the lungs. Unfortunately, patients who already have damaged lungs may need very high levels of oxygen until the lungs start to heal, which makes it difficult to reduce this risk.

As mentioned, many patients on mechanical ventilation will need some level of sedation. Different patients will react to each medication differently. At times, sedation medications can build up and the patient may remain in a deep sleep for hours or days, even after the medication is stopped. The doctors and nurses try to adjust the medications so that the right amount is being delivered at all times.

The breathing tube can allow germs and bacteria from the mouth to get into the lungs more easily. This can cause an infection such as pneumonia, which can be a serious problem and could mean that the patient has to stay on the machine longer. People who are very sick can be more prone to infection than others. All members of the medical staff take maximum precautions to prevent this from happening; however, if an infection occurs, it can be treated with antibiotics.

HOW LONG ARE MECHANICAL VENTILATORS USED?

Ventilators can be lifesaving, but they do not fix the primary disease or injury. Ventilators help support a patient until other treatments become effective. The medical team will always try to help patients get off the ventilator at the earliest possible time, but will not do so until there has been an improvement or a reversal of the problem at hand.

Weaning refers to the process of getting the patient off the ventilator. Depending on the patient, this process may take a few hours up to a few days or longer. Specific criteria are used to decide whether a patient is ready to come off of the respirator including blood oxygen levels, chest X-ray results, and physical examination. Some patients will never improve enough to be taken off the ventilator completely and may require long-term ventilator support.

Not all patients improve just because they are on a ventilator, and patients can die even though they are on a respirator. It is hard to predict or know for sure whether a person will recover with treatment. Sometimes, doctors feel very sure

the ventilator will help and the patient will recover. Other times, the doctors only have a rough idea of the chances a person will survive. For patients who are very sick and at the end of life, mechanical ventilation sometimes only postpones death.

Pulmonary Embolism and Deep Vein Thrombosis

Pulmonary embolism (PE) and deep vein thrombosis (DVT) are two categories of a broader disease known as venous thromboembolism (VTE). VTE can have a wide range of clinical presentations ranging from an asymptomatic incidental finding to hemodynamic collapse and death. The incidence of VTE is estimated at approximately 200,000 new cases per year in the United States, with a slightly higher predominance of DVT compared to PE.[1]

Not only is VTE a fairly common disease but it is also a significant cause of mortality. Previous autopsy studies have demonstrated PE as a direct cause of, contributing to, or accompanying death in approximately 15% of hospitalized patients over the past 40 years.[1] In the International Cooperative Pulmonary Embolism Registry (ICOPER) study published in 1999, the 3-month mortality rate of all patients diagnosed with PE before autopsy was 15.3% and it increased to 58.3% in patients who presented with hemodynamic instability.[2]

PATHOGENESIS

While the exact cause of VTE is unknown, it has been associated with a number of factors and is likely dependent on the interplay between them. Three of these

factors, venous stasis, endothelial injury, and a hypercoagulable state, oftentimes referred to as Virchow triad, are all associated with the development of VTE.[1] The likelihood of developing VTE is significantly increased when multiple risk factors are present simultaneously.

Pulmonary emboli typically originate from thrombi present in the deep veins. The proximal veins of the lower extremities, specifically the iliac and femoral venous system, are believed to be the source of most diagnosed pulmonary emboli. Right heart, pelvic vein, renal vein, and upper extremity thrombi are also potential sources of pulmonary emboli. Patients with PE are also found to have clots in the right heart, otherwise known as emboli in transit, and are at high risk of mortality.[1]

PHYSIOLOGY OF THE RIGHT VENTRICLE AND THE PULMONARY VASCULATURE

The pulmonary circulation can be modeled similarly to electrical circuits using Ohm's law, which states that voltage difference (***V***) equals the current of electrons (***I***) multiplied by the resistance (***R***). The pressure difference between the pulmonary artery ($\boldsymbol{P}_{PA}$) and the left atrium ($\boldsymbol{P}_{LA}$) in the pulmonary circulation is analogous to the voltage difference in the electrical circuit. The cardiac output (CO), which is the flow of blood through the pulmonary artery (PA), is analogous to the current in the electrical circuit. And, the pulmonary vascular resistance (PVR) is analogous to the resistance in the electrical circuit (**Figure 43.1**).

Ohm's law: $V = I \times R$

Physiologic correlate for pulmonary circulation:

$P_{PA} - P_{LA} = CO \times PVR$ $\qquad$ $P_{PA} = (CO \times PVR) + P_{LA}$

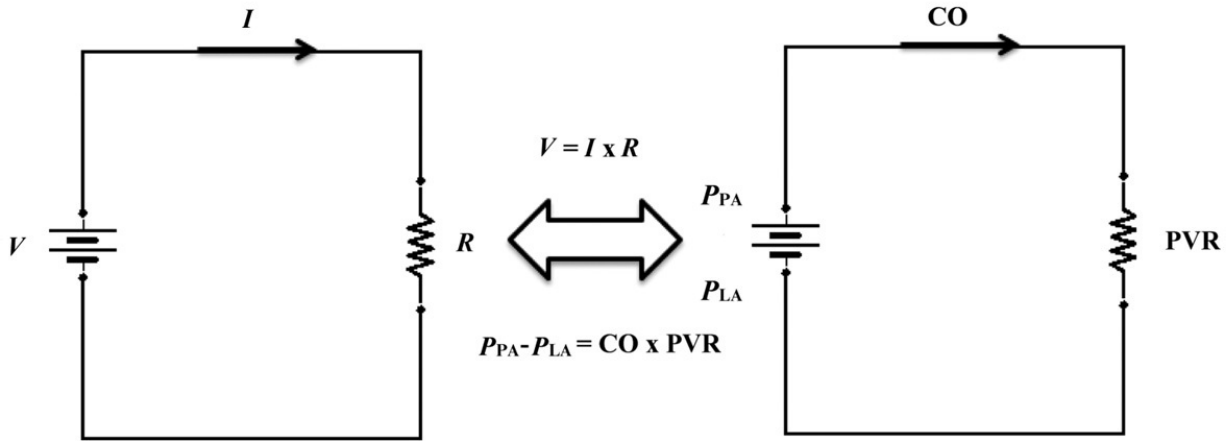

FIGURE 43.1 Circuit diagram of the pulmonary circulation. CO, cardiac output; I, current; PLA, left atrial pressure; PPA, mean pulmonary artery pressure; PVR, pulmonary vascular resistance; R, resistance; V, voltage.

The normal pulmonary circulation is a low-pressure and low-resistance circuit due to differences in blood vessel structure compared to the systemic circulation. The structure and function of the right ventricle (RV) are different compared to that of the left ventricle (LV), because the RV does not have to generate nearly as much pressure to produce the same CO as the LV. The RV is crescentic and relies more heavily on longitudinal shortening for force generation, whereas the LV is concentrically shaped and relies more on circumferential constriction. Overall, the RV is a thinner walled, more compliant, and more energy-efficient chamber than the LV. However, the operating characteristics of the RV are heavily dependent upon the low-pressure nature of the pulmonary circulation, leaving the RV very susceptible and poorly equipped to handle acute increases in RV afterload.[3]

PATHOPHYSIOLOGY OF INCREASED PULMONARY

VASCULAR RESISTANCE

Emboli cause an increase in PVR through two mechanisms. The primary mechanism for the increase in PVR is mechanical obstruction of the vasculature. The relationship between clot burden and PVR is hyperbolic. At low levels of mechanical obstruction, blood is able to be diverted to regions of distensible vasculature, which minimizes the increase in PVR. However, with more significant clot burden, this compensatory mechanism is overwhelmed as the remaining vessels become over-distended, leading to rapid rises in PVR for small increases in obstruction. The second mechanism for increased PVR is the release of humoral factors, leading to vasoconstriction of the pulmonary vasculature.[4] The major humoral factors that have been associated with changes in PVR following PE are thromboxane-A_2, which is an end product of arachidonic acid metabolism, and serotonin.[5] Thromboxane-A_2 is both a systemic and pulmonary vasoconstrictor that is released by platelets with the purpose of causing vasoconstriction to achieve homeostasis. Platelets are also the likely source of serotonin release because serotonin plays an important role in platelet aggregation and is a very potent pulmonary vasoconstrictor despite causing systemic vasodilation. Because pulmonary emboli are composed primarily of fibrin and small amounts of platelets, it is unlikely that the embolus itself is the source of thromboxane-A_2 and serotonin release. Instead it is probable that fresh platelets that have amassed around the embolus are activated and release these vasoactive substances which then lead to significant pulmonary vasoconstriction. The roles that these two substances play in pulmonary vasoconstriction are supported by multiple animal studies looking at receptor antagonists that demonstrate significant attenuation to abolishment of the rise in PVR with blockade of the receptors.[5] The initial symptomatic relief resulting from treatment with heparin that is observed within hours likely stems from blockade of platelet activation and prevention of further release of humoral vasoconstrictors, not clot resolution, because not enough time has elapsed for significant fibrinolysis to have occurred.

EFFECTS ON HEMODYNAMICS

PE increases PVR both through mechanical obstruction as well as through

substrate-mediated pulmonary vasoconstriction. In non–hemodynamically significant PE, obstructing emboli and local vasoconstriction divert blood flow to unaffected regions of the vasculature, causing them to dilate and thus minimizing the overall increase in PVR. If enough of the vasculature is obstructed or constricted, PVR rises significantly and the RV afterload increases. To maintain CO, the RV must generate higher pressures. Although the RV is able to generate higher pressures to some degree, as discussed earlier, the RV in a healthy individual without prior cardiopulmonary disease is ill-equipped to deal with significant increases in afterload.

The maximal mean PA pressure that can be generated by a normal RV is approximately 40 mm Hg.[6] Increases in RV afterload beyond this point result in decreases in RV CO. The decreased RV CO leads to a drop in LV preload and subsequent LV CO. Increases in RV afterload lead to increased RV wall stress, which results in increased RV ischemia that can decrease RV CO. In addition, because of the compliance of the RV, increases in RV afterload result in RV dilation, which further exacerbates RV wall stress. As the RV dilates, the leaflets of the tricuspid valve are pulled apart, leading to poor coaptation and worsening tricuspid regurgitation, which leads to decreased RV output. Because the heart is encased in the pericardium, the free wall of the dilating RV cannot expand outward, and, instead, RV dilation leads to a leftward shift of the intraventricular septum, causing a decrease in the size of the LV cavity and a further decrement in LV preload. Notably, because of the drop in LV CO, there is a decrease in right coronary artery (RCA) perfusion, leading to further RV ischemia. These events continue to cascade in a downward spiral leading to further deterioration in RV function and resultant declines in CO, ultimately progressing to cardiogenic shock (**Figure 43.2**).[7,8] This vicious cycle can be exacerbated by additional factors. Excessive fluid loading will cause worsening RV dilation. Although sometimes unavoidable, intubation is especially dangerous because the sedatives used for induction can cause peripheral vasodilation, leading to decreased RCA perfusion pressure and RV ischemia. Furthermore, positive intrathoracic pressure from mechanical ventilation can lead to increased RV afterload because of the compression of pulmonary vessels.

For patients with underlying chronic cardiopulmonary disease resulting in pulmonary hypertension, the RV has been chronically exposed to increased afterload, and thus has had time to adapt by undergoing hypertrophy, allowing it to generate pressures significantly higher than that which a normal RV can generate.[9] Nevertheless, patients with underlying cardiopulmonary disease are at increased risk for hemodynamic decompensation in the setting of a significant PE because of their baseline compromised state.

EFFECTS OF PULMONARY EMBOLISM ON GAS EXCHANGE

One of the major physiologic effects of PE is the creation of dead-space ventilation, which is defined as areas of the lung that receive ventilation but no perfusion. An increase in dead-space ventilation would normally result in hypercapnia because of a reduced ability to eliminate carbon dioxide from the blood stream; however, hypercapnia is not a common finding in PE because patients compensate by hyperventilating other areas of the lung that are participating in gas exchange. Typically, if the clot burden is severe enough to cause hypercapnia, the hemodynamic effects often prove fatal.[10]

Hypoxemia is a common finding in PE and is due to a combination of multiple factors. One factor is the development of an intrapulmonary shunt, defined as blood traversing areas of the lung that receive no ventilation. This lack of ventilation may occur because of effects from the embolism, which includes atelectasis, pulmonary infarction, and bronchoconstriction. Shunt physiology is also present in a small subset of patients who develop intracardiac shunting, typically through a patent foramen ovale that has opened because of increased right atrial pressure from RV failure. Low mixed venous saturations from decreased CO may contribute to hypoxemia because the venous blood starts at a lower oxygen saturation before traversing abnormal lungs. Hypoxemia is typically accompanied by an increased gradient between the alveolar oxygen concentration (Pa_{O_2}) and the arterial oxygen concentration (Pa_{O_2}). An increased

gradient may even be present in patients with a normal Pa_{O_2} because of the effects of hyperventilation on arterial CO_2 partial pressure.[10]

DIAGNOSIS OF DEEP VEIN THROMBOSIS

DVT, although not fatal by itself, has the potential to fragment and cause a fatal PE. On the other hand, inappropriate anticoagulation of patients exposes them to unnecessary risks, such as a potentially life-threatening hemorrhage. Therefore, it is important to make a proper diagnosis in patients suspected to have a DVT. The gold standard for diagnosis of DVT is venography, which involves the injection of iodinated contrast dye into a dorsal foot vein to outline the entire venous system of the lower extremity. Venography has been demonstrated to have a risk of approximately 1.2% for the development of symptomatic DVT or PE during 3 months of follow-up after a normal venogram. Venography is no longer commonly used to establish or rule out the diagnosis of DVT because of its invasive nature, associated risks, high cost, lack of availability at many centers, and the fact that it is contraindicated in some patients, such as those with renal dysfunction or severe allergies to the contrast material.[11]

Current practice typically uses combinations of clinical probability assessments, D-dimer assays (high sensitivity and moderate sensitivity), and imaging such as venous ultrasonography (US), computed tomography (CT) venography, or magnetic resonance imaging (MRI). The decision on the combination of tests used is dependent upon the pretest probability of the presence of DVT, the suspected location (lower vs upper extremity), and suspected first episode versus recurrence.[11]

Multiple clinical probability assessments for DVT exist. One of the more commonly used tools, known as the Wells score (**Table 43.1**), was developed by Wells et al.[12] and classifies the pretest probability of patients who are suspected of having DVT into three categories: low, moderate, or high probability. The scoring system consists of multiple questions with one point assigned for each question that is answered in the affirmative followed by a subtraction of two points if there is an alternative diagnosis to DVT that is at least equally as likely as the diagnosis of DVT. A score of less than 1 is considered low probability, 1 to 2 is considered moderate probability, and 3 or more is considered high probability of having a DVT. In the initial study of 593 patients, 3% in the low-

probability group, 17% of the moderate-probability group, and 75% of the high-probability group were ultimately diagnosed with DVT.[12] A modified version of the Wells score, which incorporates the presence of prior DVT and divides patients into either low- or high-probability groups, can also be used.[13]

TABLE 43.1 Wells Scores

DVT		PE	
Active cancer (treatment within 6 mo or palliative)	+1	Clinically suspected DVT	+3.0
Calf swelling ≥ 3 cm compared to asymptomatic calf (measured 10 cm below tibial tuberosity)	+1	Alternative diagnosis is less likely than PE	+3.0
Swollen unilateral superficial veins (nonvaricose, in symptomatic leg)	+1	Tachycardia (heart rate > 100)	+1.5
Unilateral pitting edema (in symptomatic leg)	+1	Immobilization (≥ 3 d) or surgery in previous 4 wk	+1.5
Previous documented DVT	+1	History of DVT or PE	+1.5
Swelling of the entire leg	+1	Hemoptysis	+1.0
Localized tenderness along the deep venous system	+1	Malignancy (treatment within 6 mo or palliative)	+1.0
Paralysis, paresis, or recent cast immobilization of lower extremities	+1		
Recently bedridden ≥ 3 d, or major surgery requiring regional or general anesthetic in the past 12 wk	+1		
Alternative diagnosis at least as likely	−2		
High probability	>2	High probability	>6.0
Moderate probability	1–2	Moderate probability	2.0–6.0
Low probability	<1	Low probability	<2.0

DVT, deep vein thrombosis; PE, pulmonary embolism.

The D-dimer, a degradation product of cross-linked fibrin, has a high sensitivity for the presence of VTE; however, it has a poor specificity because of

numerous conditions other than VTE that can cause an elevation in D-dimer levels. This makes the D-dimer assay a useful test in low-risk patients as a test to rule out the presence of DVT. Unfortunately, the test is much less useful in acutely ill or hospitalized patients because of the high occurrence of false-positive results.[11] Multiple versions of the test exist, each with its own sensitivity and specificity.[14]

Owing to its noninvasive nature, low cost, and lack of radiation or contrast dye, US is the most commonly used modality to diagnose DVT. The two types of US studies include proximal compression US and whole-leg US. In both cases, the US probe is used to assess for the presence of a clot within the vein by compression, a positive study defined as the inability to fully compress any segment of the vein under gentle pressure with the probe. The proximal study assesses the femoral and popliteal veins, but not the calf veins. Whole-leg US assesses the proximal veins as well as the calf veins.

For patients in whom US cannot be obtained, such as those who are in a cast, or in whom US is nondiagnostic, CT venography or MRI may be used to further evaluate for DVT. CT venography requires the injection of iodinated contrast, typically into an arm vein, with CT imaging timed for opacification of the deep veins. CT venography can be combined with computed tomography pulmonary angiography (CTPA) to evaluate for both PE and DVT. MRI may be used in a variety of ways to establish the diagnosis of DVT. Magnetic resonance venography can be done without contrast; however, the use of contrast agents such as gadolinium improves visualization of the vasculature. MRI can also be used to directly image thrombi using techniques to take advantage of the composition of clots. MRI is less frequently used because of higher costs and lack of availability for this purpose at most centers.[11]

DIAGNOSIS OF PULMONARY EMBOLISM

Combinations of clinical probability calculators, D-dimer assays, and imaging modalities such as pulmonary angiography, CT angiogram, lung scintigraphy (ventilation-perfusion [VQ] scan), and echocardiography are used to make the diagnosis of PE.[15]

Similar to how venography was the gold standard for the diagnosis of DVT, pulmonary angiography was previously the gold standard for the diagnosis of PE. It is done by performing a right heart catheterization and injecting contrast

dye into the pulmonary arteries. The vasculature is then examined for filling defects or amputation of a branch of the PA. One benefit of pulmonary angiography over CT angiography is the ability to simultaneously obtain invasive hemodynamic measurements. With the improvement in CT imaging, pulmonary angiography has fallen out of favor because of its invasive nature and cost.[15]

Multiple clinical prediction rules are available to determine the pretest probability of PE. The most frequently used scoring system was again developed by Wells et al.[12], which classifies patients into three groups: low likelihood, moderate likelihood, and high likelihood with rates of diagnosed PE of approximately 10%, 30%, and 65%, respectively (**Table 43.1**). A simplified version of the Wells score separates patients into two groups.[15]

CTPA is currently the diagnostic imaging modality choice for evaluation of patients with suspected PE. CTPA involves the injection of iodinated contrast, typically into an arm vein, with imaging timed for opacification of the pulmonary arterial circulation. This allows for adequate visualization of the pulmonary vasculature at least down to the level of the segmental pulmonary arteries, providing a sensitivity and specificity of 96% and 95%, respectively.[15] CTPA also allows for evaluation of the lung parenchyma that may reveal diagnoses other than PE that may be the cause of the respiratory problems.

VQ scans are another imaging modality that can be useful for the diagnosis of PE, particularly in patients who cannot undergo CTPA because of contrast allergies, renal insufficiency, or any other reason. The test involves the injection of technetium (Tc)-99m–labeled macroaggregated albumin particles that ultimately get lodged in the pulmonary capillaries and are viewable by scintigraphy, allowing for evaluation of pulmonary perfusion. The perfusion studies are then matched with ventilation studies, which require the inhalation of radio-labeled gas or microparticles that can be imaged to evaluate ventilation of the lungs. The matched scans are then examined, looking for areas of the lung with poor perfusion but preserved ventilation, which would signify a PE. VQ scans have the benefit of requiring significantly less radiation exposure when compared to CTPA. VQ scans are frequently classified into one of the following categories, considered diagnostic in most patients: normal or near normal, low probability, intermediate probability (nondiagnostic), and high probability.[15]

Echocardiography may also be helpful in making the diagnosis of PE and is a useful tool for prognostication. Signs such as RV dilatation and signs of RV pressure overload are highly suggestive of PE. McConnell sign, defined as a

decreased contractility of the RV free wall compared to the apex, can sometimes be seen in patients with PE. Mobile right heart thrombi seen on echocardiography essentially confirm the diagnosis of PE; however, they are a rare finding. Because the overall negative predictive value of echocardiography is low, it is a poor test to rule out PE.[15]

RISK STRATIFICATION FOR PATIENTS WITH PULMONARY EMBOLISM

To determine the optimal management of patients with PE, it is crucial to assess their risk of short-term decompensation. Patients with a higher risk of decompensation are likely to benefit more from aggressive therapies compared to patients with a lower risk profile.

The Pulmonary Embolism Severity Index (PESI) score is a tool that was developed to help risk stratify patients diagnosed with PE. The model utilizes 11 criteria to stratify patients into 5 classes of risk (PESI classes I to V), the lowest group having a 30-day mortality of 0% to 1.6% and the highest class having a 30-day mortality rate between 10% and 24.5%.[16] The PESI score is particularly useful for identifying low-risk patients (PESI I and II) who can be safely treated as outpatients.[17]

For patients in higher PESI classes, it is important to further stratify based on risk of short-term morbidity and mortality. On the basis of the Management Strategies and Determinants of Outcome in Acute Pulmonary Embolism Trial (MAPPET), hemodynamic status on presentation, specifically systolic blood pressure (SBP) <90 mm Hg, not clot burden, is the major determinant of short-term mortality. The trial included patients with PE and overt signs of impending right heart failure, noting in-hospital mortality rates of 8.1%, 25%, and 65% in patients with RV dysfunction but SBP > 90 mm Hg, cardiogenic shock, and those requiring cardiopulmonary resuscitation at presentation, respectively.[18] On the basis of this elevated risk of death, the American Heart Association defines massive PE as acute PE with sustained hypotension (SBP < 90 mm Hg for at least 15 minutes or requiring inotropes in the absence of another cause of hypotension), pulselessness, or persistent profound bradycardia (heart rate < 40 beats/min with signs or symptoms of shock) (**Figure 43.3**).[19] Owing to the high risk of early mortality in these patients, immediate intervention to restore

pulmonary perfusion is required.

PE CLASSIFICATIONS

Massive PE = Acute PE + one of the following:

1. Sustained Hypotension
   - SBP < 90 mmHg for at least 15 minutes or requiring inotropic support
   - Not due to another cause such as arrhythmia, hypovolemia, sepsis, or LV dysfunction
2. Pulselessness
3. Persistent Profound Bradycardia
   - Heart rate < 40 bpm with signs or symptoms of shock

Submassive PE = Acute PE without systemic hypotension (SBP ≥ 90 mmHg) + one of the following:

1. RV Dysfunction: defined as the presence of at least one of the following
   - RV dilation (echocardiography or CT)
   - Elevated BNP or NT-proBNP
   - EKG changes (new or incomplete RBBB, anteroseptal ST elevation or depression, or anteroseptal T-wave inversion)
2. Myocardial necrosis: defined as an elevation in troponin I or troponin T

FIGURE 43.3 PE classification from the scientific statement from the AHA. AHA, American Heart Association; PE, pulmonary embolism.

Normotensive patients with RV dysfunction and/or myocardial injury are at a slightly increased risk of deteriorating into a massive PE compared to those who

are low risk, and are thus classified as “submassive” PE.[19] Tests that can be used to determine whether a patient has RV dysfunction or myocardial injury include echocardiography, CT scans, electrocardiography, brain natriuretic peptide (BNP), N-terminal (NT)-proBNP, troponin I, and troponin T. Evidence of RV dysfunction on echocardiography includes RV free wall hypokinesis, RV dilatation, increased ratio of RV to LV diameter, and elevations in calculated RV systolic pressures. CT scans can also be used to evaluate for RV dilatation and increased ratio of RV to LV diameter. Electrocardiographic findings of sinus tachycardia, new-onset atrial arrhythmias, new right bundle branch block, Qr pattern in V1, an S1Q3T3 pattern, negative T waves in V1 to V4, and ST segment shift over V1 to V4 have been associated with higher short-term risk. BNP and NT-proBNP, which are released in states of RV pressure overload that lead to increased myocardial stretch, can also be useful tests because patients with normal BNP and NT-proBNP levels have a high negative predictive value for increased risk of poor outcome. Finally, troponin levels also have a good negative predictive value because patients without troponin elevations are at low risk for early adverse outcomes.[15,19] **Table 43.2** represents a risk stratification schematic.

TABLE 43.2 PE Risk Stratification for Early Mortality Risk

EARLY MORTALITY RISK	SHOCK OR HYPOTENSION	PESI CLASS III–V	RV DYSFUNCTION ON IMAGING	+ CARDIAC BIOMARKERS
High risk	+	N/A	+	N/A
Intermediate-high	−	+	+	+
Intermediate-low	−	+	Either one or neither +	
Low risk	−	−	Assessment unnecessary, both—if done

TREATMENT OF DEEP VEIN THROMBOSIS

Because DVT itself is not a fatal condition, the decision whether to treat a DVT and the choice of treatment involves weighing the risks of the progression to PE

and recurrence versus the risks of treatment. Factors involved in determining whether to treat include location of the thrombus, the presence or absence of a known provoking factor, any underlying hypercoagulable state, prior history of VTE, bleeding risk, and patient preference. Potential treatment options include monitoring, anticoagulation (**Table 43.3**) used to prevent further clots and promote passive reduction of thrombus size, thrombolysis which actively promotes clot breakdown, catheter-directed thrombolysis (CDT), inferior vena cava (IVC) filter placement, and thrombectomy.[20]

TABLE 43.3 Available Anticoagulants

ANTICOAGULANT	DOSE	ROUTE	RENAL ADJUSTMENT	REVERSAL AGENT
Apixaban	10 mg twice daily for 7 d, then 5 mg twice daily	Oral	Yes	No
Argatroban	2 µg/kg/min Titrate to aPTT goal	IV	No	No
Bivalrudin	0.15–0.2 mg/kg/h Titrate to aPTT goal	IV	No	No
Dabigatran	150 mg twice daily	Oral	Yes	Idraucizumab
Edoxaban	60 mg daily 30 mg daily if ≤ 60 kg	Oral	Yes	No
Fondaparinux	Weight based <50 kg = 5 mg daily 50–100 kg = 7.5 mg daily >100 kg = 10 mg daily	SubQ	Yes	No
LMWH	1 mg/kg every 12 h	SubQ	Yes	Protamine for partial neutralization
Rivaroxaban	15 mg twice daily for 21 d, then 20 mg daily	Oral	Yes	No
Unfractionated heparin	80 U/kg bolus, then 18 U/kg/h Titrate to aPTT goal	IV	No	Protamine
Warfarin	Individualized dosing Titrate to goal INR	Oral	No	Vitamin K

aPTT, activated partial thromboplastin time; INR, international normalized ratio; IV, intravenous; LMWH, low-molecular-weight heparin; SubQ, subcutaneous.

In the case of patients with a first occurrence of DVT, the location of the thrombus will play a significant role in the treatment decision. For patients with clots distal to the popliteal vein (isolated distal DVT) without severe symptoms or risk factors for extension such as positive D-dimer without an alternative reason, extensive thrombosis (>5 cm in length, involving multiple veins, or >7 mm in maximal diameter), close to proximal veins, no reversible provoking factor, active cancer, prior VTE, or inpatient status, monitoring with repeat US in 2 weeks is preferred to treatment with anticoagulation. If repeat US is unable to be performed or any risk factors are present, anticoagulation is preferred in patients with low-moderate bleeding risk. In patients with high bleeding risk, serial monitoring is preferred. If extension is seen on the repeat US, then anticoagulation should be initiated. For patients with proximal leg DVT, anticoagulation is recommended if tolerated and preferred over CDT. The use of an IVC filter in addition to anticoagulation is not recommended; however, an IVC filter should be used in patients who cannot tolerate anticoagulation due to bleeding, have a contraindication to anticoagulation, or have developed VTE despite being anticoagulated. For patients with proximal upper extremity DVT (axillary or more proximal veins), typically occurring in the setting of central venous catheter usage, treatment with anticoagulation is preferable to CDT and the catheter should be removed if still present. For patients with a recurrent episode of VTE while not on anticoagulation, initiation of anticoagulation is the preferred method of treatment.[20]

The initial choice of anticoagulation is based on multiple factors such as presence of active malignancy, presence of renal dysfunction, planned procedures, prior treatment failures, need for monitoring, and cost. For patients with active malignancy, low-molecular-weight heparin (LMWH) is the preferred agent. For patients without active malignancy, novel oral anticoagulants (NOACs) such as dabigatran, rivaroxaban, apixaban, and edoxaban are preferred to vitamin K antagonists (VKAs) such as warfarin, and VKAs are preferred to LMWH. For patients who have recurrent VTE despite anticoagulation, LMWH is recommended. If the recurrence occurs while the patient is compliant with LMWH treatment, the dose of the LMWH can be increased. In both cases of treatment failure, the presence of an underlying malignancy should be considered.[20]

The duration of anticoagulation is dependent upon whether the DVT was provoked by a known reversible factor, whether it is an initial clot or a recurrence, presence of active malignancy, presence of known hypercoagulable

state, and bleeding risk. For patients with a first occurrence with a known reversible risk factor such as surgery, pregnancy, leg injury, or a flight >8 hours, 3 months of therapy is the recommended duration. For patients who are low-moderate bleeding risk with unprovoked DVT, recurrent DVT while off anticoagulation, or who have an active malignancy, indefinite treatment with anticoagulation is preferred to 3 months of treatment. In patients with similar high bleeding risk, 3 months of treatment is recommended over indefinite treatment. Patient preferences should also be taken into account when deciding on treatment duration.[20]

TREATMENT OF PULMONARY EMBOLISM

Unlike in patients with DVT alone, patients with PE may present with hemodynamic instability and respiratory abnormalities such as hypoxemia. The initial step in management should be to provide adequate support to maintain organ perfusion and gas exchange. As discussed earlier, the etiology of hypotension and shock from PE is RV failure secondary to an increase in RV afterload. Aggressive volume expansion should be avoided because it may further exacerbate RV dilation and wall stress. Vasopressors such as norepinephrine should be used to maintain arterial pressure and inotropes such as dobutamine should be used to support RV contractility. The role of inhaled pulmonary vasodilators such as epoprostenol and nitric oxide is unclear, but may improve hemodynamics given the presence of pulmonary vasoconstriction from humoral factors. Hypoxemia should be treated with supplemental oxygen and mechanical ventilation should be initiated if required; however, if intubation and mechanical ventilation is required, special care should be taken because inducing agents and the use of positive-pressure ventilation can cause further hemodynamic compromise in these very unstable patients.

The mainstay of therapy for PE is anticoagulation, which prevents the formation of new thrombi and allows the patient’s endogenous fibrinolytic system to resolve the clots that are present. Because PE is a potentially life-threatening condition, empiric anticoagulation should be started in patients with intermediate-high clinical probability of PE during the diagnostic workup. In patients with a low probability of PE, anticoagulation can be withheld until a diagnosis of PE is confirmed. Recommended initial anticoagulation choices include subcutaneous LMWH, unfractionated heparin with monitoring of the

activated partial thromboplastin time, or subcutaneous fondaparinux. In cases where heparin products cannot be used, such as with heparin-induced thrombocytopenia, non–heparin-based anticoagulation should be used. Once the diagnosis of PE is confirmed, it is crucial to risk stratify patients to help decide the most appropriate treatment and level of monitoring. A sample algorithm is provided in **Figure 43.4**.

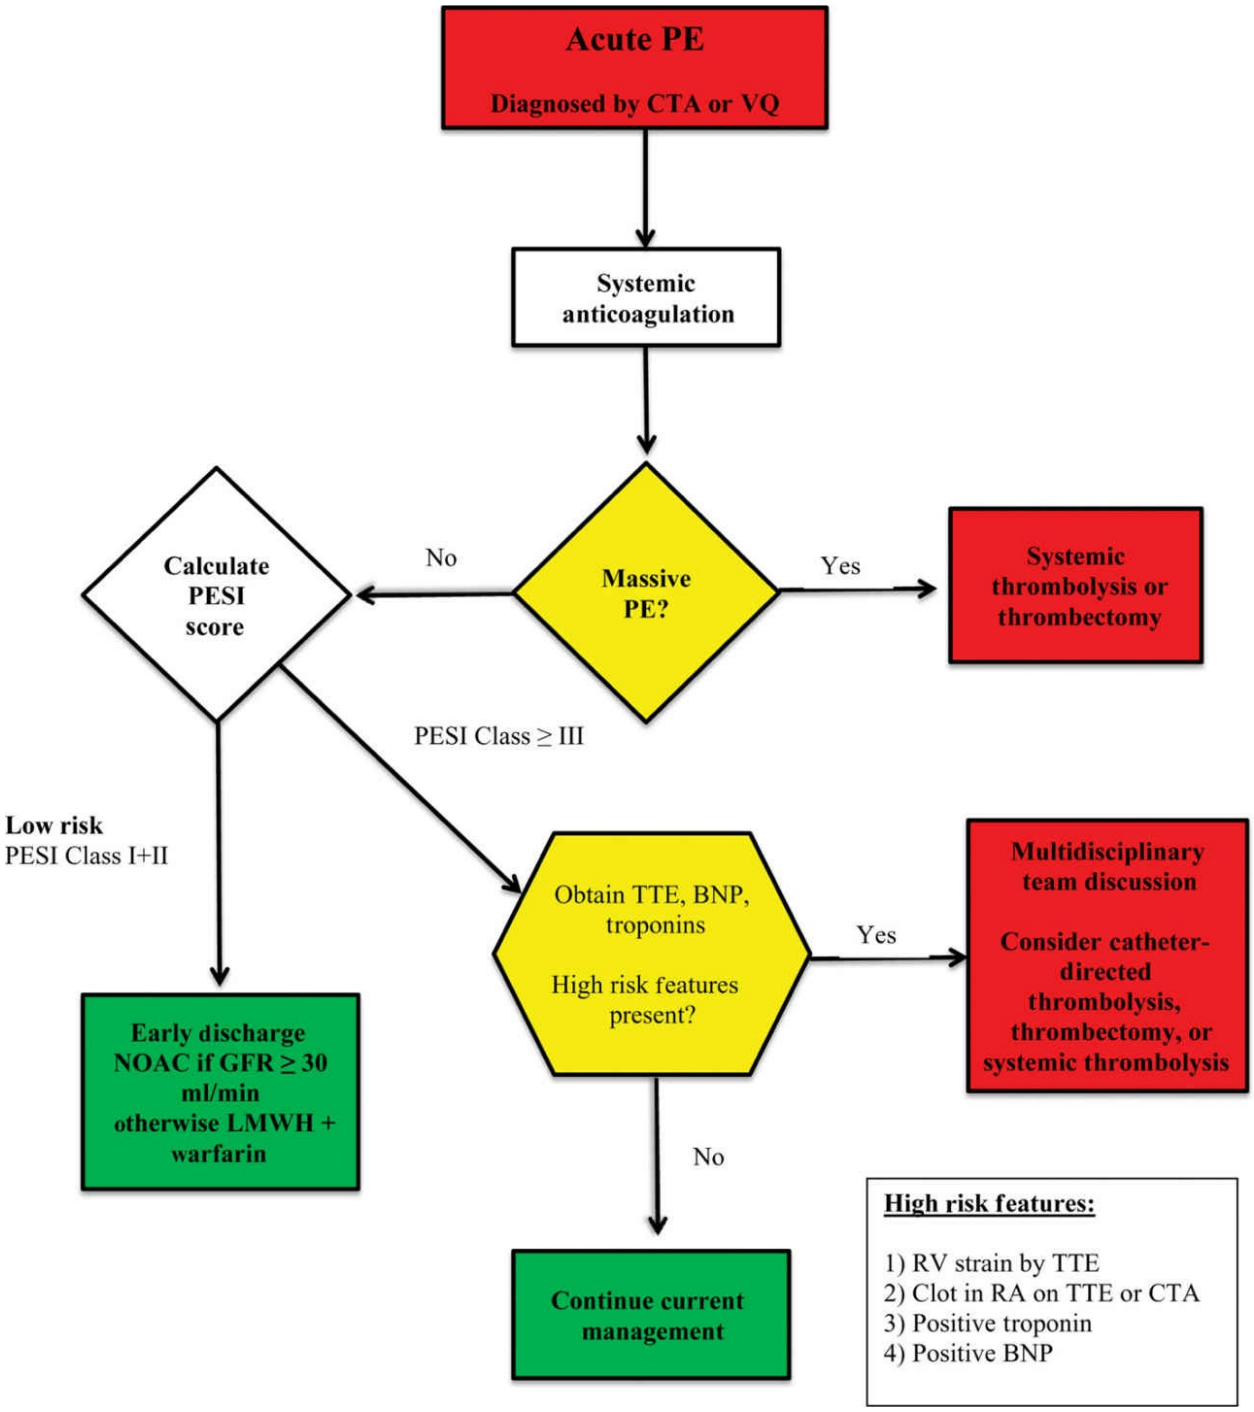

FIGURE 43.4 Sample PE treatment algorithm. BNP, brain natriuretic peptide; CTA, computed tomography angiogram; GFR, glomerular filtration rate; LMWH, low-molecular-weight heparin; NOAC, novel oral anticoagulant; PE, pulmonary embolism; PESI, Pulmonary Embolism Severity Index; RA, right atrium; RV, right ventricle; TTE, transthoracic echocardiogram; VQ, ventilation-perfusion.

For patients who are low risk (PESI I and II), no further workup for risk stratification is necessary, and these patients can be considered for early

discharge home with anticoagulation. As with DVT, the NOACs and VKAs are preferred to LMWH except for in-patients with active malignancy or recurrence while taking another form of anticoagulation. For patients at intermediate to high risk (PESI classes III to V), cardiac imaging and biomarkers should be obtained to evaluate for signs of RV dysfunction and/or myocardial necrosis.

For patients with massive PE, aggressive therapies to restore pulmonary perfusion should be undertaken given the high mortality risk. If there are no absolute contraindications, systemic thrombolysis is recommended (**Table 43.4**). Surgical embolectomy may also be considered in centers with experience with the procedure. Surgical embolectomy is also a good option in cases of clot in transit (right atrial or RV thrombus), which have a high risk of embolizing into the pulmonary vasculature.

TABLE 43.4 Contraindications to Systemic Thrombolysis

1. Prior intracranial hemorrhage
2. Structural intracranial cerebrovascular disease
3. Malignant intracranial neoplasm
4. Ischemic stroke within 3 mo
5. Suspected aortic dissection
6. Active bleeding or bleeding diathesis
7. Recent surgery encroaching on the spinal canal or the brain
8. Recent facial or closed-head trauma with evidence of bony fracture or brain injury

Adapted from 2014 AHA Statement.[19]

While the mortality rate for submassive PE is higher than that for low-risk PE, the role of thrombolysis in this population is controversial. Thrombolysis has been shown to reduce the rate of hemodynamic decompensation in patients with submassive PE; however, this benefit has not translated into a reduction in mortality, likely because of the increase in adverse events, particularly intracranial hemorrhage, which occurs in about 2% of patients receiving systemic thrombolysis. To reduce the bleeding risks of thrombolysis, lower doses can be administered. Ultrasound-assisted, catheter-directed, low-dose thrombolysis has been investigated as a potential treatment. The rationale of this therapy is to administer the thrombolytic directly at the clot while using high-frequency US to increase thrombus permeability to thrombolytic agents, allowing for use of even lower doses of thrombolytics and theoretically decreasing the risk of bleeding.[21]

Given the lack of clear consensus guidelines for the treatment of massive and submassive PEs, the use of multidisciplinary teams, often comprising physicians

from cardiology, pulmonology, critical care, interventional radiology, cardiothoracic surgery, and emergency medicine, can help determine the best treatment strategy and provide a multidisciplinary recommendation along with rapid mobilization of resources.

Patient and Family Information for: PULMONARY EMBOLISM AND DEEP VEIN THROMBOSIS

Deep Vein Thrombosis (DVT) and Pulmonary Embolism (PE) are blood clots that occur in the blood vessels of the limbs, primarily the legs, and the lungs, respectively. They are part of a spectrum of disease known as Venous Thrombo-embolism (VTE). Typically, the body maintains a balance where blood remains fluid while inside the blood vessels, but clots whenever it exits the blood vessels. This mechanism is how the body stops bleeding after a cut occurs. DVTs occur when the blood clots inappropriately inside the body and can occur if the blood flow through those veins is sluggish, as can occur during prolonged surgery or very long periods of immobility such as a long plane flight. In other cases, patients may have a "hypercoagulable state," a condition where the blood is intrinsically more likely to form clots. Occasionally, pieces of these clots from the blood vessels of the limbs may break off and travel to the lungs and get lodged in the blood vessels of the lung, a process known as pulmonary embolism. The blood clots cause symptoms by blocking the blood flow in the blood vessels they reside.

The symptoms of blood clots are variable and depend on the location. For DVTs, the most common symptoms are swelling, pain, and redness near the location of the blood clot. Some patients may have no symptoms at all. Blood clots in the lung (PE) may cause shortness of breath, chest pain, a rapid pulse, and coughing up blood. Occasionally, some people with PE do not have any symptoms at all and the blood clots are found incidentally.

Of the two, PE is the more dangerous, life-threatening form of blood clot. In severe cases of PE, the blood clots can impair the ability of the flowing blood to take up oxygen and can also prevent blood from circulating through the lungs,

possibly leading to death. DVTs themselves do not cause these problems, but pieces can break off and result in PE.

If your doctor suspects that you have a PE or DVT, there are numerous tests that may be ordered to find the clot. These tests include imaging tests such as CT scans, VQ scans, and ultrasound of the limbs. A blood test, known as the D-dimer, which is often abnormally elevated in people with blood clots, can be helpful to rule out the presence of PE or DVT.

The treatment depends upon the severity of the clots. Simple blood clots are treated with blood thinners, otherwise known as anticoagulants, to prevent growth of current clots and also to prevent the formation of new blood clots. All patients with VTE are treated for at least 3 months, and treatment may be longer depending on the cause of the blood clot. In some patients who are unable to take blood thinners, such as people with recent bleeding or some recent surgeries, a device called an IVC filter may be placed in one of the veins in the abdomen to try to prevent blood clots that form in the lower limbs from reaching the lungs.

In very severe cases where patients have very low blood pressure, medications called thrombolytics may be given to try to dissolve the blood clots. In some cases, this may be determined to be unsafe and the person with the clot may have to undergo surgical removal of the blood clots.

Sedation and Analgesia in the Cardiac Care Unit

INTRODUCTION

Patients in a cardiac care unit (CCU) experience pain, anxiety, stress and, at times, delirium, and altered mental status. Sedation and analgesia of these patients is not only a humane way to treat their discomfort but it also is an integral part of their therapy to allow them to tolerate the various other therapies, treatments, and instrumentations that they are subjected to in the critical care setting. It also is integral in reducing the metabolic response and oxygen demands of the critically ill cardiac patient.

Sedatives and analgesic medications carry with them hemodynamic, respiratory, neurologic, and other side effects, so that proper sedation is a balance between adequacy of sedation and minimizing these other effects. In addition, development of delirium in the cardiac care setting is a complication that dramatically impacts on the survival and quality of life of patients after they have recovered from their illness. Recently, the implication of the very choice of agent in the development of delirium has led to a reevaluation of the impact of all sedative/analgesic regimens in the context of their propensity to cause or help delirium.

The desired level of sedation in the cardiac care setting can vary widely

between the awake, alert, conversant, oriented and comfortable patient, and the patient who is in a drug-induced coma and therapeutically paralyzed. The precise level of sedation and the agents used are determined by the indications for sedation, whether they are anxiety, insomnia, agitation, coordination with a mechanical ventilator, prevention of removal of tubes or lines, protection against myocardial ischemia, or the need for amnesia during paralysis. Agents are chosen depending on the relative amounts of the different components of analgesia, anxiolysis, amnesia, sleep, and muscle relaxation that are needed.

Although use of pharmacologic agents is the main way to achieve these goals, it cannot be stressed enough that other measures that reduce the need for amounts or even the very need for sedation are tremendously beneficial to patients, their comfort, and the avoidance of confusion and delirium. Such measures include frequent reorientation, assurance, and communication from the nursing staff; proper environmental controls such as lighting, temperature, and noise control; assessment and management of sensations such as hunger, thirst, and need to void; providing a variety of stimuli, such as visitors and media; and maintenance of a diurnal variation, with, if possible, a window facing the outside.

EVALUATION OF LEVEL OF SEDATION

One goal of management of critically ill cardiac patients is maintaining an optimal level of pain control and sedation. Unfortunately, pain and anxiety are subjective and somewhat difficult to consistently measure from caregiver to caregiver. Over 50% of patients who were interviewed after their intensive care unit (ICU) stays rated their pain as moderate to severe, during rest as well as during procedures.[1–3] Thus, the assessment of pain and anxiety must be discussed first before moving on to the pharmacology of the agents.

Although patients in a CCU are being monitored with highly sophisticated equipment, technological methods of measuring pain and anxiety such as those using electroenphalography (EEG), cerebral function analyzing monitors, lower esophageal contractility, combinations of physiologic variables or serum concentrations of medications, among others, have all proved to be no more reliable and a lot more complicated and expensive as simple, clinically based scoring systems. Properly designed scoring systems can be used not only to assess and record pain and anxiety but also to allow bedside nurses to titrate

therapy in a more tightly defined window on their own, meeting regulatory requirements without needing repeated orders from a practitioner who is licensed to prescribe the medications.

The most basic of clinical methods of pain assessment is simply asking the patient to rate the pain on a scale of 0 to 10, with 0 being no pain at all and 10 being the worst pain imaginable. Although simple and widely used, and despite those instructions being given, the very fact that not infrequently some patients will answer “11” shows that when pain is being experienced acutely, the overall severity of the pain seems much greater than some historical control. One step up from a simple number scale is the use of a “Visual Analog Scale” (VAS)—which is simply a line that has the scale marked off in measured intervals. This scale is highly reliable and valid from patient to patient and caregiver to caregiver.[4] It can be further modified to have pictures of happy and unhappy patients or faces on the scale in varying degrees instead of numbers. Unfortunately, it is limited because it ignores qualitative aspects of pain, and many critically ill cardiac patients are not strong enough or awake enough to use such a system.

Measuring sedation and level of consciousness is similarly difficult, and requires the use of assessment of a practitioner observing the patient. The most basic method is to perform a mental status and neurologic examination and report the results. This is not practical on a repeated basis and does not allow the easy determination of changes that would allow titration of medications from time to time. The Glasgow Coma Scale (GCS) is widely used for the assessment of level of consciousness, but it was designed and validated for patients with neurologic deficits, and is not designed for assessment of sedation.

Sedation scales are subjective tools that, in general, measure the patient’s responsiveness to verbal, auditory, and or physical stimuli. The ideal scale would determine the degree of sedation and agitation, be applicable in a wide variety of patient situations, have a well-defined sedation goal, include behavioral descriptors, be easy to measure and score with minimal training, and be reproducible, reliable, and valid across caregivers. Proper use of such a scale can reduce the duration of mechanical ventilation and also reduce length of stay in both the CCU and the hospital.[5] However, even though this has been known for over 10 years, the clinical use of scoring systems still remains low.[6] It is therefore imperative that every patient care area or unit that sedates critically ill patients chooses a sedation scale that best fits its patients, trains the caregivers in its use, and develops procedures to use that information in the sedation of the

patients in the cardiac care area.

One of the most widespread of the currently used sedation scales is the Ramsay Sedation Scale (RSS), introduced in 1974 and modified slightly since then. The modified scale is shown in **Table 44.1**. As it was designed primarily for use during research into sedative agents, it was at the same time both groundbreaking but less than ideal for clinical use. Since its debut, many others have been developed for different reasons. Some of the more commonly referenced or clinically used ones include the Sedation Agitation Scale (SAS, **Table 44.2**),[7] the Motor Activity Assessment Scale,[8] the Vancouver Interactive and Calmness Scale (VICS),[9] the Richmond Agitation–Sedation Scale (RASS, **Table 44.3**),[10] the Adaptation to Intensive Care Environment (ATICE) instrument,[11] and the Minnesota Sedation Assessment Tool (MSAT).[12]

TABLE 44.1 Modified Ramsay Sedation Scale

SCORE	DEFINITION
1	Anxious and agitated or restless or both
2	Cooperative, oriented, and tranquil
3	Responds to commands only
4	Brisk response to a light glabellar tap or loud auditory stimulus
5	Sluggish response to a light glabellar tap or loud auditory stimulus
6	No response to a light glabellar tap or loud auditory stimulus

Performed using a series of steps: observation of behavior (score 1 or 2), followed (if necessary) by assessment of response to voice (score 3), followed (if necessary) by assessment of response to loud auditory stimulus or light glabellar tap (score 4 to 6).

TABLE 44.2 Sedation–Agitation Scale

SCORE	TERM	DESCRIPTOR
7	Dangerous agitation	Pulling at ET tube, trying to remove catheters, climbing over bedrail, striking at staff, thrashing side to side
6	Very agitated	Requiring Restraint and frequent verbal reminding of limits, biting ETT.
5	Agitated	Anxious or physically agitated, calms to verbal instructions.
	Calm and	

4	cooperative	Calm, easily arousable, follows command.
3	Sedated	Difficult to arouse but awakens to verbal stimuli or gentle shaking, follows simple commands but drifts off again.
2	Very sedated	Arouses to physical stimuli but does not communicate or follow commands, may move spontaneously.
1	Unarousable	Minimal or no response to noxious stimuli, does not communicate or follow command.
Guidelines for SAS assessment		
1	Agitated patients are scored by their most severe degree of agitation as described.	
2	If patient is awake or awakens easily to voice (“awaken” means responds with voice or head shaking to a question or follows commands), that is a SAS 4 (same as calm and appropriate—might even be napping).	
3	If more stimuli such as shaking are required but patient eventually does awaken, that is a SAS 3.	
4	If patient arouses to stronger physical stimuli (may be noxious) but never awakens to the point of responding yes/no or following commands, that is a SAS 2.	
5	Little or no response to noxious physical stimuli represents a SAS 1.	

ET, endotracheal; SAS, Sedation–Agitation Scale.

TABLE 44.3 Richmond Agitation–Sedation Scale

SCORE	TERM	DESCRIPTION
14	Combative	Overtly combative or violent, immediate danger to staff
13	Very agitated	Pulls on or removes tube(s) or catheter(s) or exhibits aggressive behavior toward staff
12	Agitated	Frequent nonpurposeful movement or patient–ventilator dys-synchrony
11	Restless	Anxious or apprehensive, but movements not aggressive or vigorous
0	Alert and calm	
21	Drowsy	Not fully alert, but has sustained (.10 s) awakening, with eye contact, to voice
22	Light sedation	Briefly (,10 s) awakens with eye contact to voice
23	Moderate sedation	Any movement (but no eye contact) to voice
24	Deep sedation	No response to voice, but any movement to physical stimulation
25	Unarousable	No response to voice or physical stimulation

Performed using a series of steps: observation of behaviors (score 14 to 0), followed (if necessary) by assessment of response to voice (score 21 to 23), followed (if necessary) by assessment of response to physical stimulation such as shaking shoulder and then rubbing sternum if no response to shaking shoulder (score 24 to 25).

A thorough review and comparison of these scales can be found here.[13] The decision to use one scale or the other is many times a local, multidisciplinary decision. What is important is that a scale is indeed used and that it is performed in a standard and consistent manner.

ANALGESIC AND SEDATIVE AGENTS

Critically ill cardiac patients are often treated with continuous infusions of potent medications. Some, such as sedative-hypnotics, have sedation as a primary action; whereas others, such as opioids, have a sedative action that is a secondary effect to the primary analgesic effect. Patients require sedatives because of pain, anxiety, delirium, and the desire to keep them from remembering an uncomfortable time in their lives. Especially when patients are on mechanical ventilation, it is most often much easier to administer such medications via continuous infusion. Use of such agents via continuous infusion, however, is associated with prolonged mechanical ventilation and a longer stay in the CCU, whereas daily interruption of sedative treatment has been shown to reduce the duration of mechanical ventilation and CCU duration.[14] Thus, it is no longer considered acceptable to sedate patients to a deep, deep state but rather to move to a lighter plane of sedation. This is much more difficult and requires both the use of sedation scales as mentioned, sedation protocols, and the selection of agents that are somewhat easier to titrate and have somewhat shorter durations of action than in use previously. It has also been shown that a shift toward more of an analgesic-based sedation instead of a sedative-hypnotic–based regimen is beneficial.[15,16] We therefore now review the most commonly used agents in the CCU for sedation.

Some definitions are needed to help in the classification and description of the various agents. “Analgesic agents” have as their primary mode of action the reduction of patients’ pain. They usually will have as a side effect the sedation of patients, but the sedative effect and the analgesic effect may have different potencies and durations of action. Analgesics can be broadly divided into “opioids,” meaning morphine-like in action, and “nonopioids” which are medications such as nonsteroidal anti-inflammatory agents and acetaminophen.

"Sedative-hypnotics" are medications that have as their primary effect the reversible depression of the central nervous system, inducing sleep, allaying anxiety, and causing amnesia.

Other drugs used in sedation are such drugs as "psychotropic medications," such as haloperidol or risperidone; they are antipsychotic medications that interfere with neurotransmitters in the brain that affect the way the cerebral neurons interact with each other.

OPIOIDS

Opioids are the mainstay of analgesic therapy in the CCU patient. Opioid analgesics, such as morphine, have as their mechanism of action the means of acting selectively on neurons that transmit and modulate nociception, leaving other sensory modalities and motor functions intact. Opioid receptors are found in the brain, spinal cord, and peripheral tissues. When bound to receptors, opioids produce analgesia, drowsiness, changes in mood, and mental clouding. An important feature of opioid analgesia is that it is not associated with loss of consciousness except at extremely high doses.

All opioids depress respiratory drive in a dose-dependent manner, and this depression is increased when opioids are given in conjunction with sedative-hypnotic medications. In general, opioids have minimal hemodynamic effects when given to patients who are not volume depleted, but can cause hypotension in patients who are volume depleted because of veno-dilatation. The primary problems with long-term administration of opioids are tachyphylaxis and dependence and withdrawal symptoms with discontinuation of long-term continuous infusion. A dosing summary is contained in **Table 44.4**.

TABLE 44.4 Analgesics Used in the Cardiac Care Unit

DRUG	ELIMINATION HALF-LIFE	PEAK EFFECT (IV) (min)	STARTING DOSE
Morphine	2–4 h	10–30	1–4 mg bolus 1–5 mg/h infusion
Hydromorphone	2–4 h	10–20	0.2–1 mg bolus 0.5–2 mg/h infusion
Fentanyl	2–5 h	2–3	25–100 µg bolus 25–200 µg/h infusion
Remifentanil	4 min	1.5	6–9 µg/kg/h infusion

Methadone	12–24 h	30–60	5–50 mg every 6–12 h based on previous opioid dose

IV, intravenous.

Morphine

Morphine is the prototypical opioid. It was discovered in 1804 and is the most abundant alkaloid found in opium. It has been sold commercially for almost 200 years and remains a mainstay in the sedation of critically ill cardiac patients. This is primarily due to cost and familiarity factors, because other opioids lack some of the problems associated with morphine. The dose required to produce analgesia, as with most opioids, varies and is dependent on such factors as tolerance, tachyphylaxis, and metabolic and excretory ability. Although morphine is metabolized in the liver, 6% to 20% of the metabolites are morphine-6-glucoronide, a metabolite that is excreted by the kidneys;[17,18] and while the data is variable, it is anywhere from half as potent to 20 to 40 times more potent than morphine itself[18,19] and can accumulate in renal failure. For this reason, hydromorphone is the long-acting opioid that is preferred in renal failure. When given via bolus injection, morphine causes histamine release, but this is not a factor when used via infusion in patients in the CCU. However, when given by bolus, it was one of the classical treatments for cardiogenic pulmonary edema, because the vasodilation and preload reduction it causes, along with the analgesia and anxiolysis, made patients in cardiogenic pulmonary edema much more comfortable.

It is the most hydrophilic of the opioids and therefore has the slowest onset of action. A bolus dose of morphine will take effect in 5 to 10 minutes with peak analgesic effect in 90 minutes and lasting for 2 to 3 hours—after continuous infusion, it does not exhibit prolongations in half-life (known as “context-sensitive half-life”) such as happens with fentanyl and, to a lesser extent, with sufentanil and alfentanil.[20]

Usual doses to start morphine via infusion are 0.5 to 2 mg/h. Bolus doses of morphine can be given at 2 to 4 mg every 1 to 2 hours as a start, but doses can increase as tolerance develops. It is not unusual to see patients require morphine infusions of 15 mg/h or more.

Hydromorphone

Hydromorphone, the most common name for the drug actually called either

dihydromorphone or dimorphone, is a semi-synthetic derivative of morphine. It was synthesized and researched in the 1920s. It is slightly more lipophilic than morphine and thus exhibits superior fat solubility and speed of onset than morphine.[21] It is thought to be three to four times stronger than morphine but with a lower risk of chronic dependency. It lacks the renally excreted active metabolites of morphine. It also has a slightly longer duration of action than morphine—roughly 3 to 4 hours. Its duration of action makes it slightly more cumbersome to adjust via continuous infusion, but, because it does not exhibit the context-sensitive half-life prolongation of fentanyl, it is sometimes preferable to fentanyl via infusion for long durations of sedation.

Most clinicians will start with hydromorphone at 0.1 to 0.2 mg/h and titrate as needed. Bolus doses of 0.5 mg given every 2 to 4 hours can be a starting point for intermittent intravenous (IV) dosing.

Fentanyl

Fentanyl is a fully synthetic opioid that was first developed in 1960 and has served as the parent molecule to the synthetic opioids that have been developed since then—sufentanil, alfentanil, and remifentanil. It is far more potent than morphine—roughly 40 times more potent on an mg/mg basis. As with other opioids, it works by binding to opioid receptors in the brain, spinal cord, and periphery, but its highly lipophilic chemistry causes it to cross the blood–brain barrier very easily, giving it an extremely short onset of action. It does not cause histamine release, and, similar to other opioids, is neither an arterial vasodilator nor a negative inotrope.[22] It can, however, cause veno-dilatation and hypotension in a patient who is volume depleted. It is a potent blocker of endogenous catecholamines, which can be beneficial (in preventing a patient from becoming hypertensive and/or tachycardic with procedures) and detrimental (causing hypotension in patients whose hemodynamics are dependent on an elevated level of endogenous catecholamines).

Fentanyl is primarily metabolized in the liver to inactive metabolites, but its cessation of action is primarily through redistribution from the brain to the peripheral tissues rather than metabolism of active drug. Therefore, while a single or a few bolus doses have a shorter duration of action than morphine, on the order of 60 to 90 minutes, when given by infusion, even after 2 hours, the time to decrease by 50% concentration goes from 30 minutes for a bolus dose to 120 minutes with the infusion, and the time to decrease by 80% goes from 60 minutes with a bolus to over 600 minutes with the infusion.[20] This “context-

sensitive half-life" is due to slow release from the fatty compartments that fentanyl has such an affinity for, and causes a greatly prolonged effect for fentanyl when given by infusion—to an effective half-life much longer than morphine after a few hours of infusion.

Fentanyl also has a particular problem in many patients of having rapidly escalating dosing requirements.[23] It is not uncommon for patients to start out on one dose and 24 to 48 hours later be requiring four to five times as much as they were just a day or two earlier. This tolerance seems greater for many patients than with the longer acting opioids and, combined with the context-sensitive half-life prolongation, makes fentanyl a less than ideal medication to use for critically ill cardiac patients for any longer than 24 to 48 hours.

Fentanyl dosing usually starts at 50 to 100 μg for a bolus dose or 50 to 100 μg/h via infusion with titration—it is not uncommon to rapidly (over 24 to 72 hours) require 500 to 750 μg/h via infusion.

Sufentanil

Sufentanil is similar to fentanyl in every way except that it is more potent—roughly 10 times more potent than fentanyl and almost 400 times more potent than morphine. It does not exhibit quite the same context-sensitive half-life prolongation as fentanyl. It was synthesized in 1974. It is perhaps the most potent sympatholytic opioid in clinical practice. Its use in critically ill cardiac patients has been minimal because, until recently, it was under patent protection and was much more expensive than fentanyl when used for sedation in the CCU.

Remifentanil

Remifentanil is a potent ultrashort-acting synthetic opioid.[24] It is unique in that it has a rapid onset of action, and it has an ester linkage that undergoes rapid hydrolysis by nonspecific tissue and plasma esterases, which means that it has an organ-independent metabolism and does not accumulate in either renal or hepatic failure. Its context-sensitive half-life remains at a flat 4 minutes even after prolonged infusions.[25] It is fairly potent—roughly twice as potent as fentanyl and 100 times as potent as morphine. It is very hemodynamically stable but, unlike fentanyl, it does cause histamine release when given as a bolus; and many times an antihistamine such as diphenhydramine is given as an adjunct when it is used for sedation. It is a potent respiratory depressant, and practitioners familiar with its use commonly see patients who are awake but will

not breathe until it is fully worn off, which happens minutes later.

Remifentanil seems to have all the makings of an ideal sedative agent for critically ill cardiac patients. Although studies have been promising, review of a meta-analysis of studies in critically ill patients[26] shows that while remifentanil use is associated with a reduction in time to tracheal extubation, there was no reduction in mortality, duration of mechanical ventilation, length of ICU stay, or risk of agitation. The other reason it is not currently a viable analgesic for CCU use is that it is still on patent and extremely expensive—recent change in marketing arrangements for the drug have caused the price to double in the United States. Until the price significantly decreases, remifentanil remains a theoretical but not a practical answer to analgesic needs in the CCU.

Methadone

Almost polar opposite in pharmacology to remifenanil is methadone, among the longest acting of the opioids.[27] It is a synthetic opioid that is structurally unlike morphine but still acts on opioid receptors and produces many of the same effects. It was developed in 1937 and has been used commonly because of its long duration of action and low cost. High doses of methadone can block the euphoric effects of other opioids such as heroin and morphine, and it has become a mainstay in the treatment of patients addicted to opioid narcotics. Although that is its most common use, it does have other uses as well, and one of those is in the long-term critically ill patients. Methadone has an excellent oral bioavailability (80% to 90%), an elimination half-life of 12 to 24 hours, and is equipotent with morphine. It can be given via oral tablets or suspension, or intravenously.

Patients who are on long-term opioid infusions may suffer withdrawal symptoms on cessation—others, although not experiencing true withdrawal symptoms, simply need the medication slowly tapered off to allow the patient to gradually reach a state of no sedation. Frequently, this will take place when the patient is ready to leave a CCU but is prevented from leaving by the presence of a sedative infusion. Using methadone to transition a patient from a continuous IV infusion of opioid sometimes can be an ideal way to bridge this gap. Commonly, the patient will be given methadone at a dose of 0.5 to 0.75 mg/d of the equivalent amount of morphine the patient is on. The availability of methadone in an oral suspension makes it even easier to give to patients receiving tube feeds. It has been studied in pediatric patients, but the pharmacology is applicable to adult patients as well.[28]

One consideration in patients receiving methadone that does not exist with the other opioids is that methadone is associated with prolongation of the QTc interval in high doses, and has been implicated in progressing on to torsade de pointes. The mean daily dose in one study was over 350 mg/d, a very high dose; and in usual use it is easy to limit doses to below that, but especially in cardiac patients who may be more predisposed to arrhythmias and QT prolongation, this must be considered.[29]

SEDATIVE HYPNOTICS

In addition to opioids for analgesia, patients in cardiac care settings require sedation for anxiety, restlessness, agitation, and to decrease chances of remembering bad experiences in the CCU. Anxiety is best treated after pain is controlled with analgesics and reversible conditions such as hypoxia, infections, renal or hepatic failure, and metabolic abnormalities are corrected. Most sedative-hypnotics work by binding to the inhibitory gamma-aminobutyric acid (GABA) receptor, which counterbalances the action of excitatory neurotransmitters. By themselves, they have minimal respiratory depressant effect unless patients are made unresponsive to outside stimuli, but with even minimal doses of opioids the respiratory depression is significantly augmented. The clinical effects are very, very similar—so are the differences in pharmacokinetics, cost, and side effects of administration. A dosing summary is contained in **Table 44.5**.

TABLE 44.5 Sedatives Used in the Cardiac Care Unit

DRUG	ELIMINATION HALF-LIFE (h)	PEAK EFFECT (IV) (min)	STARTING DOSE
Midazaolam	3–5	1–2	1–2 mg bolus 0.5–10 mg/h infusion
Lorazepam	10–20	2–20	1–2 mg bolus 0.5–10 mg/h infusion
Propofol	20–30	1–2	20–70 mg bolus (sedation) 100–200 mg bolus (intubation) 25–100 µg/kg/min infusion
Halperidol	10–24	3–20	2–10 mg bolus 2–10 mg/h infusion

Dexmedetomidine	2	5–15	0.2–1.5 μg/kg/h

IV, intravenous.

Lorazepam

Lorazepam is a moderately slow-onset intermediate-acting benzodiazepine that is available to be given either via IV bolus or infusion or via the oral route. Its initial onset is in 5 to 10 minutes, but a wide therapeutic dosing range means that some patients will be fairly well sedated with a small initial dose and others will require multiple, higher doses.[30] For example, patients who are withdrawing from alcohol will sometimes require very high doses, whereas elderly patients will sometimes become heavily sedated with minute doses. Elderly patients may sometimes also "disinhibit" and become very agitated with all benzodiazepines, so they should be used with caution in the elderly.[31]

Lorazepam is metabolized in the liver to inactive metabolites; it has an elimination half-life of 10 to 20 hours, and an effective duration of action of 3 to 6 hours. It is glucuronidated in the liver, and because the glucuronidation system is less affected in liver dysfunction than in the oxidative system, lorazepam may not be as affected by hepatic dysfunction as are other medications, but it should still be used with caution in patients with liver dysfunction. It is not unusual for a patient to receive 24 hours of a moderate dose of lorazepam and take 5 to 7 days to wake up.

Like all members of this class of drugs, lorazepam will cause hypotension via arterial dilatation, and will cause a more pronounced hypotension via veno-dilatation in patients who are volume depleted. Lorazepam is diluted in propylene glycol, and with long-term high-volume infusions propylene glycol toxicity, causing acute tubular necrosis, lactic acidosis, and a hyperosmolar state, can occur.[32]

Initial bolus doses of lorazepam are typically from 0.5 to 2 mg, and infusion rates usually start at 0.5 to 1 mg/h and can go as high as 20 to 25 mg/h, with rates of over 100 mg/h not unheard of for patients in severe alcohol withdrawal.

Midazolam

Midazolam is a rapid-onset, short-acting benzodiazepine. It has the characteristic of causing anterograde amnesia (amnesia after administration) perhaps better than any other sedative. When given in small doses, it is not unusual to have patients arousable and talking and later have no recollection of those events. It

has a short onset of perhaps 1 to 2 minutes; and while the half-life is 1 to 4 hours, its duration of action after a single bolus dose is less than 15 minutes. It is water soluble in the bottle and becomes highly lipophilic at body pH. Its short duration of action is due to rapid equilibration and redistribution among the various bodily compartments. Owing to its lipophilic nature, it has a prolonged context-sensitive half-life due to a high volume of distribution in fatty compartments and also due to accumulation of an active metabolite, alpha1-hydroxymidazolam.[33] The half-life more than doubles, but, more importantly, because the short duration of action after bolus dose is due to redistribution, the effective duration of action after infusions of greater than 24 hours approaches that of lorazepam.

Midazolam is the drug of choice for short-term sedation in the non-intubated patient, especially for procedures. It has minimal respiratory depressant effects when given alone, but it highly potentiates the respiratory suppression of opioids. Dosing information is found in **Table 44.5**.

Propofol

Propofol is a rather unique drug that is not a benzodiazepine and has no other drugs in its class, as an alkylphenol. It is highly lipophilic and totally insoluble in water and is thus prepared in a 10% lipid emulsion at a concentration of 10 mg/mL. Similar to the benzodiazepines, it works on the GABA receptor, and it has excellent sedative and hypnotic properties, adequate amnestic properties, and has no analgesic properties. By itself, it has minimal respiratory depressant properties at lower doses but will suppress respiration at doses used for induction of general anesthesia, 1.5 to 2 mg/kg. Rapid equilibration across the blood–brain barrier is the reason for its extremely rapid onset of action.[34] Unlike benzodiazepines, in addition to vasodilatation it also is a myocardial depressant and thus can cause hypotension after large bolus dosing in hemodynamically unstable patients.

Propofol shows a short duration of action after less than 24 hours of infusion, and infusions of longer than 24 hours show only a slight prolongation of effect; after 24 hours, patients wake up much faster than they do with midazolam or lorazepam. It is metabolized in the liver, but there is extrahepatic metabolism as well,[35] so there is little or no prolongation of effect in renal or hepatic failure.[36]

Because of its formulation, a number of considerations must be mentioned. Because it is an emulsion in lipid, with high volumes of administration fat overload is a concern, especially in patients also receiving lipid formulations as

part of total parenteral nutrition. Nutritional lipids should be adjusted downward to compensate for the lipid administered with the propofol, and patients should be followed up for hypertriglyceridemia and, with longer infusions, for pancreatitis.[37] The lipid nature of the propofol emulsion makes it an excellent medium to grow bacteria, and to reduce the chances of bacterial overgrowth propofol in the United States has additives to act as bacteriostatic agents. Depending on the formulation, propofol will have either ethylenediaminetetraacetic acid, sodium metabisulfite, or alcohol. Patients who are sulfite allergic could have an adverse reaction to the propofol solution.[38]

Propofol has also been implicated in a sometimes fatal syndrome termed "propofol infusion syndrome" (PRIS).[39] Because propofol has properties similar to barbiturates such as sodium pentothal and pentobarbital in lowering cerebral metabolic rate for oxygen and decreasing intracranial pressure, it became popular to use it at fairly high doses for prolonged periods of time in patients with head injury and elevated intracranial pressure from cerebral edema. In 2001, the first series of cases of patients receiving propofol at doses over 5 mg/kg/h who developed progressive myocardial failure with dysrhythmias, metabolic acidosis, hyperkalemia, and evidence of muscle cell destruction.[40] Other studies have confirmed a dose-dependent connection, but there also have been some patients with some of the features of PRIS who received it at lower doses for only a few hours. Therefore, anyone receiving propofol infusion must be observed for the signs of PRIS, and most institutions have installed a cap of 5 mg/kg/h on dosage of propofol for durations over 24 hours.

Dexmedetomidine

Dexmedetomidine is another unique medication with a novel mechanism of action. It binds to the α_2 receptors in the brain as an agonist, and the location of the receptors determines the action of the medication. Dexmedetomidine binds to α_2 receptors in the locus ceruleus of the brain stem, giving it its sedative and anxiolytic effects, and in the dorsal horn of the spinal cord, releasing substance P and producing its analgesic effects.[41] It causes less hypotension than another medication that is also an α_2 receptor agonist, clonidine, and much more sedation and analgesia. The hallmark of dexmedetomidine therapy is mild sedation and induction of sleep, anxiolysis, analgesia with minimal respiratory depression, and reduction of stress response to surgery and other stimuli. The type of sleep is also important, because it comes closer than any other sedative to causing a sleep

that mimics normal rapid eye movement sleep. Patients sedated with dexmedetomidine appear tranquil and comfortable, yet being readily arousable and interactive and oriented when stimulated, only to fall right back to that tranquil, sleeping state when the stimulus is discontinued.[42]

The dosing of dexmedetomidine is also different from the other sedatives mentioned earlier. Bolus doses are poorly tolerated, do not have a good clinical effect, and are rarely used. A loading infusion may be used at the start of the therapy, with a dose of 1 μg/kg of actual body weight given as an infusion over 10 minutes (which translates into 6 μg/kg/h rate of infusion for 10 minutes). Alternatively, an infusion may just be started at the desired rate. Although in the United States, the approved dose range is from 0.2 to 0.7 μg/kg/h for up to 24 hours, doses higher than that for longer periods of time have been safely used.[43] Distribution half-life is 6 minutes, and elimination half-life is 2 hours, but effective duration of action is different—after a loading infusion, onset of sleep sensation starts during the loading and is at its peak 10 to 20 minutes after the load is complete. After cessation of therapy, there is a gradual return to baseline mental status—but because the sleep is so mild and so natural, plus other medications are usually being given, it is very difficult to indeed tell when the effect of the drug has lessened significantly.

The adverse effects of dexmedetomidine include paradoxical hypertension, especially during the bolus dose, followed by hypotension and bradycardia from the sympathetic inhibition. These can be beneficial, but they also may require the adjustment of other medications, such as beta-blockers or calcium channel blocker medications.

The biggest drawback to using dexmedetomidine is a practical one. The other sedatives used via infusion in a cardiac care setting can be given via bolus, and, when given via bolus or at high enough rates of infusion, reliably produce a patient who is essentially unresponsive to painful stimuli. This level of sedation is difficult, if not impossible, to attain with dexmedetomidine alone. Thus, other medications often need to be used for sudden breakthroughs of agitation and pain, and the need for those additional medications many times discourages caregivers from gaining extensive experience with dexmedetomidine.

Because of the more natural sleep pattern that is produced by dexmedetomidine, there has been hope that it will reduce the amount of delirium seen in critically ill patients. Delirium has become an important topic of discussion in critical care, as can be seen in the next section.

DELIRIUM

Over the past 10 years delirium in all types of critically ill patients has become an important area of concern. As medical knowledge and technology over time have improved survival of severely ill patients, many times their mental state after such recovery was less than optimal. Patients would recover from their multisystem organ dysfunction, only to be left with a delirious mental status that required long-term sedation, rehabilitation, or institutionalization in a skilled nursing facility. Elderly patients in particular seemed more susceptible to the onset of delirium, and it has been diagnosed in up to 60% to 80% of patients requiring mechanical ventilation.[44] Having delirium in a CCU is associated with a higher re-intubation rate, a higher mortality, and a longer length of stay. It also has a high rate of progression to permanent cognitive impairment. Thus, it is no longer a condition that can be expected to clear once the patient leaves the CCU.

Delirium is a disturbance of consciousness with inattention accompanied by a change in cognition or perceptual disturbance that develops acutely over a short period of time, from a few hours to a few days.[45] It can be further broken down into hyperactive and hypoactive forms.[46] The hyperactive form, commonly mislabeled “ICU psychosis” in the past, is characterized by agitation, restlessness, attempting to remove catheters and tubes, and emotional lability. It has a better long-term prognosis. The hypoactive form is characterized by withdrawal, lethargy, flat affect, apathy, and decreased responsiveness. It is sometimes erroneously termed ICU or critical care “encephalopathy.” Making the diagnosis of either type with precision is sometimes difficult, and can be done with one of two validated tools that can be found here.[44,47]

For the purposes of this chapter, it is important to recognize a number of aspects of delirium in critically ill cardiac patients. First is to diagnose it, and to rule out other organic causes of the condition. Second is to realize that sedative regimens that are used in the CCU have been implicated in the development of delirium. Sedatives and analgesics work by altering neurotransmitter levels and the exposure to benzodiazepines and/or opioids are involved in 98% of patients with delirium.[48] Some agents within a class have at times been shown to be more causative of delirium than others. Morphine,[49] fentanyl,[50] midazolam,[50] and lorazepam[51] have all been implicated in the development of delirium, with lorazepam probably being the most consistently implicated one. Conversely, the newer, more expensive agents, dexmedetomidine[52] and remifentanil,[53] may have

lower incidences of delirium. It has not yet been established, however, if the costs involved in using remifentanil or dexmedetomidine, among the other disadvantages, are worth the reduction in delirium.

Lastly, it is important to know what can be used to treat the hyperactive type of delirium and what else can be done to prevent delirium in the first place. As far as treatment of the delirium goes, in the past it was thought that patients needed to be "unscrambled" and so potent antipsychotic medications, such as haloperidol or risperidone, were used. Indeed, the very initiation of using a delirium assessment tool can increase the use of haloperidol dramatically.[54] Haloperidol is the only parenteral medication available to use in the patient with delirium, because benzodiazepines do not seem to be helpful.[55] Use of an atypical antipsychotic, quetiapine, seems to be the best studied and shows promise in treating patients with delirium in combination with haloperidol.[56] We are still in an early phase of this research, and much more work needs to be done.[57] Finally, it is important not to underestimate the importance of nonpharmacologic therapy. Such things as cognitive stimulation, reorientation prompts, a sleep protocol, visual and hearing aids, reminders to prevent volume depletion, and walking/exercise all reduced the incidence of delirium, and, while labor intensive, are absolutely essential in reducing and treating delirium in the CCU.[58]

SEDATION AND ANALGESIA IN DIAGNOSTIC AND THERAPEUTIC PROCEDURES IN THE CARDIAC CARE UNIT

Increasingly, diagnostic and therapeutic procedures are performed in the CCU at the bedside, both because of lack of timely access to the operating room (OR) and cost savings.

Both pain medications, sedatives and hypnotics, are used alone or in combination to facilitate the performing of bedside procedures. Concerns related to the patient physiology and to transport to the OR have made performing bedside procedures a more viable and safer option.

Care in the CCU setting is similar to the one in the OR from the point of view of both equipment and personnel. The monitors are nearly identical to the ones in the OR, and the ventilators have the same capabilities and more regarding

mechanical ventilation of patients, despite the lack of inhalational agents. CCU nurses are also similar to the ones in the OR with regard to many skills and capabilities.[59]

There are multiple diagnostic and therapeutic procedures done at the bedside in the CCUs for many different indications. Even though the concept and goal of sedation and analgesia is the same for all of them, there are small but important differences between each procedure. Some of these procedures are more or less specific to the CCU and the field of cardiology; others are common in other critical care settings and involve other subspecialties as well.

The following are common cardiovascular procedures in the CCU requiring sedation and/or analgesia.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) is an invaluable, semi-invasive, diagnostic modality that is increasingly used both in the CCU setting as well as in the OR for structural and functional study of the heart. Owing to its proximity to posterior cardiac structures, the TEE probe offers superior visualization of these posteriorly located structures; and because use of higher frequency probes is possible with this anatomical proximity, it offers better spatial resolution compared to transthoracic echocardiography (TTE). The indications are broad, including assessment of structure and function of native or prosthetic valves, infective endocarditis, cardiac sources of emboli, acute aortic syndrome, tumors, and congenital heart diseases.[60] When performed in the OR, patients are almost always under general anesthesia, but in the CCU setting, the patients are usually consciously sedated.

Patients undergoing TEE examination in the CCU tend to be more frail, with other comorbidities (cardiovascular, cerebrovascular, heart failure, and coronary or valvular heart disease) and usually have more acute clinical scenarios, making them at least intermediate risk for anesthesia most of the times.

TEE is generally regarded as a safe procedure. It involves the placement of the ultrasound probe via the oropharynx into the esophagus and down into the stomach, which might cause nausea, shortness of breath, agitation, and pain due to pharyngoesophageal intubation, symptoms that might be alleviated by use of local anesthetics and sedation.

There is significant variation with regard to sedation for TEE. Some centers use benzodiazepines alone, specifically midazolam, whereas others use a

combination of opiates, either as a bolus or infusion, in addition to midazolam.

Several studies have explored the use of different combinations of sedatives, alone or combined, and the use of local anesthetics to the oropharynx.[62,63]

The medications used, either alone or in combination, were propofol, midazolam, alfentanil, remifentanyl, and dexmedetomidine.[63–65]

Although TEE is regarded as a safe procedure and the complications are rare, they exist and mostly involve the gastrointestinal (GI), cardiovascular, and respiratory systems. These complications are mostly related to probe insertion, medications used for sedation, and operator experience.[61,66]

Given the potentially serious complications, especially in the particularly frail CCU patient population, careful pre-procedural evaluation and monitoring during the procedure should take place. These include careful assessment of medical history, particularly assessing history of esophageal and gastric pathology or history of bleeding disorders. Performing a thorough physical examination with particular emphasis on the examination of the airway, cervical spine mobility, and dentition is important. Fasting 6 to 8 hours before the procedure should be ascertained, and monitoring of vital signs at baseline and throughout the procedure should take place.

Supplemental oxygen should be administered and emergency airway equipment should be available.

Dentures should be removed when present, and bite guards should be placed on patients with full dentition.

After local anesthetic spraying of the oropharynx and/or sedation, the TEE probe is lubricated and then inserted, avoiding any resistance. Supplemental doses of the medications can be administered during the procedure to assure the patient’s comfort and optimal examination.

Obese patients pose a particular challenge both from the standpoint of safe sedation and analgesia and optimal examination. They have a higher incidence of coronary artery disease, hypertension, and sleep apnea; hence there is a higher potential for complications such as hypoxemia, especially in class III obesity.[67]

DIRECT CURRENT CARDIOVERSION

External electric cardioversion is used to treat abnormal heart rhythms to restore the normal sinus rhythm. Most non-emergent cardioversions in the CCU are performed to treat atrial fibrillation or atrial flutter. It is also performed on an emergent basis to correct dangerous rhythms when they are associated with

hypotension, chest pain, confusion, or shortness of breath. The procedure can be quite painful and requires sedation. Performing the procedure involves coordinating several teams: cardiology/electrophysiology, anesthesiology, and, when a prior TEE is required, the echocardiography team. This coordination can be sometimes difficult, because it could be needed at short notice. The ideal medication for sedation for cardioversion would have rapid onset and offset, cardiovascular stability, and no respiratory depression. Propofol has been the most widely used drug followed by etomidate and often a short-acting opiate.[68,70] The goal of sedation for cardioversion is a short period of deep sedation or general anesthesia using agents with a rapid recovery. Considering the potential risk of hypotension and respiratory depression associated with the procedure, the presence of an anesthesiologist to assure airway control is required. Supplemental oxygen and proper monitoring with blood pressure (invasive or noninvasive), pulse oximetry, electrocardiogram (ECG), and capnography are required.[69]

Because of the strong jolt associated with the electric shock and the resultant skeletal muscle contraction, lip and tongue laceration can occur despite sedation; it is therefore important to insert a soft bite block between the teeth right before induction of the sedation/anesthesia.

PERICARDIOCENTESIS

Pericardial effusion is accumulation of fluid around the heart, which in time can lead to pericardial tamponade and can be life threatening if not evacuated in a timely manner.

Pericardiocentesis is the aspiration of the fluid from the pericardial space and it can be lifesaving. Cardiac ultrasound is the gold standard for detection and assessment of the pericardial effusion.

Typically, the drainage of the pericardial fluid is performed by pericardiocentesis in the catheterization laboratory under fluoroscopic or echocardiographic guidance, or by establishing a pericardial window in the OR. When there are acute signs of pericardial tamponade, the pericardiocentesis can be performed at the bedside under echocardiographic guidance.[71] The procedure involves scanning with the ultrasound for the place where the effusion is the largest, sterile skin preparation, sterile drape cover, and requires local anesthetic injection and IV sedation, especially for anxious patients. If the decision is made for use of sedation, utmost care must be taken to use drugs with the least amount

of hemodynamic impairment, because these patients are already in a very frail hemodynamic state. Drugs such as midazolam and short-acting opiates are a good choice. If a deeper level of sedation is needed for a short period of time, etomidate and etamine are other good options.

INTRA-AORTIC BALLOON PUMP

Intra-aortic balloon pump (IABP) is a device that improves cardiac function by balancing the myocardial oxygen demand and supply. It inflates during diastole, increasing the coronary perfusion pressure and then deflates during systole leading to decreased afterload and left ventricular work. It is usually placed in the catheterization laboratory under fluoroscopy guidance but occasionally it is necessary to place the IABP in the CCU setting in unstable patients in cardiogenic shock, acute myocardial infarction, acute severe mitral regurgitation, or ischemic ventricular septal defect. IABP is placed percutaneously via the femoral artery using a Seldinger technique and rarely via the subclavian, axillary, or iliac artery. Considering the large lumen of the device, and the need for the patient to be still during insertion, local anesthetic and mild sedation might be necessary, with careful monitoring of the cardiovascular and respiratory status, especially because some patients might already be in pulmonary edema.

TEMPORARY TRANSVENOUS PACEMAKER

Emergent insertion of a temporary transvenous pacemaker is the treatment of choice for patients with different conduction abnormalities, such as Mobitz II, symptomatic bradycardia, complete heart block, and ischemic or nonischemic new-onset bifascicular block. It is usually used as a bridge to more permanent solutions for underlying conduction abnormality, such as treating the reversible underlying cause or insertion of a permanent pacemaker.[72]

Temporary transvenous pacing involves two components: obtaining central venous access and intracardiac placement of the pacing wire. The preferred route is the internal jugular vein, followed by the subclavian and femoral veins. The central venous access is obtained under ultrasound guidance and requires local anesthetic infiltration of the skin and sometimes mild sedation, especially because the procedure can be slightly prolonged by the need for proper positioning of the intracardiac wire, which is achieved by following the ECG waves.

MISCELLANEOUS PROCEDURES IN THE CARDIAC CARE UNIT

1. Upper GI endoscopy is sometimes performed at the bedside in patients in the CCU, to assess upper GI tract pathologies, such as bleeding or esophageal pathologies. The sedation and analgesia are similar to the ones for performing a TEE, because the procedure is quite similar and involves the same steps.
2. Placement of invasive monitoring or access lines, such as arterial and central venous lines, is a common procedure in patients in the CCU. Arterial line insertion involves placement of a catheter inside an artery (radial, brachial, femoral, or dorsalis pedis) for the purpose of continuous blood pressure monitoring on patients who are on inotropes or pressor infusions, or require multiple arterial blood sample drawings. The vast majority of times, the procedure only requires injection of a local anesthetic at the site, but on occasion, on very anxious or agitated patients, addition of other medication is required. Small, divided doses of benzodiazepines, opiates, or a combination of both are warranted in these settings with close monitoring of the patient's hemodynamic and respiratory status.

Because of necessity of patient positioning in a Trendelenburg position for central venous line placement with the head turned to the side and the need to cover the face with sterile drapes, and the slightly longer time for insertion, the central line placement poses more challenges than arterial placement; hence more frequent requirements for sedatives and analgesics in addition to the local anesthetic infiltration.

CONCLUSION

Patients in a cardiac care setting often need sedative or analgesic medications to help them through their course of CCU stay and while undergoing different therapeutic or diagnostic modalities. These medications have benefits but also side effects that need to be considered before administering the medications. The choice of medications may have long-lasting implications for patients in their recovery phase. Using a method of treating these patients that is balanced between personal professional experience and judgment and an evidence-based approach is the best way of properly choosing the optimal regimen.

Patient and Family Information for: SEDATION AND ANALGESIA IN THE CARDIAC CARE UNIT

WHY PATIENTS NEED SLEEP OR PAIN MEDICATIONS IN THE CARDIAC CARE UNIT

Patients who are in a CCU can experience pain, anxiety, stress and, at times, an altered mental status. Quite simply, a CCU is a stressful and uncomfortable place to be in for any length of time. Many patients need some form of medication to help them cope with these conditions. Often, it is the most severely ill patients who require the most sedation.

Patients in a CCU will, at the very least, have attached to them a number of wires connecting them to the monitor, in addition to some sort of IV catheter. Patients who are more seriously and acutely ill may have IV catheters in their neck or chest, or larger tubes in their groin supporting their hearts. The most seriously ill patients will have a tube in their mouth, an endotracheal tube, to connect their lungs to an artificial respirator. Usually, the more support or monitoring an apparatus provides to the patient, the more uncomfortable it tends to be. The endotracheal tube, being hard plastic in contact with the main airway, is quite possibly the most irritating. Although some patients can tolerate an endotracheal tube without sedation, most patients need some sedation to tolerate the tube.

Treatments given to patients also tend to be, at best, uncomfortable, and, at worst, painful. Critically ill patients in a CCU do not tend to cough or breathe deeply enough and need help getting phlegm up from their lungs. Sometimes this is done by clapping on their backs, which can be uncomfortable. Sometimes, however, that maneuver is not enough, and a small tube needs to be placed into

the patient's nose or mouth and into their lungs to get the phlegm out before the patient develops pneumonia.

Increasingly, diagnostic and therapeutic procedures are performed in the CCU at the bedside, both because of lack of timely access to the OR and acuity of patients' condition. These procedures are often uncomfortable and sometimes painful, and patients need appropriate means to decrease their pain and suffering while undergoing a procedure.

In addition to being able to tolerate devices in the CCU, there is also the need for patients to get some sleep. It is very, very difficult to sleep in a CCU, because things are happening at all hours of the day and night, and it is difficult to make it dark enough for people to fall asleep. In addition, the monitors make noises, often with each heartbeat, and the attached cables and tubes frequently pull and wake patients up as they turn. The beds in a CCU are optimized for both durability and to keep from damaging the skin, but may not be the most comfortable for sleeping.

For these and other reasons, many times it is necessary to give patients either pain medications or sleep-inducing medications as part of their treatment in a CCU.

GOALS OF SEDATION AND PAIN MANAGEMENT IN THE CARDIAC CARE UNIT

Very often, family members do not have the same goals in mind as their caregivers when it comes to the treatment of pain or of the sedation of a loved one in the CCU. Some families think it is bad for the patient to be sedated, and want them to be more awake and interactive, going so far as to overstimulating the patient during visits. They get the mistaken impression that if the patient is not awake, he/she is in either an unintended or an induced coma which they perceive as a bad thing. They repeatedly ask for the sedation to be turned down. Other families are concerned that the patient is feeling too much discomfort or will remember too much of these traumatic events and want them more deeply sedated.

It is important to realize that sedation of patients in the CCU has become an important area of research and concern over the past 15 years. It was always known that patients needed sedation and pain medication in a CCU for them to not pull out their tubes or hurt themselves. It was also felt that sedating patients

fairly heavily was a good thing, to reduce the stress of being in the CCU, and, simply, to just be humane to the patient. Although there were always concerns that too much sedation was a bad thing, it was not until the year 2000 that research was published showing clearly that it was important not to over-sedate patients. That one study, and others following it, showed that waking patients up every day—even for a short period of time—and then reevaluating the need and dose of sedation leads to less time on the respirator, less time in the CCU, and an improved survival rate. But it is not an easy thing to do—there is a risk of patients getting too awake and hurting themselves, and so it must be done in the right patients at the right time and speed. It also has become clear through recent research that the type and amount of sedation can have a strong influence on the patients' mental state, long after they have recovered from their physical ailments and have left the CCU.

Usually, some type of rating scale that makes it very easy to tell if the patient is at the desired level of sedation or not is used. The scales are generally of two types. In the more basic scale, a patient is asked to rate the pain either on a number scale or by pointing at a line or chart, sometimes with happy or sad faces on it, sometimes with just a line or ruler on it. These are used primarily to rate the patient's pain, and will be used before and after every dose of pain medication to try to put a number rating to the pain a patient is feeling. In this way, the doctors caring for the patients can adjust the amount of medication by seeing what dose produces what response.

The other type of scale is one where the nurse evaluates a patient, and many times will do something like talk to a patient or touch a patient, to see the reaction, then gives the patient a number scale rating to determine their level of sedation. The physicians taking care of the patient, or the CCU nurse, will sedate the patient according to those ratings. Many sedation scales have been developed over the years.

It is important to have discussions with the physicians and nurses taking care of a family member about the precise goals of sedation. To be able to fully understand the sedation of a family member, ask to see the sedation scale in use in that particular CCU, discuss the desired level of sedation, and ask whether they perform a daily wake-up test. A family could also offer to help in the daily wake-up test, but that takes a skilled staff of the CCU and a family member who can avoid getting too emotional at the bedside, as the wake up may not be pleasant sometimes to watch. Once a family member understands the goals of sedation, then the member can try to help the staff in the CCU keep the patient at

the desired level of sedation.

NONSEDATIVE METHODS OF KEEPING PATIENTS COMFORTABLE

Using medications is not the only method we have to keep patients comfortable in the CCU. There are a number of other methods that are tried and true. The most important among these is to continually reorient the patient to the time, place, and, if necessary, names. The CCU is a very confusing place, and lack of sleep plays havoc with the patient's ability to keep track of time. It is not unusual for patients in a CCU to become confused and not know where they are, or what day it is, or to overestimate the amount of time that has passed since they have seen a family member. This is much more common with older patients, but younger patients can also be affected. Families tend to get very depressed and upset at such actions. Some even can get angry at their family member. It is important to remember that this happens all the time, and is not at all unusual. It also does not signify any permanent damage. This is probably where family members can be the most help to the staff in the CCU and to the patient. It may have to be done more than once on a visit. Another good thing for family members to do is to try to get patients to remember things from outside the CCU —bringing up events, people, foods, clothing, and so on. Bringing pictures to the CCU, especially with the patient in them with other people, is a very good way to aid in this process. Repeatedly reorienting patients, telling them the day, reminding them what day or what hour they last saw one or another family member can help the staff in the CCU use less sedating medications and ultimately help get the patient out of CCU faster and in better mental shape.

SEDATIVE AND PAIN MEDICATIONS IN THE CARDIAC CARE UNIT

It is helpful for the family to understand the different types of medications that are used in the CCU to promote sleep and treat pain. This is because some of them may have different meanings to the lay person, incorrect meanings that may have a negative connotation. For patients in the CCU, most of the time they get either strong pain relievers such as morphine, strong sleep medications such

as Ativan (lorazepam), or tranquilizers such as haloperidol. It is important for the family member to understand why each of those is used.

PAIN MEDICATIONS

Patients in the CCU have pain—if they are on the respirator, just the breathing tube alone causes a fair amount of discomfort and pain. Lying in bed for long periods of time is also uncomfortable. They may have surgical incisions, and many of the procedures that are done are painful. To treat those pains, most often patients are given medications such as morphine—others might receive Dilaudid (hydromorphone), fentanyl, or even methadone. This class of drugs is commonly called "opiates" or "narcotics." They are given via the IV line, either continuously all the time or intermittently. They differ primarily in how long they last, and some of the minor side effects. For example, morphine and hydromorphone may have more of a mind-altering quality to their effect than methadone or fentanyl. Fentanyl is the shortest acting, at about 45 minutes to an hour; then morphine which lasts 2 to 3 hours; hydromorphone, which lasts 3 to 4 hours, and, finally, methadone which can last 8 to 12 hours. Patients who are less ill may be able to receive pain medications by mouth—these generally last longer, from 6 to 24 hours each dose.

Pain medications such as these have a number of effects. First, they are used to reduce the amount of pain a patient feels. It is important to realize that these medications do not work like when something is taken for a headache—1 minute, there is pain; soon afterwards, the pain is totally gone. Most often, the patient will still feel the sensation that was painful, but it will not be as intense, they may not care that they feel it, they will be more comfortable; they may even say that the sensation is still there but it does not hurt. Second, these medications will have somewhat of a sleep-inducing effect, but this effect is shorter than the pain-relieving effect and if small enough doses are given may be minimal, if present at all. The most common side effects that are concerning about these medications is that they interfere with the patient's desire to breathe—so, if they go to sleep, they may not breathe, which is why they are monitored after they receive the medications. The other major side effect these medications have is that they can cause nausea and vomiting. So when these medications are given, physicians and nurses have to balance the desirable effects with the undesirable side effects.

When to give these medications is usually decided in a number of ways. If the patient is awake, it might only be given when they ask for them and at no other

times. Sometimes, a patient might be connected to a patient-controlled analgesia (PCA) pump where the patient gets small amounts of pain medication through the IV line whenever they push the button. The safety mechanism with both of these is that if the patient is too sleepy to either ask for the medication or push the button—they will not get too much and they will not make themselves too sleepy. This is why a nurse might be heard saying that the patients have to ask for the medication themselves, that they cannot give it just because family members want the patients to get more medication because they are grimacing or making a look on their face that looks like pain—it might be dangerous to give patients the pain medication in that state. For sicker patients, the nurse might be instructed by the physicians to use a pain scale such as described earlier to administer medications. Lastly, patients, especially those on mechanical ventilators, may be on a continuous amount of the medications so that they are getting a small amount every minute to provide constant comfort, and the rate at which they give the pain medication is determined by the scales mentioned earlier.

SEDATIVE (SLEEP) MEDICATIONS

In addition to medications to treat pain, to treat patients' anxiety and help them sleep, patients may also get sedative medications such as midazolam (Versed) or lorazepam (Ativan), which are more modern versions of a similar drug many people know about called diazepam (Valium). These medications have a wide range of effects that depend on dose, ranging from treating anxiety and making a patient feel calm, to inducing a comfortable sleep, to rendering a patient unconscious. Even low doses can cause amnesia, and the patient may not remember things that happen while under the influence of these medications. Although this may many times be a beneficial effect, because the CCU can be a scary place, it also can make it more difficult for the family to reorient the patient the way discussed earlier. Also, elderly patients can sometimes get wild and agitated with these medications and lose control of inhibitions—a side effect called "dis-inhibition." When combined with the pain medications described earlier, they can enhance the pain medications' ability to depress breathing, so they have to be used with caution when used together. Also, the combination of the deep sleep of the sedatives and the nausea and vomiting from the pain medications can be dangerous because patients can then have stomach contents go into the lungs and cause pneumonia. This is not at all to say that they cannot be used together, just that these are concerns that need to be watched for. Both

lorazepam and midazolam can be given either intermittently or continuously via the IV line. They differ only in that midazolam, when given once or twice, is very short acting, on the order of 15 to 30 minutes, whereas lorazepam can last for 2 to 4 hours. When given continuously, depending on what dose is required and how long the infusion is running for, can take a few hours to a few days to wear off.

Another medication that can be used continuously, usually in patients on mechanical ventilation, is called propofol. Propofol is easy to remember because it is a milky white liquid, sometimes nicknamed “milk of anesthesia.” It is a powerful sleep-inducing agent, and is usually not used to just treat anxiety, but, rather to go further and either makes patients very, very sleepy or even unconscious. Its ability to cause amnesia is not quite as great as for lorazepam or midazolam, so patients need to be more asleep with this medication if the goal is to keep them from remembering things. It is very, very short acting, which is why it usually is used only continuously. Similar to lorazepam or midazolam, it can cause blood pressure to drop; and when given with the narcotic pain relievers, it can cause a patient to stop breathing.

Still a different type of medication used in these settings is a relatively new drug called dexmedetomidine (Precedex). This drug causes a very natural and restful sleep, and does not work like other drugs to depress the patient’s drive to breathe. The sleep it causes is totally different from other medications—the patient will appear to be asleep, not responsive to verbal stimulation, yet, with gentle touch, will wake up and be totally coherent and appropriate, only to drift back to sleep when the stimulus is removed. It also has very nice pain-relieving qualities, and treats pain in a manner different from that of narcotics, so the combination of the two is a very effective way to treat pain. It does not have any amnesia effects, so it is not useful to make patients not remember their time in the CCU. It has a ceiling effect, so that it never will produce the deep sleep or near coma condition as midazolam, lorazepam, or propofol will produce, and it cannot be given intermittently, only continuously, and takes a while both to work and stop working, about 20 to 30 minutes on either end. It is most useful in combination with the other medications. Its main advantage is that it recently has been shown to cause less delirium in the CCU, as is discussed here.

DELIRIUM

When a patient is in the CCU and is subject to all the stresses of being there, the constant stimulation, the lights, the noise, the lack of natural sleep, and the administration of the medications, can all sometimes result in the patient developing a state of altered consciousness, called “delirium.” Delirium is an acute state of confusion. It is characterized by some combination of drowsiness, disorientation, hallucination, a sudden inability to focus attention, sleeplessness, and severe agitation and irritability. When it develops, it carries with it a longer time in the CCU and the hospital and a higher rate of complications such as infections and death. It is much more common in older patients, and one out of four elderly patients admitted to the hospital will suffer some form of delirium. Preventive measures include the daily wake up and lessening the use of sedatives mentioned, and the reorientation and helping the patient focus also help tremendously. Use of dexmedetomidine for sedation, with its more natural sleep tendencies, has been shown in some studies to decrease the incidence of delirium. Once it starts, it may require the use of tranquilizers that act on the chemicals in the brain that are out of balance and help straighten them out again. A number of tranquilizers can be used. If it is decided that the patient needs to get the medication fast, a medication called haloperidol (Haldol) can be given either via IV or into the muscle. If they are given orally, in addition to haloperidol, another common one is risperidone, and there are others as well. Tranquilizers such as these will cause a dazed and stunned look, and the patient will frequently be awake, answer questions in a rather flat toned voice, show little emotion, and have a very slow reaction to any stimuli. This is just a phase the patient will go through on the way to recovery, but it can last a while, sometimes days or weeks, until the patient is back to the usual state of mind.

ADDICTION

A very common reaction of families to hearing that their relative is getting these medications, some of them whose names they associate with drug abuse, is “Will they become addicted?” Strong pain killers such as morphine cause two types of dependence, commonly termed “addiction.” Patients may get chemically or physically dependent, where their bodies cannot tolerate a sudden withdrawal of the drug and it needs to be reduced slowly over time; otherwise the patient can get withdrawal symptoms. This is easily treated with slowly tapering off the medication over time, and the risk for it goes up depending on the dose and the

duration of medications the patient received in the CCU, which is another reason to give as little as possible. However, people mistake this for psychological dependency, in which the patient mentally craves for the drug and needs it from a mental standpoint. Only a minute fraction of patients receiving morphine-like drugs in the CCU ever become psychologically dependent on the medications, and the risk is considered small for the benefit most patients get from these important medications. The sedative drugs such as lorazepam are much less likely but still can cause a physical dependence.

ANESTHESIA AND PAIN CONTROL FOR BEDSIDE PROCEDURES IN THE CARDIAC CARE UNIT

Patients in the CCU oftentimes require certain procedures, either for diagnostic purposes or for therapeutic purposes.

Examples of different procedures done in the CCU include the following.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE is a special form of echocardiogram, performed by esophageal placement of a probe with a transducer at its tip. It is very similar to the probe used by gastroenterologists to perform upper endoscopies. It is performed in patients who either await heart surgery to give the cardiac surgeon and anesthesiologist more information about the heart structures, confirm the success of the surgical repair or if additional repair is needed, or in patients who are treated in the CCU to assess and monitor medical treatment. It gives a very good image of the heart because the esophagus or swallowing tube is very close to the heart. An approximately 6- to 8-hour fasting is required before undergoing the procedure.

For the patient to tolerate this procedure, a combination of local anesthetic to the back of the throat and IV sedation are frequently used.

The local anesthetic is usually lidocaine spray or a solution to be gurgled to numb the oropharynx, and the tolerance of the procedure is enhanced by administering IV sedatives and analgesics. The combination of local anesthetics and IV sedatives and analgesics blocks the stress response, the laryngeal reflex to the TEE probe insertion, and the pain, and is very useful especially for very anxious patients or patients who are unable to cooperate.

The medications used are usually a combination of pain relievers such as

morphine and fentanyl, and sleeping medications such as midazolam or lorazepam. On occasion, a stronger sleeping medication might be used, such as propofol. The amount of medications used differs depending on the patient's weight, age, and how strong the heart is. Patients with weaker hearts might require less medication and it might take longer to achieve the desired effect. The same pattern is true for older patients.

Heavier patients might require more medication, although this pattern does not always stay true; however, the patients require more careful monitoring of their breathing, because they are prone to obstruct the air passage secondary to obstruction by the back of the tongue and might require additional maneuvers or equipment (such oral airways to lift the tongue and clear the throat to allow free air movement) to ensure safety.

CARDIOVERSIONS

If the heart has an irregular, abnormal rhythm or is beating too fast, a cardioversion might be necessary. The most commonly treated arrhythmias are atrial fibrillation and flutter.

Cardioversion is a procedure that includes applying an external electrical shock to the chest wall to restore the normal heart rhythm. The procedure involves placement of patches on the chest and back, in addition to the existing monitors already in place. Because the procedure can be painful, it requires deep sedation or general anesthesia. The shock lasts only a fraction of a second and it might need to be repeated. The whole procedure might last 20 to 30 minutes.

The sedatives will be administered via the IV catheter already in place, and the shock will be delivered through the patches on the patient's chest, once the patient is rendered unconscious. Sometimes more than one shock needs to be delivered to convert to the normal rhythm. Once the procedure is completed, the medication is stopped and the patient will wake up shortly. There are few potential complications that can occur with the cardioversion and they are related to the sedation used for the patient to tolerate the procedure, new arrhythmias, stroke, lip or tongue lacerations, or skin burns.

The deep sedation used to allow the delivery of the shock can result in aspiration of the stomach content into the lungs, which could lead to pneumonia. Also, the sedation can cause obstruction of breathing, especially in heavier patients or in those who have sleep apnea, so careful, divided administration of medication for sedation and careful monitoring of breathing has to take place.

The shock is timed with the heart beat so it does not produce dangerous

rhythms after cardioversion, but sometimes the heart is slow to go into the normal rhythm and a temporary pacemaker might be necessary to bridge this period.

Stroke can happen as a result of a preexisting, or a newly formed clot which can travel to the brain. The use of blood thinners before the cardioversion greatly reduces the risk of stroke.

An oxygen mask will be placed on the patient's face and a soft block will be placed between the teeth to avoid lip or tongue injury.

INSERTION OF CATHETERS AND DEVICES

Oftentimes the patients in the CCU require insertion of catheters for continuous monitoring of the blood pressure and access to frequent blood draws, such as arterial lines, which consists of placement of a small catheter into an artery, either at the wrist (most commonly), groin or foot (rarely).

Central venous catheters are inserted for both monitoring of pressures inside the heart and as the means of administering potent medications or blood if needed. They are typically placed in the veins in the neck (most frequently) or groin (rarely).

On occasion, a critically ill patient might require placement of a device called IABP to help with heart function and oxygen delivery to the heart. It is placed via one of the arteries in the groin and advanced all the way in the chest to the aorta, which is the main artery carrying blood out of the heart. It requires the patient to keep the leg straight afterwards, often being accomplished by placing a brace on the leg.

When patients have rhythm problems, the placement of a temporary transvenous pacemaker is required. It involves the placement of a catheter into one of the veins in the neck or in the groin and then advancing a wire into the heart.

The insertion of the central venous catheters or the IABP necessitates the patient to be still, on his/her back, in a "head down "position, sterile preparation of skin, and placement of sterile drapes which sometimes cover the patient's face, and can lead to significant anxiety.

The insertion of these catheters is facilitated by injecting the skin with local anesthetic, such as lidocaine, and most of the times is sufficient to assure the patient's comfort, especially for the small catheters (arterial lines, central venous catheters), but the larger catheters, such as IABP or temporary transvenous pacemakers, require the administration of sedatives, such as midazolam, and

analgesics, such as fentanyl.

PLACEMENT OF A BREATHING TUBE

Critically ill patients might need to be intubated, which involves deep sedation with drugs such as propofol or etomidate and placement of a breathing tube in the wind pipe, to adequately oxygenate them. After the intubation, to tolerate the breathing tube and the mechanical ventilation they will need continuous sedation with drugs such as midazolam, lorazepam, propofol, or etomidate. Sometimes pain medication such as opiates can also be added.

A careful balance has to be achieved by the CCU team between administering drugs for sedation and pain and maintaining stable blood pressure and breathing, and hence the need for multiple monitors.

CONCLUSION

It is important to understand the choice of medications and why each is used. The doctors and nurses must balance the need to treat pain and the need to reduce stress and anxiety with the very real side effects all of these medications can cause. By discussing with the doctors and nurses exactly what medications the patient is receiving, and what the goals of therapy are, helps understand better the treatment plan and also be more helpful to both the staff and to the patient, because the best calming effect usually is a calm family member being at the bedside working with the CCU staff to keep a patient oriented, calm, and tranquil. It will also allow the family member to endure the stay of the relative in the CCU with less stress to the member as well.

Renal Failure in the Cardiac Care Unit

INTRODUCTION

Acute kidney injury (AKI), previously called acute renal failure, is a common problem in the cardiac care unit (CCU) and is characterized by an abrupt decline (over hours to weeks) in the glomerular filtration rate (GFR), leading to accumulation of nitrogenous waste products. AKI can result in uremia, oliguria, or anuria, and volume imbalance as well as electrolyte and acid base abnormalities. AKI is independently associated with an increased length of stay, increased morbidity, and short- and long-term mortality and imposes a heavy economic burden on the health care system.

There is substantial interaction between the heart and the kidneys that is now referred to as cardiorenal syndrome (CRS). In patients admitted to the CCU, AKI frequently complicates acute coronary syndromes, revascularization procedures, coronary artery bypass graft (CABG) surgery, decompensated heart failure, cardiogenic shock, and cardiac arrest. In critically ill patients, more often than not, AKI is multifactorial resulting from several insults occurring at once.

Early recognition, adequate hemodynamic support, and withdrawal of nephrotoxic agents are of paramount importance to help reduce the risks and the costs associated with AKI. AKI is associated with worsening outcomes,

particularly if occurring in critical illness and if severe enough to require renal replacement therapy (RRT). Hence, preventive measures should be part of appropriate management.

DEFINITIONS

AKI is diagnosed by an increase in serum creatinine (SCr) and blood urea nitrogen (BUN) on routine laboratory examination and/or by a decrease in urinary volume over a certain period of time. With the development of the RIFLE[1] classification and subsequently the acute kidney injury network (AKIN) criteria[2] (**Table 45.1**), the definition of AKI became more objective. Both criteria were very useful for quantitating renal function and for research purposes but less so for clinical practice.

TABLE 45.1 Summary of the RIFLE Classification, the AKIN Criteria, and the KDIGO Classification and Staging for AKI

RIFLE[1]				AKIN[2]			KDIGO[3]		
RIFLE Criteria	*SCr Increase*	*GFR Decrease*	*Urine Output*	*AKI Stage*	*SCr Increase*	*Urine Output*	*AKI Stage*	*Serum Creatinine*	*Urine Output*
Risk	1.5 × ULN	>25% decrease	<0.5 mL/kg/h for 6 h	Stage 1	1.5–2 × baseline	<0.5 mL/kg/h for 6 h	Stage1	SCr 1.5–1.9 times baseline OR > 0.3 mg/dL	<0.5 mL/kg/h for 6–12 h
Injury	2 × ULN	>50% decrease	<0.5 mL/kg/h for 12 h	Stage 2	2–3 × baseline	<0.5 mL/kg/h for 12 h	Stage 2	2.0–2.9 baseline	<0.5 mL/kg/h for >12 h
Failure	3 × ULN (or rise by 0.5 mg/dL if baseline SCr > 4 mg/dL)	>75% decrease	<0.3 mL/kg/h for 24 h OR anuria for 12 h	Stage 3	>3 × baseline (also if on RRT)	<0.3 mL/kg/h for 24 h OR anuria for 12 h	Stage 3	3.0 × baseline OR increase in SCr to >4 mg/dL OR initiation of renal replacement therapy	<0.3 mL/kg/h for >24 h OR Anuria for >12 h
Loss	Persistent acute kidney disease > 4 wk								
ESRD	End-stage renal disease (requiring dialysis > 3 mo)								

ESRD, end-stage renal disease; RRT, renal replacement therapy; SCr, serum creatinine; ULN, upper limit of normal.

More recently, building off the previous criteria, the Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines[3] simplified the definition of AKI (**Table 45.1**); KDIGO defines AKI as any of the following:

1. An increase in SCr by at least 0.3 mg/dL within 48 hours; or
2. An increase in SCr to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or
3. A decline in urine volume to <0.5 mL/kg/h for 6 hours.

A new terminology, CRS[4], has been proposed to define the spectrum of disorders secondary to the hemodynamic interdependence between the heart and the kidneys. It includes those disorders of the heart and kidneys where acute or chronic dysfunction in one organ induces acute or chronic dysfunction of the other. Five subtypes have been defined:

Type 1 acute CRS: Acute worsening of cardiac function leading to renal dysfunction;

Type 2 chronic CRS: Chronic cardiac dysfunction (ie, chronic heart failure) leading to renal dysfunction;

Type 3 acute renocardiac syndrome: Acute worsening of renal function (due, eg, to renal ischemia or glomerulonephritis) causing cardiac dysfunction (eg, heart failure);

Type 4 chronic renocardiac syndrome: Primary chronic abnormalities in renal function leading to cardiac disease (eg, coronary disease, heart failure, or arrhythmia);

Type 5 secondary CRS: Acute or chronic systemic conditions (eg, sepsis or diabetes mellitus) causing simultaneous dysfunction of the heart and kidney.

EPIDEMIOLOGY

Prior to the RIFLE criteria,[1] more than 30 different definitions of AKI were reported in the literature. Consequently, epidemiologic studies used various clinical and physiologic endpoints, yielding a discrepant incidence of AKI in different clinical settings ranging from 1% to 31% in hospitalized patients (with an average incidence of 5% to 7%)[5] and 35% to 40% in the critically ill.[6] The diagnosis of AKI independently increases the risk of mortality by 5.5- to 6.5-fold as compared to a similarly ill patient without AKI. The incidence of AKI requiring RRT was 5% in a large, multicenter study[7] with a 90-day mortality in the range of 50% to 60%.

RISK FACTORS

In a large tertiary center CCU, characteristics such as older age, African-American race, diabetes, hypertension, previous coronary disease, and heart failure were incrementally more common across increasing renal dysfunction patient strata.[7] Decompensated heart failure, cardiogenic shock, use of iodinated contrast media, aggressive diuresis, and use of nephrotoxic medications are common precipitants of AKI. Patients with underlying chronic kidney disease are also at higher risk of developing AKI, referred to as acute on chronic kidney injury.

RENAL NEUROHORMONAL REGULATION AND RESPONSE TO RENAL HYPOPERFUSION

The kidney plays a central role in maintenance of fluid balance and excretion of waste products. Renal hypoperfusion is initially compensated for by various systemic mechanisms in an attempt to restore tissue perfusion. Hypovolemia, of any cause, reduces release of atrial natriuretic peptide, increases production of antidiuretic hormone, and increases sympathetic (and decreases parasympathetic) activity through the baroreceptor reflex. In the kidney, the combination of hypotension and sympathetic activation leads to reduced perfusion pressure in the afferent arteriole and a decrease in the GFR. A decrease in tubular sodium chloride (due to slower transit and increased proximal reabsorption) is sensed by the macula densa in the distal convoluted tubule, and this causes the juxtaglomerular apparatus to release renin. Renin activates angiotensin, which is converted peripherally to angiotensin II. Apart from being a potent vasoconstrictor, angiotensin II also acts on the adrenal cortex to produce aldosterone, which increases salt and water reabsorption in the kidney. In addition to these mechanisms, the kidney possesses the ability to autoregulate, that is, to maintain its perfusion pressure despite changes in the mean blood pressure over a wide range of 80 to 180 mm Hg. As a consequence of this compensatory mechanism, the renal tubules remain intact despite renal hypoperfusion. When normal renal perfusion is restored, urine flow returns to normal.

A concept important to understanding the pathophysiology of AKI in the CCU is effective circulating volume (ECV). ECV is the arterial blood volume effectively perfusing tissue. ECV is a dynamic quantity and not a measurable distinct compartment, which normally varies directly with extracellular fluid (ECF). The ECV may not vary directly with the ECF volume in certain diseases, such as congestive heart failure (CHF) or hepatic cirrhosis; therefore, in these clinical settings, renal hypoperfusion may occur despite apparent volume excess.

In contrast to prerenal AKI, if the hypovolemia is severe or sustained, the renal tubules can become necrotic and lose their ability to conserve salt and water. Tubular obstruction by necrotic cells at the pars recta (where the proximal tubule narrows into the descending loop of Henle) leads to a rise in the intraluminal pressure, decreasing the glomerular tubular gradient. This reduction in GFR may persist even after restoration of normal hemodynamics.

Furthermore, injury to the tubular basement membrane can result in back leak of tubular fluid into the interstitial tissue. In this situation, urine flow may not be restored despite restoration of normal renal perfusion.

ETIOLOGIES OF ACUTE KIDNEY INJURY

Based on this pathophysiology of renal adaptation to injury, AKI is classically divided into three large pathophysiologic categories of prerenal, renal, and postrenal AKI (**Table 45.2**).

TABLE 45.2 Common Etiologies of AKI

Prerenal AKI

1. Hypovolemia, eg, renal (overly aggressive diuresis) or extrarenal fluid loss (bleeding, diarrhea, vomiting, sequestration)
2. Decreased renal perfusion: decreased forward flow secondary to low cardiac output, renal vasoconstriction, systemic vasodilatation, hepatorenal syndrome, impairment of renal autoregulation (NSAIDs, ACEIs, ARBs)

Renal AKI

1. Acute tubular necrosis
   a. Ischemic
   b. Toxic, eg, use of radiocontrast media, aminoglycosides, amphotericin B, calcineurin inhibitors, mannitol, hemolysis, rhabdomyolysis
   c. Infection, with or without sepsis
2. Glomerular diseases or vasculitis
   a. Glomerulonephritis, eg, as a complication of bacterial endocarditis, lupus nephritis
   b. Thrombotic microangiopathies, eg, malignant hypertension, scleroderma crisis
3. Interstitial nephritis commonly related to antibiotic use
4. Renovascular obstruction, eg, atheroembolic disease, arterial dissection

Postrenal AKI

Urinary retention owing to use of anticholinergic agents, obstruction, and compression by hematoma or mass

ACEIs, angiotensin converting enzyme inhibitors; AKI, acute kidney injury; ARBs, angiotensin receptor blockers; NSAIDS, nonsteroidal anti-inflammatory drugs.

Prerenal azotemia results from ineffective renal perfusion and is the most common cause of AKI in patients presenting to the emergency room. Renal or intrinsic AKI in the CCU most commonly results from ischemic or toxic acute tubular necrosis (ATN). The prerenal and intrinsic renal categories are not mutually exclusive but rather represent a continuum of renal injury where persistence of the ischemic insult may deteriorate into ATN.

A prerenal state also sensitizes the kidney to nephrotoxic insults, thus accounting for the increase in the incidence of AKI owing to nephrotoxic agents in hypovolemic states. Postrenal AKI due to obstruction in the urinary collecting system is an uncommon cause of AKI in the CCU but should always be ruled out promptly because of its reversibility. Nephrotoxicity can result from various drugs, such as aminoglycosides, amphotericin, calcineurin inhibitors, foscarnet, ifosfamide, cisplatin, and crystal-forming drugs. Additionally, conditions such as multiple myeloma and rhabdomyolysis can cause nephrotoxicity resulting in AKI. The pathophysiologic mechanism for renal injury differs among the agents and conditions.

CLINICAL EVAULATION

Either a rise in BUN and SCr or a drop in the urine output should alert the clinician to the presence of AKI. One of the earliest signs of AKI may be oliguria that is usually defined as decline in urine output to <0.5 mL/kg/h. However, a patient who is fluid overloaded or with a high catabolic rate may require a urine flow rate considerably higher than this minimum standard. A number of etiologies of AKI present with nonoliguric rises in the BUN and creatinine; therefore, absence of oliguria does not preclude an evaluation of renal injury.

The history should be focused on identification of risk factors of AKI, determination of baseline renal function to ascertain the presence of CKD if possible, careful assessment of symptoms and precipitants of volume depletion (careful review of the intake and output), careful review of vital signs to identify episodes of hypotension, and a thorough review of all home medications as well as all recently administered in-hospital medications to identify potential nephrotoxins. The history is essential in determining the etiology of AKI because it may help the clinician to prevent further exposure to ongoing nephrotoxic insults.

Another important historic feature is the temporal correlation between the possible nephrotoxic insult and the clinical course of AKI. The SCr rises rapidly (within 24 to 48 hours) in patients with AKI following renal ischemia and radiocontrast exposure. Peak SCr concentrations are usually seen after 3 to 5 days with contrast nephropathy and return to baseline after 5 to 7 days. In contrast, SCr concentrations usually peak later (7 to 10 days) in ATN and

sometimes even later in atheroembolic disease. The rise in SCr seen with many tubular epithelial cell toxins (eg, aminoglycosides) or in the setting of drug-induced acute interstitial nephritis usually happens 7 to 10 days after onset of therapy, although the latent period may be as short as 1 day after some antibiotics or as long as several months with nonsteroidal antiinflammatory drugs (NSAIDs).

Information from the physical examination is invaluable and must be integrated with the historic and laboratory data. The patient's volume status must be carefully assessed by examination of skin turgor, edema, jugular venous distension, orthostatic hypotension, and pulmonary vascular congestion. In addition, certain findings on physical examination can be diagnostic, for example, the presence of a distended bladder in a patient with urinary retention, a skin rash in suspected drug-induced interstitial nephritis, papilledema in malignant hypertension, or retinal cholesterol plaques in a patient with atheroembolic disease.

DIAGNOSTIC EVALUATION

Even with a careful history and examination, the determination of the etiology of AKI may be challenging. **Figure 45.1** is a clinical pathway that simplifies the diagnostic approach to AKI.

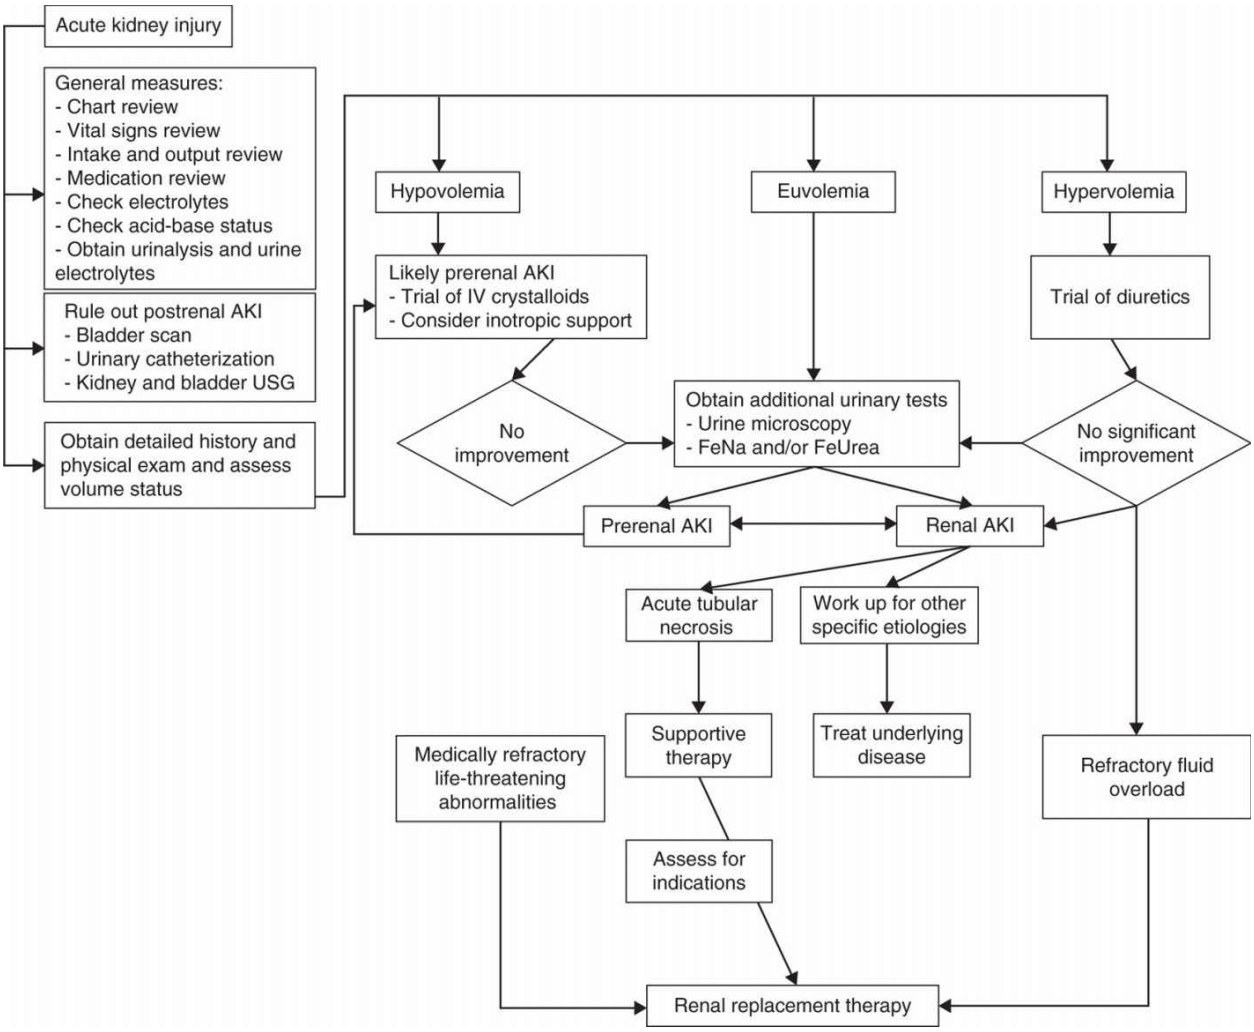

FIGURE 45.1 AKI pathway. AKI, acute kidney injury; FeNa, fractional excretion of sodium; FeUrea, fractional excretion of urea USG: Ultrasonogram.

Microscopic examination of the urine and urinary indices can be informative. Certain findings on urinalysis can point toward specific diagnoses as shown in **Table 45.3**. In prerenal or postrenal AKI, the urinalysis should be devoid of cells and protein. The absence of casts is usual in postrenal kidney injury but hyaline casts can be present in the setting of prerenal AKI.

TABLE 45.3 Urinalysis in Acute Kidney Injury

FINDING	SUGGESTED DIAGNOSIS
Muddy brown granular casts or epithelial cell casts	Acute tubular necrosis
RBC casts, dysmorphic RBCs	Acute glomerulonephritis

WBC casts, eosinophils	Acute interstitial nephritis
Large blood on dipstick with no RBCs	Hemoglobinuria or myoglobinuria
Specific crystals	Crystalline nephropathies, eg, Indinavir, Trimethoprim-sulfamethoxazole, or acyclovir associated, urate nephropathy

RBC, red blood cell; WBC, white blood cell.

Various urinary indices are commonly used to differentiate prerenal AKI from renal AKI. Urinary sodium concentration varies with the rate of water reabsorption. A patient who is in a prerenal state (both sodium and water avid) could have a decreased amount of sodium content in the urine but at a relatively high urine concentration (more than 20 to 40 mEq/L) due to a low urine volume in the setting of concurrent water avidity. Fractional excretion of sodium (FeNa) is a more reliable index since it does not vary with urine volume. FeNa measures the percentage of filtered sodium that is excreted in the urine. FeNa is calculated as follows:

$$\text{FeNa} = [(\text{urine sodium}/\text{plasma sodium})/(\text{urine creatinine}/\text{plasma creatinine})] \times 100.$$

A FeNa < 1% is indicative of a prerenal etiology. It is important to recognize that the FeNa value of 1% that distinguishes prerenal disease from acute tubular necrosis applies only in patients with a markedly reduced GFR. It is also important to remember that diuretics inhibit tubular sodium reabsorption so that in the CCU, patients receiving diuretics can have a FeNa > 1% despite intravascular volume depletion. A fractional excretion of urea nitrogen (FeUrea) and fractional excretion of uric acid (FeUric acid) may be more helpful in this setting. Similarly, the FeNa can be >1% despite volume depletion in patients with underlying CKD secondary to impaired tubular function at baseline. Also, prerenal states are not the only causes of low FeNa; it can also be low in acute glomerulonephritis, early obstructive nephropathy, liver failure, contrast nephropathy, pigment-induced nephropathy, and normal renal function. Some of the other diagnostic indices in this regard are listed in **Table 45.4**.

TABLE 45.4 Diagnostic Indices to Differentiate Prerenal and Renal Acute Kidney Injury

DIAGNOSTIC INDEX	PRERENAL AKI	RENAL AKI

Serum BUN to creatinine ratio	.20	,10–15
Urine Na (mEq/L)	,10	.20
Urine/serum creatinine ratio	.50	,20
Urine osmolality	.500	Variable
Urine specific gravity	.1.020	~1.010
FeNa (%)	,1	.1
FeUrea (%)	,35	.50
FeUric acid (%)	,12	.20

AKI, acute kidney injury; BUN, blood urea nitrogen; FeNa, fractional excretion of sodium; FeUrea, fractional excretion of urea; FeUric acid, fractional excretion of uric acid; Na, sodium.

Because the most commonly used marker of AKI, that is, SCr only rises 24 to 48 hours after the inciting injury, there is active research toward identifying newer serum and urine biomarkers for the early diagnosis of AKI. Some of the most promising markers are serum and urine neutrophil gelatinase-associated lipocalcin (NGAL),[8,9] interleukin 18 (IL-18),[10] kidney injury molecule-1 (KIM-1),[11] and cystatin C.[12] Further research is needed before these markers replace SCr as a marker of AKI in the clinical setting.[13]

Although glomerular diseases are an uncommon cause of AKI in the CCU, the finding of red blood cell casts or dysmorphic casts should prompt further evaluation. Estimation of urinary protein excretion is an important adjunct to further classify these patients. The use of random, spot urine protein/urine creatinine ratio as an estimate of 24-hour protein excretion has simplified this task by eliminating the need for cumbersome and often inaccurate 24-hour urine collections. A random urine protein/creatinine ratio >1 g protein/g of creatinine is usually seen in the presence of glomerular diseases. This ratio should be used only when kidney function is in steady state because the result may not be accurate in the setting of AKI. A number of serologic tests for secondary etiologies could help narrow the differential diagnosis; however, a definite diagnosis would require a kidney biopsy.

All patients with AKI should have periodic monitoring of serum electrolytes (sodium, potassium, magnesium, calcium, and phosphorus) and acid-base status because these are frequently abnormal and can become life threatening, for

example, severe hyperkalemia or severe metabolic acidosis.

Even though postrenal AKI is relatively uncommon in the CCU, a renal ultrasound should be obtained in all cases of unexplained AKI. A false negative study may be due to concomitant volume depletion or extrinsic compression, for example, secondary to a retroperitoneal hematoma. In the latter scenario, a noncontrast CT scan of the abdomen may be diagnostic.

DRUG DOSING

AKI affects renal drug elimination and other pharmacokinetic processes involved in drug disposition (eg, absorption, drug distribution, and metabolism). Drug dosing errors are common in patients with renal impairment and can cause adverse effects and poor outcomes. Dosages of drugs cleared renally should be adjusted according to estimated creatinine clearance. The most commonly used formulas are listed in **Table 45.5**. We recommend using the Cockcroft–Gault formula where creatinine clearance is estimated as a function of age, sex, and body weight. However, all those formulas were studied in patients with CKD with stable creatinine clearances and not in patients with AKI who have a day-to-day variation in the GFR. The actual GFR is much lower than the estimated GFR (often <10 mL/min in oliguric patients) for patients who are developing AKI and higher than the estimated GFR in patients who are in the recovery phase of AKI.

TABLE 45.5 Common Formulas Used to Estimate Glomerular Filtration Rate or Creatinine Clearance

NAME	FORMULA
MDRD formula, estimates GFR	eGFR (mL/min/1.73 m^2) 5 175 3 [serum creatinine (μmol/L) 3 0.0113]$^{-1.154}$ 3 age (years)$^{-0.203}$] (3 0.742 if female)
Cockcroft–Gault, estimates creatinine clearance (C_{Cr})	C_{Cr} 5 [(140 – age) 3 weight (kg)/(72 3 Cr)] (3 0.85 if female)
CKD-EPI, estimates GFR	eGFR 5 141 3 min (SCr/κ, 1)α 3 max(SCr/κ, 1)$^{-1.209}$ 3 0.993^{age} 3 1.018 [if female] 3 1.159 [if black]

κ is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, min indicates the minimum of SCr/κ or 1, and max indicates the maximum of SCr/κ or 1.
CKD-EPI, chronic kidney disease epidemiology collaboration; eGFR, estimated glomerular filtration rate; MDRD,

modification of diet in renal disease; SCr, serum creatinine.

Loading doses of medications should not be decreased in patients with AKI or CKD. Recommended methods for maintenance of dosing adjustments are dose reductions, lengthening the dosing interval, or both. Physicians should be familiar with commonly used medications that require dose adjustments; however, it is impossible to be aware of all the subtle adjustments that are often needed. Before prescribing any new medication, dosing in AKI/CKD should be verified using any reliable print or electronic resource. Careful monitoring of drug levels, when available, can ensure therapeutic efficacy while minimizing toxicity.

In patients who are on RRT especially those on intermittent hemodialysis (IHD), the drug dosing for those drugs that are significantly dialyzed should be scheduled to be given post dialysis. Some of the common drugs used in the CCU that are likely to be significantly dialyzed include aspirin, dabigatran, atenolol, lisinopril, and antimicrobials like cefepime.

PREVENTION OF ACUTE KIDNEY INJURY

Because very few specific treatments are available for renal AKI, the key is prevention. This is especially true for patients who are at higher risk for developing AKI, for example, patients with advanced age, preexisting renal impairment, diabetes, hypertension, CHF, sepsis, or hypovolemia.

In addition to patients with prerenal azotemia, specific groups of patients may benefit from fluid administration to prevent AKI (ie, patients with early sepsis, rhabdomyolysis, and those receiving drugs such as amphotericin B and contrast media, or drugs associated with crystal deposition such as acyclovir and sulfonamides). Overaggressive fluid resuscitation should be avoided to prevent complications of fluid overload.

Maintenance of a mean arterial blood pressure > 65 mm Hg with optimization of volume status and use of vasoactive agents is critical to maintain optimal renal perfusion. In the setting of decompensated heart failure, the judicious use of inotropes can be necessary to prevent and treat AKI. Low-dose dopamine does increase renal plasma flow; however, clinical studies do not support the use of “renal dose” dopamine to prevent AKI or reduce the requirement of RRT.[14,15] The use of dopamine (or of fenoldopam,[16] a short-acting dopamine receptor-1

agonist) for this purpose is not recommended at present.

When using potentially nephrotoxic antimicrobials, attention to drug levels, adjusted dosing, and dose interval may minimize the risk of drug-induced nephrotoxicity. Furthermore, daily assessment of continued need for broad-spectrum antibiotics based on culture results is essential. Early identification of drug-induced AKI and discontinuation of the offending agent can prevent further renal injury.

ACUTE KIDNEY INJURY—SPECIAL SITUATIONS

CONTRAST-INDUCED NEPHROPATHY

Contrast-induced nephropathy (CIN) or contrast-induced acute kidney injury is generally defined as an increase in serum creatinine concentration of >0.5 mg/dL or 25% above baseline within 48 hours after contrast administration. Risk factors for CIN include advanced age, preexisting CKD, dehydration, hypotension, intra-aortic balloon pump, concomitant administration of nephrotoxic drugs, sepsis, diabetes mellitus, and CHF requiring active diuretic use. Various scoring systems are available to quantify this risk.[17] In patients with established AKI, avoiding the use of contrast media if possible until AKI has resolved should be considered.

Certain measures such as the following may be useful in minimizing the risk of CIN:

1. The use of low osmolar or isoosmolar contrast media and use of lowest possible volume (eg, avoiding left ventriculogram in patients at risk);
2. Optimization of volume status: Discontinuation of diuretics and use of isotonic saline starting 6 to 8 hours before contrast administration to ensure adequate hydration is a commonly used strategy.
3. Discontinuation of angiotensin converting enzyme inhibitors (ACEI)/angiotensin receptor blockers (ARBs) prior to contrast administration can sometimes be done but this strategy is not routinely recommended because data have shown conflicting results.
4. Isotonic sodium bicarbonate has been shown to be superior to isotonic saline in some studies but the evidence is equivocal.[18]
5. Another agent sometimes used is oral *N*-acetylcysteine (NAC). Evidence for the preventive efficacy of NAC is equivocal and cannot be routinely

recommended at this time.[19]

6. Recent data suggest a beneficial effect of statin administration although the quality of this data is weak.
7. All other potential nephrotoxins should be discontinued when possible.
8. Periprocedural hemodialysis has no role in the prevention of CIN.[20]

ACUTE KIDNEY INJURY POST CARDIAC SURGERY

AKI complicates up to 30% of cardiac surgery. The risk factors most commonly associated with AKI in this setting include female sex, left ventricular dysfunction, diabetes, peripheral vascular disease, chronic obstructive pulmonary disease, emergent surgery, use of intra-aortic balloon pump, prolonged cardiopulmonary bypass time, and, most importantly, preoperative elevations in SCr.[21] The avoidance of cardiopulmonary bypass has been shown to be associated with lower incidence of postoperative AKI[22] and should be considered whenever possible. Recently, nesiritide,[23] a recombinant human BNP and fenoldopam, a renal vasculature dilator, have shown mixed results in preventing postcardiac surgery AKI.

TREATMENT OF ACUTE KIDNEY INJURY

The treatment of AKI depends on its etiology. In postrenal AKI, rapid relief of obstruction will reverse the AKI. Prerenal AKI owing to hypovolemia should be managed with prompt restoration of the effective circulatory volume, usually by administration of crystalloid solutions. Hypovolemia can be caused by renal or extrarenal causes, and careful history and examination as outlined earlier is essential to determine absolute or effective hypovolemia. The adequacy of restoration of intravascular volume can be guided by periodic assessment of the central venous pressure (CVP). However, the possibility of right-sided heart failure, pulmonary arterial hypertension, or positive pressure ventilation can elevate CVP; this needs to be kept in mind while interpreting the results. The use of Swan-Ganz catheter guided therapy has fallen out of favor after the results of trials showed that use of these catheters increased anticipated adverse events and did not have any effect on overall mortality and hospitalization length.

In acute decompensated CHF, preload and afterload reduction with diuretics and vasodilators are the cornerstones of therapy. The judicious use of diuretics

with close monitoring of hemodynamics and renal parameters can increase cardiac output and lower renal venous hypertension, thereby improving renal perfusion. Appropriate use of inotropes may restore normal renal perfusion especially in patients with acute systolic heart failure or advanced left ventricular systolic dysfunction. The temporary discontinuation of ACEIs or ARBs and avoidance of NSAIDs may also help increase renal perfusion.

The management of intrinsic AKI depends on the underlying etiology. The management of individual diseases, especially that of glomerular diseases, is beyond the scope of this chapter.

We focus on the special considerations in patients with ATN, which is a common cause of renal AKI in the CCU. In case of any doubt regarding whether the patient has prerenal AKI or established ATN secondary to sustained renal hypoperfusion, an adequate trial of crystalloids and/or the use of vasoactive agents may be the only differentiating feature; rapid reversibility indicates a prerenal mechanism. While fluid resuscitation is ongoing, frequent monitoring of respiratory status in patients with heart failure is essential to avoid pulmonary edema. Withdrawal of all possible nephrotoxic agents to avoid further injury to the kidney should be done concurrently. Once ischemic or nephrotoxic ATN is established, there is no specific therapy. The main goal of treatment is to treat the complications of AKI and prevent further injury.

A number of drugs have been tried to reduce the requirement for RRT and to accelerate renal recovery in ATN but none has shown a conclusive benefit. Diuretics are commonly used in oliguric AKI; however, randomized controlled trials have failed to show a reduction in the need for RRT. Hence the role of diuretics in AKI is limited to management of volume overload and/or hyperkalemia in the setting of AKI. Similarly, the use of selective renal vasodilators such as dopamine or fenoldopam is not supported by current clinical evidence and thus is not recommended.[13]

RENAL REPLACEMENT THERAPY

Conventional indications for initiation of RRT include refractory fluid overload, intractable hyperkalemia and metabolic acidosis, and uremic syndrome. Other indications include uremic pericarditis, uremic encephalopathy, uremic neuropathy, and suspected drug/toxin overdose with a dialyzable substance. Traditional triggers for treatment were based on studies in CKD patients,

whereas patients with AKI who are critically ill may have a reduced tolerance of metabolic derangements.

Furthermore, the identification that iatrogenic fluid overload may play a role in perpetuating multiorgan dysfunction in critically ill patients has led to the belief that early initiation of RRT in this population may have beneficial effects on overall morbidity and mortality. However, timing of RRT initiation in critically ill patients remains unclear. Recently, a French multicenter trial showed no benefit of early versus late RRT initiation,[24] in discordance with another recent German single center trial that suggested that early initiation reduced mortality at 90 days as compared to late initiation.[25]

The available modalities for RRT include IHD, continuous renal replacement therapy (CRRT), hybrid therapies such as sustained low-efficiency dialysis and peritoneal dialysis. The choice of modality depends on institutional availability, physician preference, patient hemodynamic status, and the presence of other comorbidities. CRRT has been postulated to be more physiologic owing to its continuous nature. It is especially useful in the hemodynamically unstable patients with AKI where use of IHD could lead to further ischemic insult and delay in renal recovery. However, no randomized study has proven this theoretical benefit over conventional, intermittent dialysis.

One modality of CRRT, especially useful in the CCU, is slow continuous venovenous ultrafiltration that can allow removal of large amounts of fluid from the patient while minimizing the risk of hemodynamic instability. It can be considered as a therapeutic option in the management of a fluid overloaded patient with diuretic resistance even in the absence of AKI.

RECOVERY FROM ACUTE TUBULAR NECROSIS

Recovery from ATN is the rule rather than the exception. More than 90% of patients with ATN recover renal function sufficient to discontinue dialysis. The timing of this recovery varies among individual patients and can happen even after weeks of AKI. A post-ATN diuresis can commonly be seen in the recovery phase owing to osmotic diuresis. It is important to monitor these patients closely as they are often at the risk of developing new prerenal azotemia and electrolyte derangements if volume intake does not match urinary loss.

DEDICATION

This chapter is dedicated to the memory of Dr. James Jones who was a cherished colleague in the Division of Nephrology at Mount Sinai, St. Luke's and West. His untimely passing at the end of 2016 has left a void in our hearts and minds.

Patient and Family Information for: Renal Failure in the Cardiac Care Unit

WHAT ARE THE KIDNEYS?

The kidneys are two bean-shaped organs located in the middle of the back, one on each side. Each measures about the size of a fist. These are vital organs and each is made up of about 1 million nephrons (filters) and tubules that process approximately 2 L of blood every 5 minutes.

WHAT ARE THE FUNCTIONS OF THE KIDNEY?

The human body consists of 60% to 70% water. This water also contains a variety of dissolved materials such as different salts (sodium chloride, potassium chloride, sodium bicarbonate, etc). All the water in the body is distributed between three spaces: the intracellular compartment (in the cells), interstitial spaces (between the cells), and intravascular (the blood). In an ideal setting, there is a perfect balance of water and salts between all these compartments. If any deregulation occurs, for instance if we get dehydrated (eg, diarrhea) or if we get fluid overloaded (eg, in patients with heart failure leading to lower extremity swelling and/or pulmonary edema), the kidneys jump into action to restore the equilibrium. Therefore, control of fluid and salt balance is an essential function of the kidneys.

Another important function of the kidneys is to excrete toxic wastes (such as urea, acid, etc) produced by the body on a daily basis. The kidney does this by filtering the blood that flows through it. In other words, the urine is actually a filtered form of blood that has all the waste material in it (urea, extra water, acid, salts, etc).

The third function of the kidney is to act as an endocrine organ. The main hormone that the kidneys produce is erythropoietin that is required by the body to produce red blood cells (that carry oxygen in the blood). In addition, the kidneys also activate other inactive products such as vitamin D (helps maintain healthy bones).

WHAT ARE THE TYPES OF KIDNEY DISEASE?

Depending on the duration of onset, kidney disease can be acute, chronic, or acute on chronic.

Acute: Such patients may have normal functioning kidneys at baseline. AKI is a potentially life-threatening condition and may require intensive care treatment. ATN is one of the most common subtypes of AKI in a critically ill patient. In ATN, the kidney tubules get damaged owing to various reasons (infections/pneumonia, low blood pressure resulting from heart failure/heart attack, etc). With time, and if the reason for damage is fixed, the tubules may start functioning again as before.

Chronic (when decrease in function takes place gradually over time): Common causes are hypertension and diabetes. Such patients may have CKD. Those who have had regular follow-up with their primary doctors may be aware of their underlying CKD. However, as kidney disease is usually painless, it is not uncommon for patients not to know of their underlying CKD until the disease is in an advanced stage.

Acute on chronic: Such patients have acute worsening of their CKD owing to critical illness, for example, pneumonia, heart attack, and heart failure.

WHAT ARE THE COMMON CAUSES OF ACUTE KIDNEY INJURY?

An injury to the kidneys is generally because of another disease process. Sometimes there may be more than one cause, and therefore it may be impossible to pinpoint the exact cause of AKI. Death is most common when AKI is caused by surgery, trauma, or severe infection in someone with heart disease, lung disease, or recent stroke. Old age, infection, loss of blood from the intestinal tract, and progression of kidney failure also increase the risk of death.

Some of the common causes of AKI are as follows:

Shock: Shock is a life-threatening condition that may accompany severe injury or illness, whereby the body suffers from insufficient blood flow to its vital organs. This can therefore result in decreased oxygen delivery to the organs (hypoxia) leading to organ failure, for example, kidney failure, heart attack (cardiac arrest), and so on. Shock may be of different type/causes: septic (owing to an infection in the body, pancreatitis, etc), hemorrhagic (owing to acute blood loss—as in a patient with bleeding from a stomach ulcer), cardiogenic (owing to heart failure from a weak heart or acute heart attack), and hypovolemic (eg, excess fluid loss from body after severe diarrhea or excessive use of diuretics).

Damage from medicine/dyes: Unfortunately, many of the medications used to treat patients may themselves cause kidney damage. People who have serious, long-term health problems are more likely than others to have such adverse effects. Some examples of such medications are as follows:

- Antibiotics used to treat life-threatening infections
- Pain medicines such as ibuprofen (and all other NSAIDs)
- Some blood pressure medicines and ACEIs (such as enalapril)
- The contrast/dyes used in imaging (CAT scan as discussed in the ensuing section)
- Some of the HIV medications, for example, tenofovir.

Urinary tract obstruction: This may happen in patients with a known history of kidney stones, benign prostate hypertrophy, or rarely in patients with cancers that invade or press on the urinary tract system.

WHAT ARE THE SIGNS AND SYMPTOMS OF KIDNEY FAILURE?

Kidney failure is almost always painless. In the setting of an intensive care unit, the following signs and symptoms may point toward a failing kidney:

Accumulation of fluid/water: Because the failing kidneys are unable to excrete water, accumulation of water in the body manifests as swelling of the feet, lower legs, face, and/or the hands. Sometimes when the kidneys fail, a lot of protein is lost in the urine, which can also cause worsening edema and labored breathing owing to accumulation of fluids in the lungs. If this is severe, the patient may

require intubation (whereby the patient is sedated and a breathing tube is inserted in the windpipe) and breathing support with the help of a machine (ventilator).

Irregular heart rate: Owing to the accumulation of toxins and electrolyte imbalance (hyperkalemia or high potassium), the heart rhythm may become irregular or dangerously slow, leading to cardiac arrest.

Symptoms resulting from accumulation of toxins/waste products such as urea: Loss of appetite, nausea, vomiting, weight loss, fatigue, sleepiness, itching, twitching, and a metallic taste in the mouth. They often indicate that the person is accumulating dangerous amounts of waste products (urea) because the kidneys are not working to excrete them.

Abnormal blood tests suggesting impaired kidney function: Sometimes the patient may be totally asymptomatic but the blood tests may suggest severe kidney failure, for example, hyperkalemia (high potassium), increased blood acidity, high creatinine, and BUN levels.

HOW TO DIAGNOSE KIDNEY FAILURE?

Nephrologists are specialists in kidney diseases. When a patient has evidence of kidney failure, the intensive care team will seek the help of nephrologists to manage it. The following tests will help to determine the severity and cause of kidney failure:

Blood test: In most cases, two parameters in the blood, namely the BUN and creatinine, can give a fair assessment as to the degree of kidney failure. Urea is a byproduct of protein breakdown, and creatinine is a byproduct of normal muscle functioning. In a normal person, the level of creatinine is 0.7 to 1.2 mg/dL and that of BUN is 12 to 24 mg/dL. In addition, blood levels of some important electrolytes such as potassium are also taken into consideration while treating a patient with kidney failure.

Urine tests: Microscopic analysis of patients' urine can give some indication as to the type of kidney failure (eg, AKI owing to ATN). Other urine tests such as urine protein concentration and urine electrolytes (sodium, creatinine) can also prove helpful in making the diagnosis: for example, a high protein and blood concentration in the urine with AKI may be suggestive of lupus nephritis (owing to autoimmune disease called systemic lupus nephritis).

Imaging tests: Noninvasive procedures such as ultrasound and CAT scan help in assessing the condition of the kidneys.

Ultrasound: It is a painless, harmless (uses sound waves that bounce off structures in the body and give images), and quick way to assess the size and texture of the kidneys. Kidneys are usually normal in size in patients with AKI unless the patient also has some underlying CKD. Ultrasound is also the procedure of choice to diagnose any obstruction of the urinary tract and it is important to rule this out as the cause of kidney injury in all patients.

Computed axial tomography scan: A CAT scan uses X rays to produce pictures in crosswise slices. CAT scans can detect kidney stones, blockage, tumors, cysts, and so on. In addition to the kidneys, an abdominal CAT scan can also be used to assess other abdominal organs. Sometimes CAT scans require using contrast dye, which itself carries the risk of causing kidney injury, especially in people who already have reduced kidney function.

Kidney biopsy: Very rarely would a nephrologist decide to do a kidney biopsy in a patient with AKI. He/she may decide on doing this if conventional analysis is unable to provide sufficient clues as to the underlying cause of AKI and/or if the treatment modality would require the exact diagnosis rather than the most probable cause of AKI. In kidney biopsy, a piece of kidney tissue is taken out under guidance of ultrasound or CAT scan. This tissue is then analyzed by experts to provide the exact cause of kidney failure. Kidney biopsy unfortunately carries a high risk of bleeding (10%) and even death in <1% of patients.

HOW TO MANAGE A PATIENT WITH KIDNEY FAILURE (HEMODIALYSIS)?

The most definitive treatment of kidney failure is to fix the underlying cause. For example, if the patient is having severe heart failure, the optimization of the heart failure will most likely help in resolving acute kidney failure. However, treating the underlying disease may take time, thus necessitating the initiation of renal replacement therapy (RRT). The decision to start RRT may be taken if the patient's serum potassium levels are dangerously high and/or if the patient has mental status changes, and/or if the patient has too much fluid, and/or if the patient develops pericarditis (inflammation of the heart covering owing to high urea). RRT basically implies the use of artificial methods (dialysis) to carry out the function of the kidneys. The commonly used technique for acute kidney failure is hemodialysis.

Hemodialysis is the most common intermittent method of artificial RRT,

wherein the blood is allowed to flow through a special filter that removes waste and extra fluids. The clean blood is then returned to the body. For hemodialysis, the patient needs to have a large bore catheter in one of the deep veins of the body (such as a nontunneled catheter that has to be typically changed after a few days of placement, and, a tunneled catheter that can be used for a longer period of time). It is therefore placed either in the neck or the groin. Each session of hemodialysis lasts for 3 to 4 hours and is done either daily or three times a week. However, the frequency may be adjusted based on the blood tests, degree of edema, and so on.

HOW LONG WILL THE PATIENT NEED HEMODIALYSIS?

Acute kidney failure is a potentially life-threatening condition and may require intensive care treatment. However, the kidneys usually start working again within several weeks to months after the underlying cause has been treated. Such patients may therefore require hemodialysis temporarily.

The recovery also depends on the baseline function of the kidneys, the underlying cause, and the severity of the AKI. In some cases, chronic kidney failure or end-stage kidney disease may develop, thus requiring hemodialysis lifelong.

Acute Neurologic Emergencies in the Cardiac Care Unit

Some of the most feared complications from acute cardiac disease are neurologic in nature. When acute brain injury occurs, significant morbidity and mortality may follow. A team-based approach that incorporates cardiology, neurology, and critical care expertise is desirable to maximize patient outcomes and address each patient's complexities. There are four common neurologic emergencies in the cardiac care unit (CCU): delirium, hypoxic ischemic encephalopathy (HIE), acute ischemic stroke, and intracranial hemorrhage (**Table 46.1**). This chapter is tailored to patients admitted to or being admitted to a CCU, and so a broader differential diagnosis is applicable to patients in other care environments (such as the emergency department or general medical floor).

TABLE 46.1 Common Acute Neurologic Emergencies in the CCU

Delirium
Hypoxic ischemic (anoxic) encephalopathy
Acute ischemic stroke
Intracranial hemorrhage

CCU, cardiac care unit.

DELIRIUM

Delirium is acute brain dysfunction characterized by a change in both the level and content of consciousness. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) defines delirium as a "disturbance in attention (ie reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment)" that occurs over hours to days, often fluctuates (waxes and wanes), and is different from the patient's normal state of being. There may also be abnormalities of higher cognitive function or even focal neurologic deficits such as language difficulty, visuospatial changes, or changes in perception. In delirium, the symptoms are not due to an underlying or preexisting condition such as dementia. Finally, there needs to be evidence from the history, examination, or supporting data that the cause is due to a medical condition or is multifactorial. Synonyms for delirium include encephalopathy, acute brain failure, intensive care unit (ICU) psychosis, acute confusional state, and altered mental status. A diagnosis of delirium implies that there is no other underlying primary neurologic condition accounting for the patient's syndrome, such as a stroke causing aphasia or nonconvulsive status epilepticus.

RECOGNITION OF DELIRIUM

As with any medical problem, the diagnosis of delirium starts with a history and physical examination. With delirium, key questions include the following:

- How is the patient confused? Is he or she seeing objects, having difficulty speaking, or is he or she somnolent?
- When did the change start? Has this ever occurred before? Are the patient's symptoms coming and going or are they constant?
- Does the patient have pain?
- What are the vital signs?
    - Fever suggests infection. Tachycardia may be due to fever, dehydration, or atrial fibrillation. Severe hypertension should bring hypertensive encephalopathy into the differential diagnosis.
- What is the blood glucose?
    - Hypoglycemia can cause acute confusion and should be immediately treated with oral or intravenous glucose, as appropriate. Thiamine 100 mg intravenous (IV) should precede any IV dextrose administration whenever possible. Fingerstick glucose can be falsely normal or high from many factors, including sugars on uncleaned skin; a venous glucose or chemistry should be sent to the laboratory. To avoid prolonged profound hypoglycemia that can lead to permanent coma, thiamine and IV dextrose

should be given while awaiting the venous glucose result if there is *any* clinical suspicion for hypoglycemia as the cause of acute encephalopathy.

- What is the past medical history?
  - Patients with known dementia are at higher risk for delirium.
  - Patients with acute or chronic kidney or liver dysfunction are at risk for uremic or hepatic encephalopathy, respectively, as well as increased risk for medication toxicities if doses are not adjusted or organ function is changing rapidly over time.
- What is the patient's history regarding tobacco, alcohol, and substance abuse?
  - Delirium tremens should be considered in patients admitted to the hospital in the previous 12 to 72 hours.
  - Cocaine and amphetamine withdrawal can result in a somnolent, stuporous state.
  - Nicotine withdrawal can be prevented by prescribing a 21 mg nicotine transdermal patch for chronic smokers.
- Did the patient recently receive any medications (**Table 46.2**)?

TABLE 46.2 Common Medications in the CCU That Can Cause Delirium

Antibiotics: cefepime, flouroquinolones
Anticonvulsants: phenytoin, phenobarbital, levetiracetam, valproic acid
Antihistamines: diphenhydramine, dextromethorphan, famotidine
Benzodiazepines, zolpidem
Corticosteroids
Dopaminergic drugs: L-dopa, rotigotine
Digoxin
Lidocaine
Opiates

CCU, cardiac care unit.

  - Thoroughly review the patient's home medications, scheduled medications, and the medication administration record for one-time or as-needed doses.
  - If the patient received opiates and has other signs of opiate intoxication such as pinpoint pupils or hypoventilation, consider naloxone 0.4 mg IV.

BEDSIDE EXAMINATION IN DELIRIUM

Make a general assessment of the patient. Does he or she appear disheveled to suggest underlying psychiatric or dementing process? Is there nuchal rigidity? Auscultate heart and lungs to evaluate for tachypnea, rhonchi, or decreased

breath sounds, irregular rhythms, or cardiac valvular abnormalities. Make note of Janeway lesions, splinter hemorrhages, hepatomegaly, abnormal bowel sounds, or jaundice.

The neurologic examination starts when you first enter the room, in how the patient is able to (or unable to) give a history. Note the level of alertness. Using terms such as “lethargic” or “stuporous” can be nebulous and easily misinterpreted, making it difficult for another practitioner to later discern if the patient has had a change in his or her examination. Instead, consider describing how long the patient can sustain attention (for a few seconds, or a minute or 2), and what intensity of stimulus was required to awaken them (voice, nonnoxious tactile stimuli, noxious stimulus, or continuous noxious stimulation). For alert patients, the mental status examination starts with orientation questions. Simple tests of attention include counting backward from 20 to 1 and naming the days of the week or months of the year in reverse order. Formal language testing can include the naming of objects, repetition, and the ability to follow verbal commands (either simple such as “show me two fingers” or more complex like “touch your left ear with your right thumb”). Do not simultaneously demonstrate the verbal command, so that the request is testing receptive language and not the patient’s ability to mimic. Depending on the patient’s attention and ability to participate, further mental status testing might include a formal score such as the Montreal Cognitive Assessment (MoCA, available free at mocatest.org), Confusion Assessment Method for the ICU (CAM-ICU, icudelirium.org), or Intensive Care Delirium Screening Checklist (ICDSC).

The rest of the neurologic examination is focused on finding clues to a metabolic or systemic cause for delirium and identifying focality that would suggest a primary neurologic problem as opposed to delirium. Small pinpoint but reactive pupils suggest opiate effect. Eye motion abnormalities and nystagmus can be seen with Wernicke encephalopathy or with posterior fossa pathology. Facial movements should be assessed for symmetry. The precision of the motor exam will depend on the patient’s ability to participate. In a severely encephalopathic patient, strong and symmetrical withdrawal to pain in all extremities is reassuring that intracranial pathology is absent. With more cooperative patients, subtler signs of weakness such as pronator drift may be elicited. Additionally, arms should be held with elbows and wrists extended (“as if you are stopping traffic”) to test for asterixis—a sign of hepatic or uremic encephalopathy. Asterixis is also called negative myoclonus and manifests as a “quick release” or fast drop from a sustained posture with a return close to the

previous posture. Tremulousness can be seen with alcohol withdrawal. Tone can be tested in all patients. Deep tendon reflexes and Babinski signs should be checked. Sensory examination is almost always unreliable during a delirium evaluation and generally does not help narrow the diagnosis.

INITIAL LABORATORY AND IMAGING WORKUP FOR DELIRIUM

After evaluating the patient clinically and ensuring the fingerstick glucose is normal, the following tests should be considered:

- Chemistry, ammonia, complete blood count, therapeutic drug levels, urine toxicology:
  - Abnormalities of sodium, calcium, and glucose can cause encephalopathy and/or seizures. Profound uremia and hyperammonemia can cause metabolic encephalopathy.
- Urinalysis and urine culture; blood cultures;
- Arterial blood gas:
  - Acute respiratory acidosis or hypoxia can cause stupor. Respiratory alkalosis can suggest hyperventilation and tachypnea from sepsis. Hypoxia can be seen with pneumonia or pulmonary embolus.
- Chest X-ray should be ordered for any patient with fever, tachypnea, or hypoxia.
- Noncontrast head computed tomography (CT) should be considered for all patients and ordered emergently for any patient with a focal neurologic examination. If the patient has a new acute focal neurologic examination or an examination concerning for posterior fossa pathology, a CT angiogram (CTA) of the head and neck should be immediately and simultaneously acquired to rule out large vessel occlusion (LVO) causing stroke, which is treatable and reversible.
- Electroencephalograph (EEG) may give additional information. Triphasic waves suggest toxic or metabolic encephalopathy. Diffuse slowing of the background can be seen in either delirium or dementia. Epileptiform discharges do not diagnose seizures but may change one’s post-test probability for seizures as a cause of change in mental status.

TREATMENT OF DELIRIUM

Ultimately, the treatment of delirium requires diagnosis and correction of the underlying cause. If acute pain is the cause, pain medications should be given. If

agitation limits the ability to obtain initial studies, or if the patient is a threat to himself/herself or to others, then IV medications should be given with the goal of resolving the agitation (**Table 46.3**). Antipsychotics are first-line treatment for acute agitation.[1] Benzodiazepines are first line in the treatment of alcohol-withdrawal delirium, benzodiazepine-withdrawal associated delirium, or in acute hepatic failure.[2] Additionally, benzodiazepines may be considered as first-line treatment in patients with extreme or life-threatening prolongation of the QT interval. Overall, however, the total dose of benzodiazepines is associated with an increase in delirium, and so they should not be the initial treatment in a generalized patient population. Dexmedetomidine (Precedex) infusion may be used for patients who are intubated or spontaneously breathing. Dexmedetomidine has the advantages of being associated with a decreased prevalence of delirium and a decrease in ventilator days in intubated patients compared with benzodiazepines or morphine.[3] Side effects of dexmedetomidine include hypotension and bradycardia.

TABLE 46.3 Drugs for the Treatment of Acute Agitated Delirium

	INITIAL DOSE	SELECTED SIDE EFFECTS
Antipsychotics		
Haloperidol Olanzapine Quetiapine	1–10 mg IV/IM/po 5–10 mg po/IM 25–50 mg po	Prolonged QT, EPS Hyperglycemia
Benzodiazepines		
Lorazepam Midazolam	1–4 mg po/IV/IM 1–4 mg po/IV/IM	
Alpha 2 adrenergic agonists		
Dexmedetomidine	0.4 µg/kg/h IV infusion	Hypotension, bradycardia

IV, intravenous; IM, intramuscular. EPS, Extrapyramidal symptoms.

Nonpharmacologic treatments for delirium include frequent verbal redirection, ensuring comfort, and isolated hand restraints to prevent pulling of lines while allowing for freedom of movement. Wrist restraints and 4-point restraints may worsen agitated delirium. Treatment and prevention of delirium also include maintaining normal sleep-wake cycles: minimizing sleep interruptions at night,

decreasing light stimulus to the eyes at night (including televisions and smartphones or tablets), and increasing stimulation during the day including mobilization and physical therapy. Indwelling urinary catheters, nasogastric tubes, and multiple IV lines not only serve as a source of discomfort and potential infection, but also physically restrain patients; they should be discontinued or minimized as soon as they are no longer medically necessary. Finally, protocols and automatic order sets should avoid deliriogenic medications, such as diphenhydramine for sleep.[4]

HYPOXIC ISCHEMIC ENCEPHALOPATHY

The number one cause of morbidity and mortality post cardiac arrest is continued coma and persistent encephalopathy after resuscitation. Treating patients aggressively gives the best chance for neurologic recovery and prevents the self-fulfilling prophecy of a poor neurologic prognosis.

RECOGNITION OF HYPOXIC ISCHEMIC ENCEPHALOPATHY

Any patient who is not awake and following commands after return of spontaneous circulation (ROSC) after cardiac arrest should be considered to have HIE. The initial neurologic examination should include pupil size and reactivity, corneal reflexes, oculocephalic reflexes (barring any concern for cervical spine injury), cough reflex, gag reflex, motor response, and verbal response. The Glasgow Coma Scale (**Table 46.4**) is a simple tool that communicates the level of coma and easily tracks changes in the neurologic examination. Note any extraneous movements such as myoclonus, nystagmus, flexor or extensor posturing, or shivering.

TABLE 46.4 Glasgow Coma Scale

EYE OPENING	BEST MOTOR RESPONSE	BEST VERBAL RESPONSE
4—eyes open spontaneously	6—follows commands	5—oriented
3—eyes open to voice	5—localizes to pain	4—disoriented
2—eyes open to pain	4—withdraws from pain	3—inappropriate words
1—none	3—flexor posturing to pain	2—incomprehensible sounds

	2—extension posturing to pain	1—none
	1—none	

It is extremely important to provide aggressive care to all patients on admission to the emergency department or hospital, regardless of their neurologic examination, to prevent the self-fulfilling prophecy of a poor neurologic outcome. Patients with coma shortly after ROSC, including those with some absence of cranial nerve function, can improve and even regain consciousness with aggressive medical care. Even if the patient meets criteria for brain death immediately after resuscitation or soon thereafter, aggressive critical care allows time for family discussions and for consideration of organ donation.

DIAGNOSTIC EVALUATION

Neuron-specific enolase (NSE) should be sent between 24 and 72 hours post arrest to assist with prognosis. Without hypothermia, an NSE of greater than 33 μg/L is associated with a poor prognosis. With hypothermia, patients may have a higher number (up to 80 to 100 μg/L have been reported) and still have a good outcome, although the higher the value, the less likely a good neurologic outcome.

Many centers perform noncontrast head CTs in the emergency department or directly after stabilization from cardiac arrest to rule out massive intracranial hemorrhage or acute hydrocephalus as the cause for cardiac arrest. This is a reasonable practice, but not one that is required if there is a known precipitant of cardiac arrest such as prolonged QT interval or a preceding period of hypoxia. Noncontrast head CTs have not been validated for use in neurologic prognostication, although the degree of changes can give the treating neurologist a flavor of the severity of the initial brain injury (**Figures 46.1–46.3**).

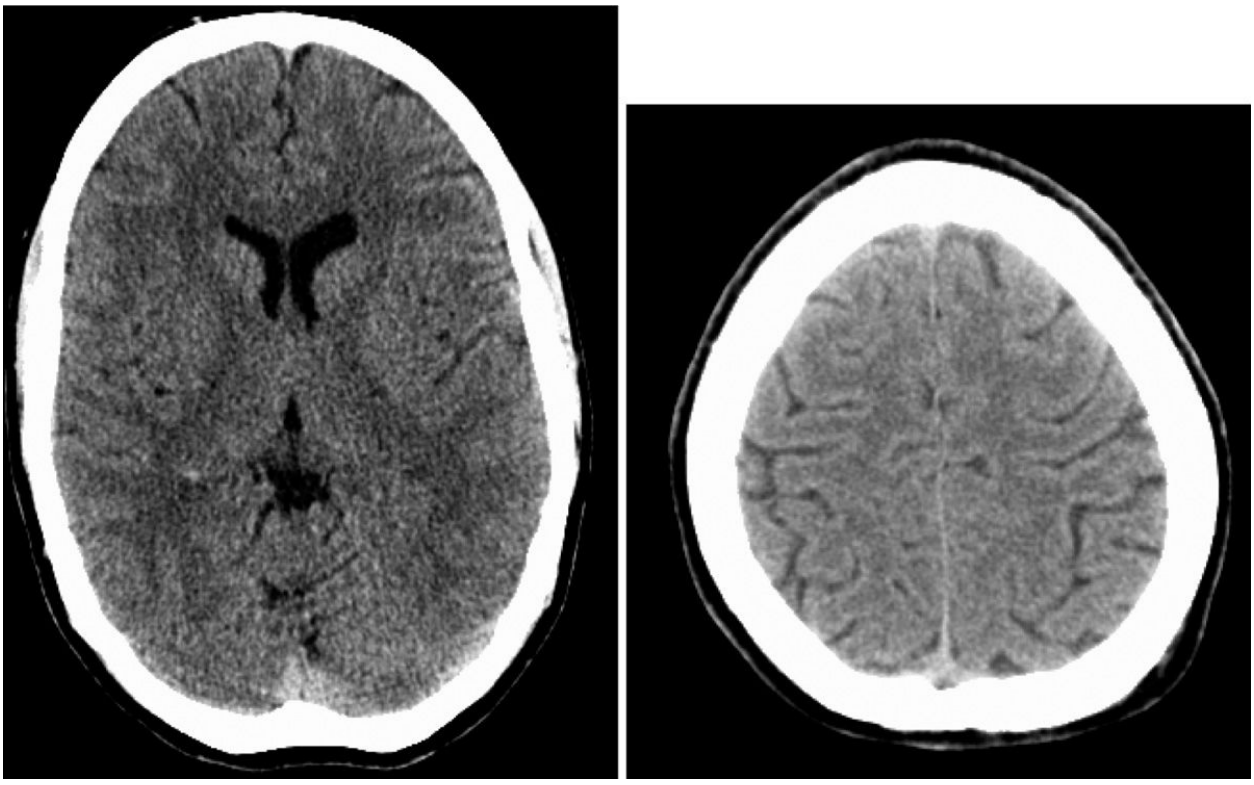

FIGURE 46.1 Two axial images from a normal noncontrast CT of the brain. CT, computed tomography.

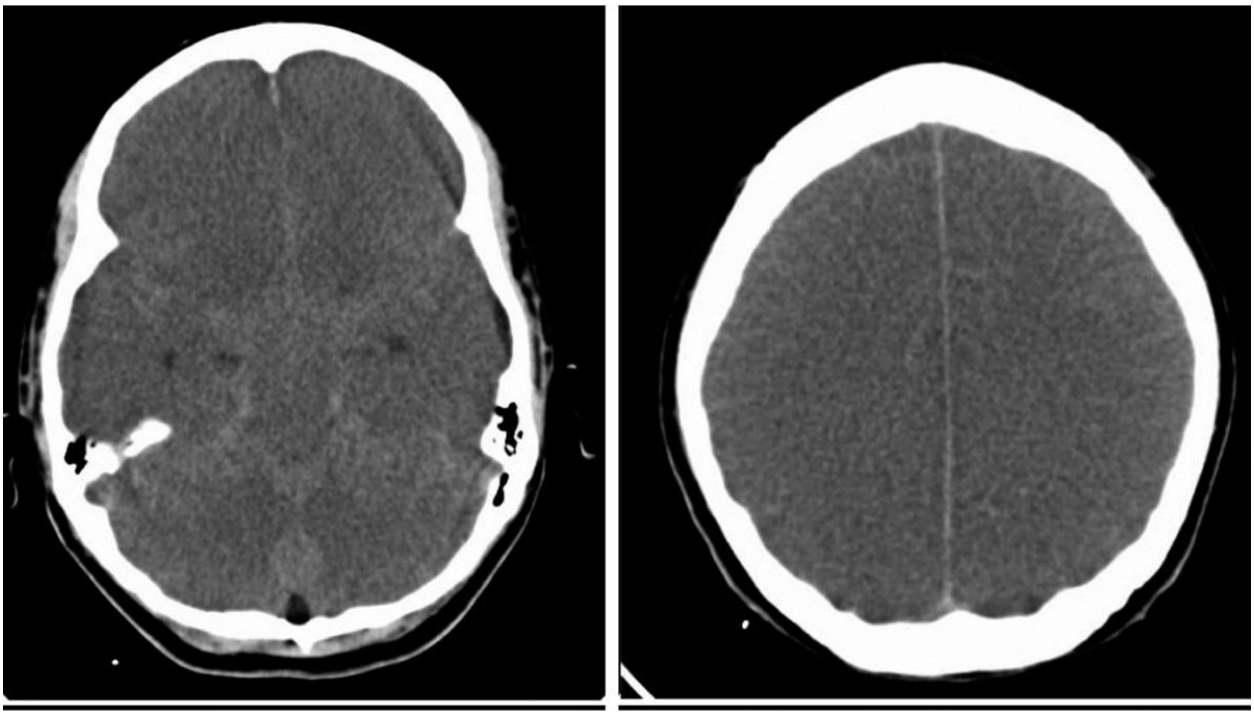

FIGURE 46.2 Noncontrasted CT scan of the head of a patient approximately 100 hours after an out-of-hospital asystolic cardiac arrest. The left panel shows pseudosubarachnoid hemorrhage and blurring of the

gray-white junction throughout all the structures of the brain. The right panel shows blurring of the gray-white junction with sulcal effacement. The patient's admission noncontrast CT scan of the brain was unremarkable. At this time, the patient had flexion posturing and nonreactive pupils. The patient expired on hospital day 7 after removal of life support. CT, computed tomography.

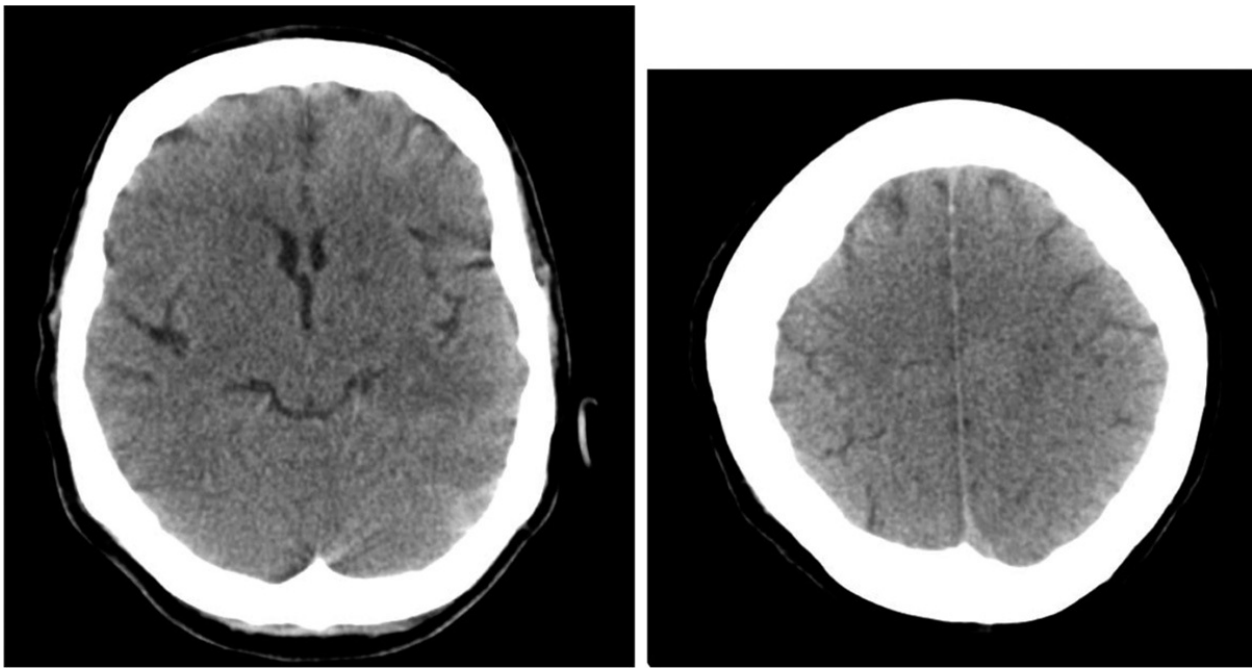

FIGURE 46.3 These two images are axial cuts of a noncontrasted head CT of a patient approximately 8 days after an out-of-hospital PEA cardiac arrest. There is loss of gray-white differentiation throughout the cerebral hemispheres, including loss of differentiation in both the basal ganglia and internal capsule (left panel), as well as the cortex. There is sulcal effacement especially at the vertex (right panel). These findings are consistent with diffuse anoxic injury. CT, computed tomography. PEA, pulseless electrical activity.

Magnetic resonance imaging (MRI) should not be ordered acutely after a cardiac arrest. However, noncontrasted MRI of the brain may be helpful in prognostication (**Figure 46.4**). The volume and intensity of Diffusion-Weighted Imaging (DWI) and Fluid-Attenuated Inversion Recover (FLAIR) signal changes in the cortex of the brain have prognostic value for neurologic recovery, when the MRI is performed between days 3 and 6 after the cardiac arrest. A greater amount of change prognosticates a poor neurologic outcome.[5]

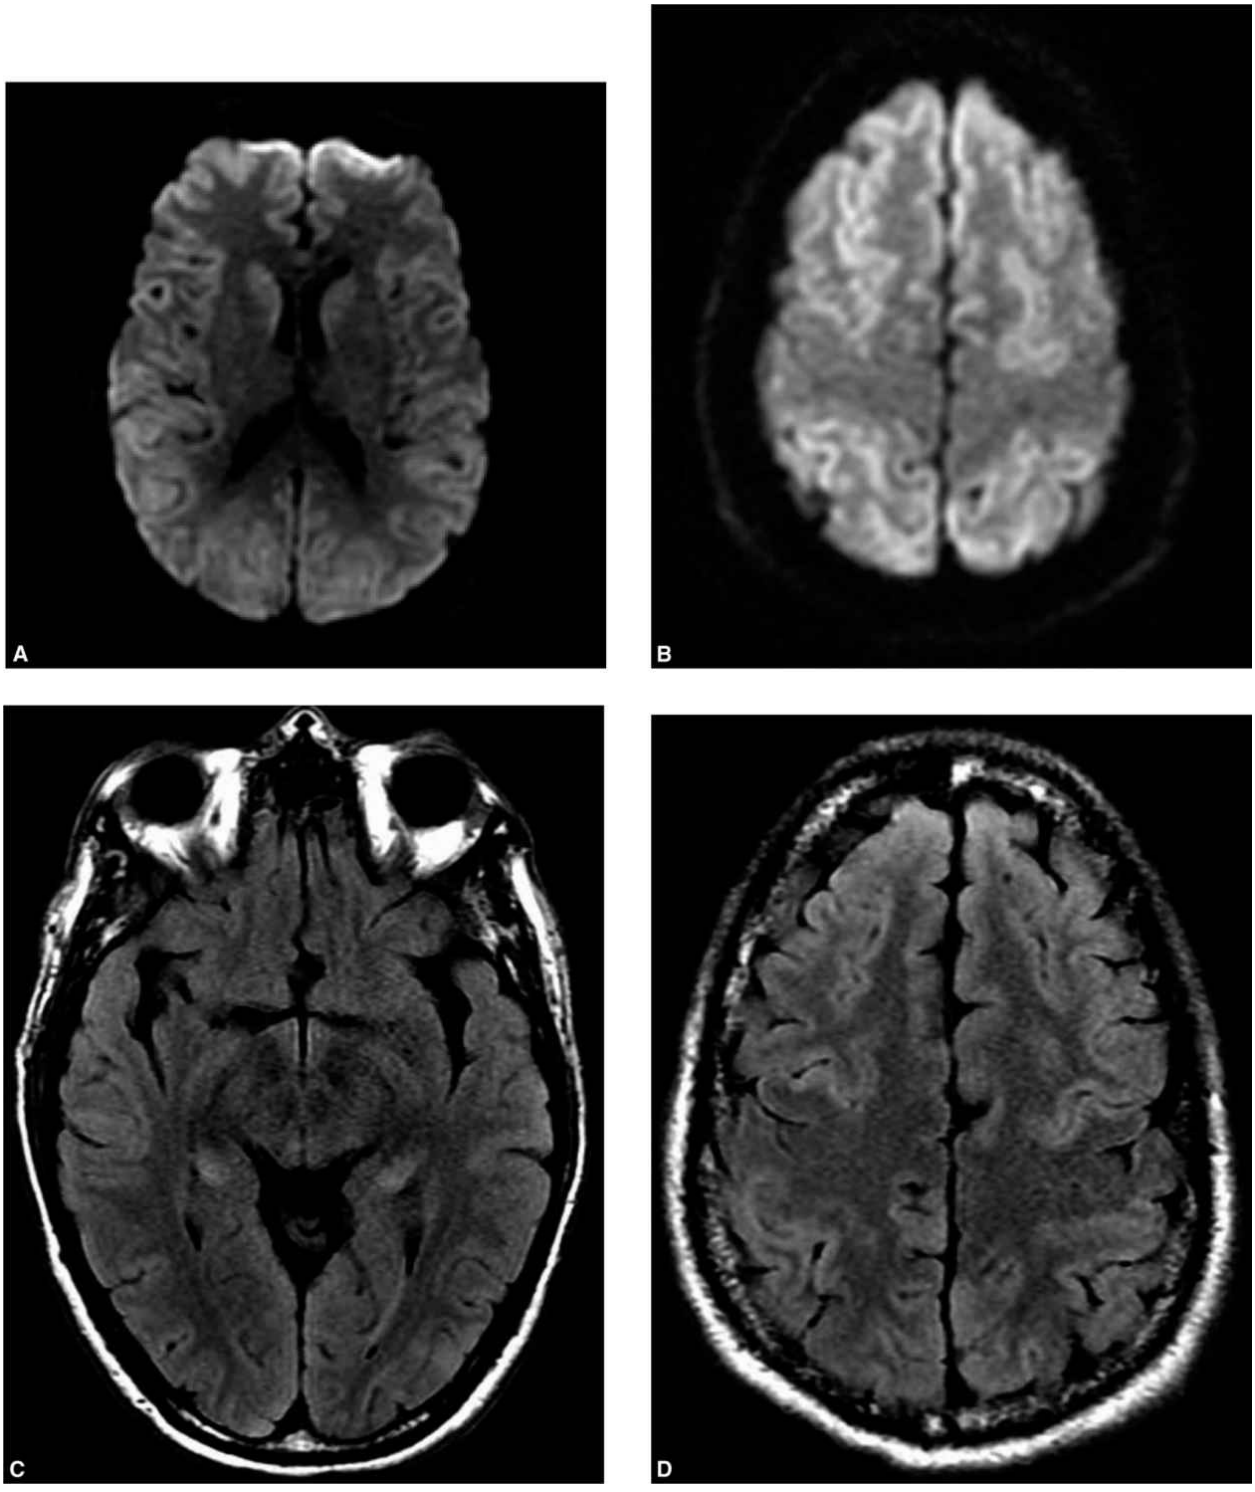

FIGURE 46.4 A, B, Axial diffusion-weighted images of the brain in a patient 5 days after an out-of-hospital asystolic cardiac arrest. There is restricted diffusion throughout the cortical ribbon. C, D, Axial FLAIR images of the brain. There is FLAIR signal hyperintensity throughout the cortical ribbon, and especially prominent in the lateral temporal lobes, occipital lobes, and frontal lobes. The total cortex score for this patient was 27, consistent with a poor neurologic prognosis.[5]

Seizures and nonconvulsive status epilepticus are common in the setting of HIE, occurring in approximately 20% of patients. Continuous EEG should be considered for all patients and started as soon as possible on any patient with myoclonus or suspicion for ongoing seizure.

Finally, somatosensory evoked potentials (SSEPs), where available, are a useful prognostic tool. Traditionally, absence of the N20 cortical responses bilaterally after median nerve stimulation prognosticates a poor neurologic outcome with a 0% false negative rate. The lack of bilateral cortical SSEP responses in patients after hypothermia continues to be highly predictive of a poor neurologic outcome. SSEPs can be performed as soon as 24 hours after cardiac arrest.[6]

TREATMENT

The only therapy shown to improve mortality and neurologic outcomes for patients with coma after cardiac arrest is targeted temperature management (TTM; hypothermia). The landmark hypothermia trials were published in the New England Journal of Medicine in 2002.[7] These studies evaluated patients after out-of-hospital ventricular fibrillation or ventricular tachycardia cardiac arrest. Hypothermia at a depth of 32°C to 34°C was started post arrest and maintained for 12 to 24 hours. The hypothermia group had a 20% absolute increase in survival and good neurologic outcome. However, in these studies, the patients in the standard therapy arm had fever to approximately 38°C. In 2013, the TTM study[8] demonstrated no differences in mortality or neurologic outcomes with the temperatures post cardiac arrest actively controlled at either 33°C or 36°C. The American Heart Association guidelines[9] now recommend using TTM for all cardiac arrest patients with coma after ROSC, at a constant temperature goal chosen between 32°C and 36°C, and maintained for at least 24 hours.

Only core temperatures should be used during hypothermia or TTM. Rectal, bladder (urinary catheter), or esophageal probes provide reliable and continuous temperature measurement. Temperature can be controlled in many ways. Simple methods include ice packs to the groin, axilla, and around the neck; rapid infusions of 4°C cold saline (useful for induction); cooling blankets; and fans. Most temperature-regulating technologies use feedback mechanisms that continuously measure the body’s core temperature and automatically adjust the amount of cooling by the device to maintain a consistent body temperature.

Examples include body-wrapping pads through which cold water circulates to cool the skin, central venous catheters through which cold water circulates in a closed loop and cools the surrounding venous blood as it passes, and esophageal probes with internally circulating cold water that cools the core via surrounding soft tissues.

There are no randomized controlled trial data on blood pressure management. Hypotension can worsen cerebral perfusion and observational data suggests worse outcomes with hypotension. Significant hypertension could be associated with cerebral edema if cerebral autoregulation is impaired. Overall, hypotension should be aggressively treated to maintain systolic blood pressure ≥90 mm Hg and mean arterial pressure ≥65–80 mm Hg.[9]

Any patient with suspicion for seizure should be treated with a stable continuous infusion of benzodiazepines (such as midazolam at a starting dose of 0.05 to 0.1 mg/kg/h) or propofol, and an EEG ordered as soon as feasible. Until the EEG interpretation is obtained, the goal of treatment should be suppression of the abnormal movements, including subtler movements such as nystagmus or eye or facial twitching. Whether or not to start a nonsedating antiepileptic drug such as levetiracetam, phenytoin, or valproic acid depends on the clinical suspicion for seizure and/or nonconvulsive status epilepticus as a cause for the abnormal movements. Seizure-like activity at ictus of the cardiac arrest is not necessarily indicative of ongoing seizure activity or of primary seizure as the cause of the arrest; it can occur due to cerebral ischemia during the no-flow or low-flow period.

Prognosis in Hypoxic Ischemic Encephalopathy

Prognostication of neurologic outcome is based on a collection of physical examination findings and diagnostic tests. In the prehypothermia era, and today in patients who have not received hypothermia, the physical examination can be used to guide prognosis between 24 and 72 hours. Patients who have received hypothermia may continue to have an improving motor response for up to 7 days post arrest. The reason may be related to increase in sedation given during the hypothermia protocol, slowed metabolism of sedation during hypothermia, and actual delay in the recovery of the brain due to slowed metabolic processes during hypothermia.

In patients who did not receive hypothermia, any one of the following findings traditionally predicts poor neurologic prognosis: lack of pupillary responses at days 1 to 3 post arrest, lack of corneal reflexes at days 1 to 3 post

arrest, NSE > 33 μg/L, lack of bilateral cortical responses on SSEPs on day 1 or later, myoclonic status epilepticus, or no motor response better than extension posturing at 3 days post arrest. The lack of these findings does not ensure a good prognosis but makes the prognosis indeterminate. A poor prognosis is defined as one of severe neurologic disability, where the patient has limited understanding or consciousness and requires long-term, full nursing care.[10]

In patients who did receive hypothermia, at least 7 days should be given for the motor examination to be used in prognostication.[6] The motor response in the neurologic examination is done without sedation or paralytics and is best described in terms of the Glasgow Coma Score. The arm movements are more reliable than the leg movements, as triple flexion in the legs can mimic withdrawal. The possible arm motor responses are as follows:

- No response/no movement;
- Extensor posturing (internal rotation of the arms with extension at the elbow, pronation of the forearm, and adduction at the shoulder, and may include extension and internal rotation of the legs simultaneously);
- Flexor posturing (a stereotyped movement of flexion at the elbows, wrists, and fingers, and may include extension and internal rotation of the legs simultaneously);
- Withdrawal (purposeful pulling away from noxious stimuli in a nonstereotyped manner);
- Localizing (reaching to a noxious stimuli at or across the midline, ie to take the examiner’s hand away from a sternal rub or endotracheal suctioning);
- Following commands.

A poor neurologic prognosis can be expected if the motor response is not better than extension 7 days post cardiac arrest. Take care not to attribute purposeful intent to stereotyped movements, because this may confuse both the care team and the family, and lead to additional difficulty with discussions regarding prognosis. As patients emerge from coma, movements are often small and difficult to classify. One approach is to undercall the examination so as not to build up false hope (in other words, if the movement is so small that one cannot distinguish between flexion posturing and withdrawal, call it flexion posturing initially). Serial neurologic examinations unobscured by sedation and tincture of time will clarify the true examination. The statement that any patient who has been comatose is now following commands should be taken with the

utmost seriousness; following commands implies that there is a clear and reproducible motor response to a verbal command. Generally, squeezing hands should be avoided as a command to follow due to potential confusion from a grasp reflex. Useful verbal commands for examining intubated and previously comatose patients include, “Close your eyes” followed by “Open your eyes,” “Stick out your tongue,” “Hold up two fingers,” “Hold up your thumb,” or “Wiggle your toes.”

Continuous EEG and noncontrast brain MRI are two modalities of current interest to assist in prognostication. EEG patterns associated with poor neurologic outcomes after cardiac arrest include spontaneous burst suppression, status epilepticus, and an EEG without change in the background to alerting maneuvers (also known as a “nonreactive” EEG background). MRI was previously discussed in this chapter.

Some patients will progress to brain death due to the severity of the initial hypoxic ischemic injury or from herniation due to cerebral edema. Clues that the patient may have progressed or be progressing to brain death include poikilothermia and diabetes insipidus (DI). Consider DI if the urine output is greater than 300 mL/h for more than 2 consecutive hours, or with high volume urine output with hypernatremia. It is important to continue aggressive critical care and maintain metabolic homeostasis as a brain-dead patient may be an organ donor candidate. Blood pressure should be supported, generally targeting a mean arterial pressure of 65 mm Hg or greater, using fluids or pressors as needed. If there is a high volume of urine output, consider desmopressin acetate IV or vasopressin infusion, titrating to a urine output of 75 to 150 mL/h. The goal is euvolemia. Hypernatremia should be corrected with half-normal saline or D5W, as appropriate. Warming blankets may be needed. Antibiotics for intercurrent infections should be continued.

ACUTE ISCHEMIC STROKE

Acute ischemic stroke can occur in patients already admitted to the CCU from a number of causes: atrial fibrillation, systolic heart failure with left ventricular thrombus, endocarditis, prosthetic cardiac valves, aortic dissection, ventricular assist devices, or postcardiac catheterization. Patients admitted to the CCU often have comorbid conditions that predispose them to stroke, such as diabetes, hypertension, hyperlipidemia, and atrial fibrillation. Other risk factors for in-

hospital strokes are vascular procedures or endovascular procedures (such as cardiac catheterization), active cancer causing hypercoagulable state, or withholding of anticoagulation.

RECOGNITION OF ACUTE ISCHEMIC STROKE

With in-hospital stroke, one major barrier to timely acute treatment is recognition by the staff of an acute stroke in the patient. Time to intravenous tissue plasminogen activator (IV tPA), the medical "clot-busting" therapy for acute stroke, with in-hospital patients has been shown to be significantly longer than for those patients admitted with acute ischemic stroke through the emergency room.[11] Reasons for this delay include lack of understanding regarding the urgency of the situation, personnel and treating teams not familiar with the protocol because it is not a part of their routine practice, retrieval of tPA itself from the inpatient pharmacy, and increased transport time to CT.

First, determine that the patient clinically seems to be having a stroke. Vital signs should be checked with particular attention to blood pressure; hypertension of greater than 185/110 mm Hg should be immediately treated with a short-acting intravenous medication to a goal of < 185/110 mm Hg. A fingerstick glucose should be obtained to rule out hypoglycemia or hyperglycemia as the cause for the neurologic deficit. Hypoxia with an oxygen saturation < 94% should be treated with supplemental oxygen. Labs should be drawn and sent stat for chemistry, complete blood count (CBC), prothrombin time (PT)/international normalized ratio (INR), partial thromboplastin time (PTT). A brief neurologic examination, often the National Institutes of Health Stroke Scale (NIHSS, **Table 46.5**), is then performed to define presence and extent of deficits. Always score what the patient *actually* does, not what you *think* they can do. An NIHSS ≥ 8 has a strong predictive value for LVO, which may be amenable to endovascular therapy.

TABLE 46.5 A Summary of the National Institutes of Health Stroke Scale (NIHSS)

ITEM	POINTS ON NIHSS			
1: Level of consciousness				
1A: Alertness	0—alert	1—not alert, arousable by minor	2—not alert, repeated stimulation to attend, or	3—only reflexive movements, or completely unresponsive

		stimuli	obtunded		
1B: Month and age	0—both questions correct	1—one correct	2—none correct		
1C: Simple commands: open and close eyes, make a fist and release	0—does both correctly, or mimics both correctly	1—follows one command	2—no commands		
2: Best gaze—look to both sides	0—normal	1—partial gaze palsy	2—forced deviation		
3: Visual fields	0—normal	1—partial hemianopia or extinction	2—complete hemianopia	3—blind	
4: Facial palsy	0—normal	1—minor paralysis	2—partial paralysis (upper motor neuron facial weakness pattern)	3—complete paralysis (lower motor neuron facial weakness pattern) on one or both sides	
5: Motor arm 5A: left 5B: right	0—no drift	1—drifts down in 10 s but does not hit bed	2—drifts down and hits bed within 10 s	3—no effort against gravity	4—no movement
6: Motor leg 6A: left 6B: right	0—no drift	1—drifts down in 5 s but does not hit bed	2—drifts down and hits bed within 5 s	3—no effort against gravity	4—no movement
7: Ataxia	0—absent	1—one limb	2—two limbs		
8: Sensory (pinprick testing)	0—normal	1—some sensory loss	2—severe or total sensory loss		
9: Language	0—normal	1—mild to moderate aphasia	2—severe aphasia	3—global aphasia or mute	
10: Dysarthria	0—normal	1—mild to moderate	2—severe or mute		
11: Extinction and Inattention: sensory or visual extinction	0—normal	1—extinction or inattention in 1 modality	2—profound hemi-inattention or deficits in more than 1 modality		

In order to determine if the patient is a candidate for IV tPA, the last known normal time must be clearly defined. This may be different from the time of discovery. For example, if the patient went to sleep and woke up with a hemiplegia, then the last known normal time is the time of sleep onset. IV tPA may be given in ischemic strokes where the last known normal time is within 3 hours,[12] or within 4.5 hours with additional contraindications.[13]

INITIAL WORKUP AND TREATMENT

After establishing that there is a new neurologic deficit, checking vital signs and glucose, and drawing appropriate labs, the patient should be taken emergently for a noncontrasted CT of the brain and a CTA of the head and neck (**Figures 46.5 and 46.6**). A CTA of the head and neck should be done with any patient with a NIHSS ≥ 8 or cortical signs or symptoms. In the setting of an acute stroke, CTA (which uses iodinated contrast) can and should be performed without regard to the patient's creatinine, because studies have shown the risk of acute kidney injury due to contrast in this setting to be small, and in some studies, no different than patients who did not receive a CTA.[14] A neurologist or neuroradiologist should immediately review and interpret the noncontrast head CT for contraindications for IV tPA therapy, and the CTA of the head and neck for indications that intraarterial (IA) therapy is indicated (mainly LVO).

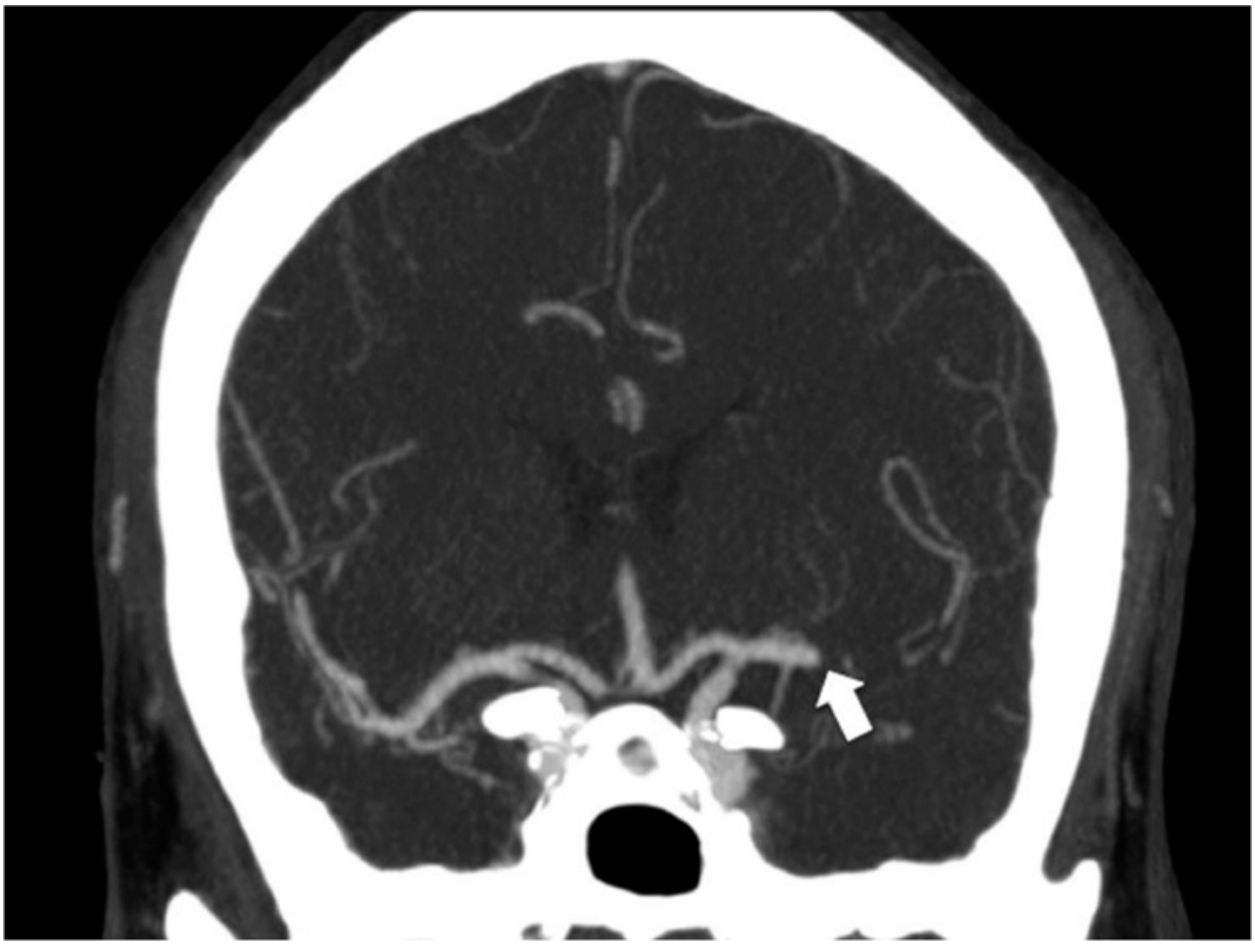

FIGURE 46.5 Coronal image of CTA of the head demonstrating an M1 segment occlusion of the left middle cerebral artery caused by thromboembolism. This type of lesion may be amenable to endovascular therapy. CTA, computed tomography angiogram

For patients with an acute ischemic stroke who qualify for IV tPA (**Tables 46.6 and 46.7**), it should be given as soon as possible, because there is an inverse relationship between benefit from tPA and time to administration. IV tPA is given at a dose of 0.9 mg/kg, with a maximum dose of 90 mg.[13] The first 10% is given as an IV bolus over 1 minute, and the additional 90% as an infusion over 1 hour. Blood pressure should be closely monitored and maintained at less than 185/110 mm Hg during the infusion. Neurologic checks should be performed to look for significant improvement or worsening. If the patient worsens during or after the infusion, any remaining tPA should be held and a stat noncontrast head CT obtained to rule out intracranial hemorrhage. Once tPA is given, generally no antiplatelet or anticoagulant therapy should be used for 24 hours. Blood pressures are maintained at less than 180/105 mm Hg. All patients are made nothing per oral at the time of an acute stroke, until they have a bedside swallow

evaluation or a formal speech therapy evaluation.

TABLE 46.6 IV tPA Inclusion Criteria

Acute ischemic stroke causing new significant neurologic deficits
Time within 3–4.5 hours of onset (last known normal time)
Blood pressure < 185/110 mm Hg

IV tPA, intravenous tissue plasminogen activator.

TABLE 46.7 Contraindications for IV tPA

CONTRAINDICATIONS FOR IV TPA WITHIN 3 H OF ONSET	ADDITIONAL CONTRAINDICATIONS FOR IV TPA WITHIN 3–4.5 H OF ONSET
Intracranial hemorrhage on noncontrast CT[a]	
CT with well-established acute or subacute infarctM[a]	
CT showing infarct greater than 1/3 the size of the MCA territory[a]	
Active bleeding or major acute trauma[a]	
Resolved neurologic symptoms[a]	
Rapidly improving neurologic symptoms	
Minor or nondisabling neurologic symptoms	
Suspected subarachnoid hemorrhage[a]	
Major head trauma or stroke within the last 3 mo	Age > 80 y
Myocardial infarction in the last 3 mo	Anticoagulant use, regardless of INR
Genitourinary or gastrointestinal hemorrhage in the last 21 d	NIHSS ≤ 25
Major surgery in the last 14 d	History of both previous stroke and diabetes
Arterial puncture at a noncompressible site or lumbar puncture in the last 7 d	
History of previous ICH	
If on oral anticoagulants, INR > 1.7	
If on heparin in the last 48 h, elevated PTT	
Receiving DOACs within 24–48 h	
Platelets < 100,000	
Blood glucose < 50 mg/dL	
Seizure at symptom onset	

[a]Absolute contraindications. CT, computed tomography; ICH, intracerebral hemorrhage; IV tPA, intravenous tissue plasminogen activator; INR, international normalized ratio; NIHSS, National Institutes of Health Strokes Scale. MCA, middle cerebral artery; DOACs, direct oral anticoagulants.

There has been a recent revolution in acute stroke treatment, as multiple randomized controlled trials published in the last 2 years have definitively proven the benefit of IA clot extraction techniques for acute strokes caused by LVOs. Pooled analysis of the six trials showed that good outcomes at 90 days increased in the intervention arm from 26% to 47% and mortality decreased from 18% to 8%.[15] Endovascular or IA therapy, combined with IV tPA when appropriate, is definitively superior to IV tPA alone for ischemic strokes due to

LVO. The fastest and least invasive way to diagnose an LVO is with a CTA of the head and neck (**Figures 46.5 and 46.6**). For this reason, all patients with suspected acute stroke should get a CTA of the head and neck at the time of the initial noncontrast head CT.

B

A

C

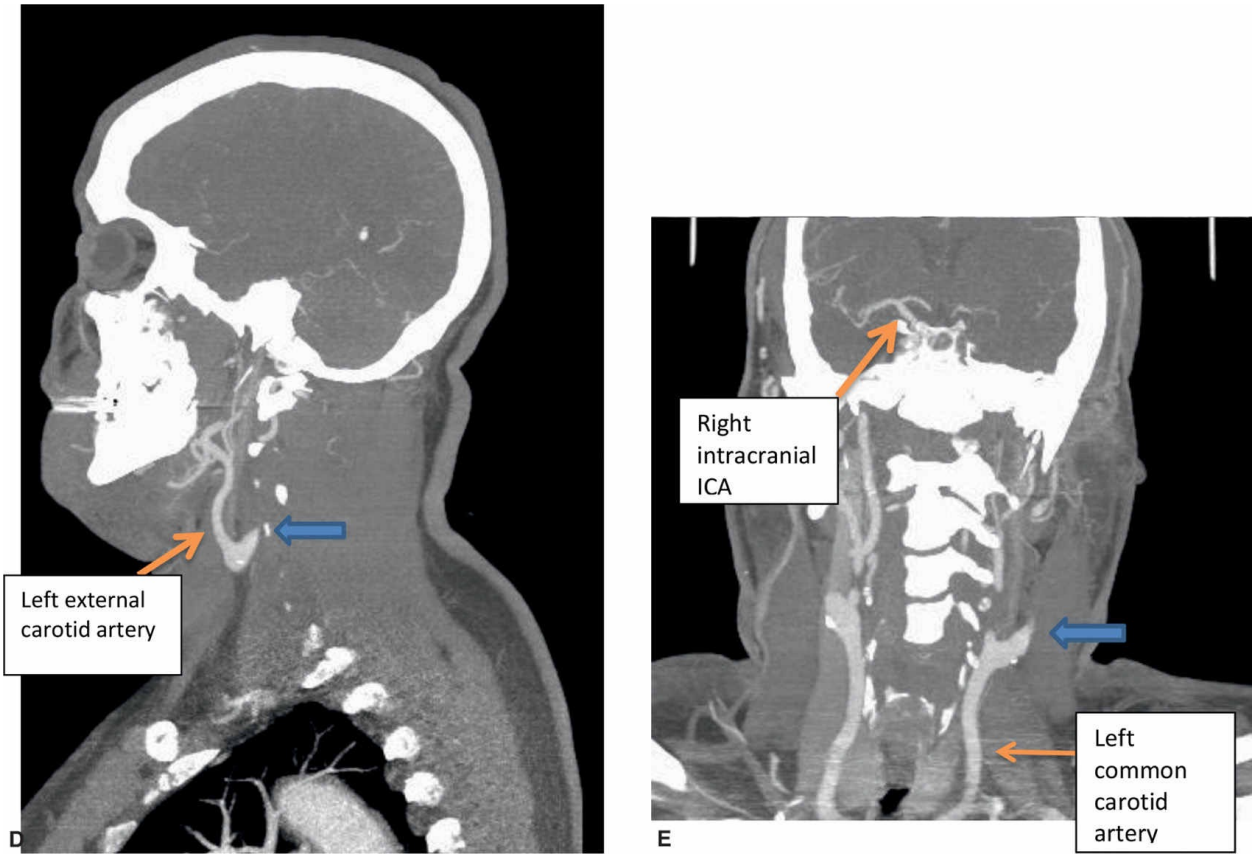

FIGURE 46.6 A-C, Initial, normal, non-contrasted head CT in a patient with an acute left internal carotid artery occlusion leading to a left middle cerebral artery syndrome (aphasia and right hemiplegia). The images were obtained 49 minutes after the onset of symptoms. D-E, MIPs from the CTA of the head and neck. Panel D is a sagittal MIP image at the level of the left internal carotid artery. There is no flow distally in the left internal carotid artery after this flame-shaped cutoff (large blue arrow). Panel E is a coronal MIP image showing occlusion of the cervical left internal carotid artery and the subsequent lack of opacification of the intracranial left internal carotid artery, middle cerebral artery, and anterior cerebral artery. The few vessels visualized in the left hemisphere appear to have been collateral flow from the anterior communicating artery or from meningeal collaterals. The patient was given IV tPA 153 minutes after the onset of symptoms. He underwent emergent revascularization of the left internal carotid and middle cerebral arteries. His initial NIHSS was 20; it improved to 5 by acute hospital discharge.

For most patients with acute stroke, 162 to 325 mg of aspirin is appropriate secondary stroke prevention in the acute setting. Aspirin can be started immediately if the patient is not an IV tPA candidate; it may be given per rectum or via nasogastric tube if the patient has dysphagia. Some patients will have indications for anticoagulation for secondary stroke prevention, the most common being atrial fibrillation. When the cohort of all ischemic stroke patients is analyzed, no benefit of IV heparin is seen acutely because the risk of serious harmful effects such as intracranial hemorrhage equals the benefit of additional decrease in thromboembolic events. Instead, patients who have an indication for

anticoagulation will often be bridged to warfarin with aspirin, or the initiation of new oral anticoagulants (NOACs) delayed until safe. The timing of anticoagulation initiation is an art dependent upon the size of the stroke, any hemorrhagic transformation, and the indication for anticoagulation. High dose statins should be used for all patients with low density lipoprotein (LDL) >100, unless a clear contraindications exists. Chemical deep vein thrombosis prophylaxis can be started 24 hours after tPA, or on admission if the patient did not receive tPA. Further workup and treatment of any particular stroke is beyond the scope of this chapter.

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage is classified based on the hemorrhage's location in relationship to the brain parenchyma: epidural hemorrhage is between the dura and inner table of the skull, subdural hemorrhage (SDH) is beneath the dura and above the arachnoid mater, subarachnoid hemorrhage is between the arachnoid mater and the pia mater, and intracerebral hemorrhage (ICH) is within the substance of the brain. In the absence of trauma, the common use of anticoagulants in the CCU predisposes patients to SDH or ICH.

ICH presents in a similar manner to acute ischemic stroke, with focal neurologic deficits. Headache is a common prominent symptom. If the hemorrhage is large and causing intracranial hypertension or intraventricular hemorrhage with hydrocephalus, there may also be hypertension, lethargy, nausea, or vomiting. The diagnosis of ICH is made by noncontrast head CT (**Figures 46.7 and 46.8**), where acute blood is hyperdense and seen inside the brain parenchyma. A CTA of the head and neck may still be appropriate in the initial workup, depending on the size, location, and clinical characteristics of the patient, to look for an underlying vascular malformation or the presence of a "spot sign," which can predict early hemorrhage expansion.

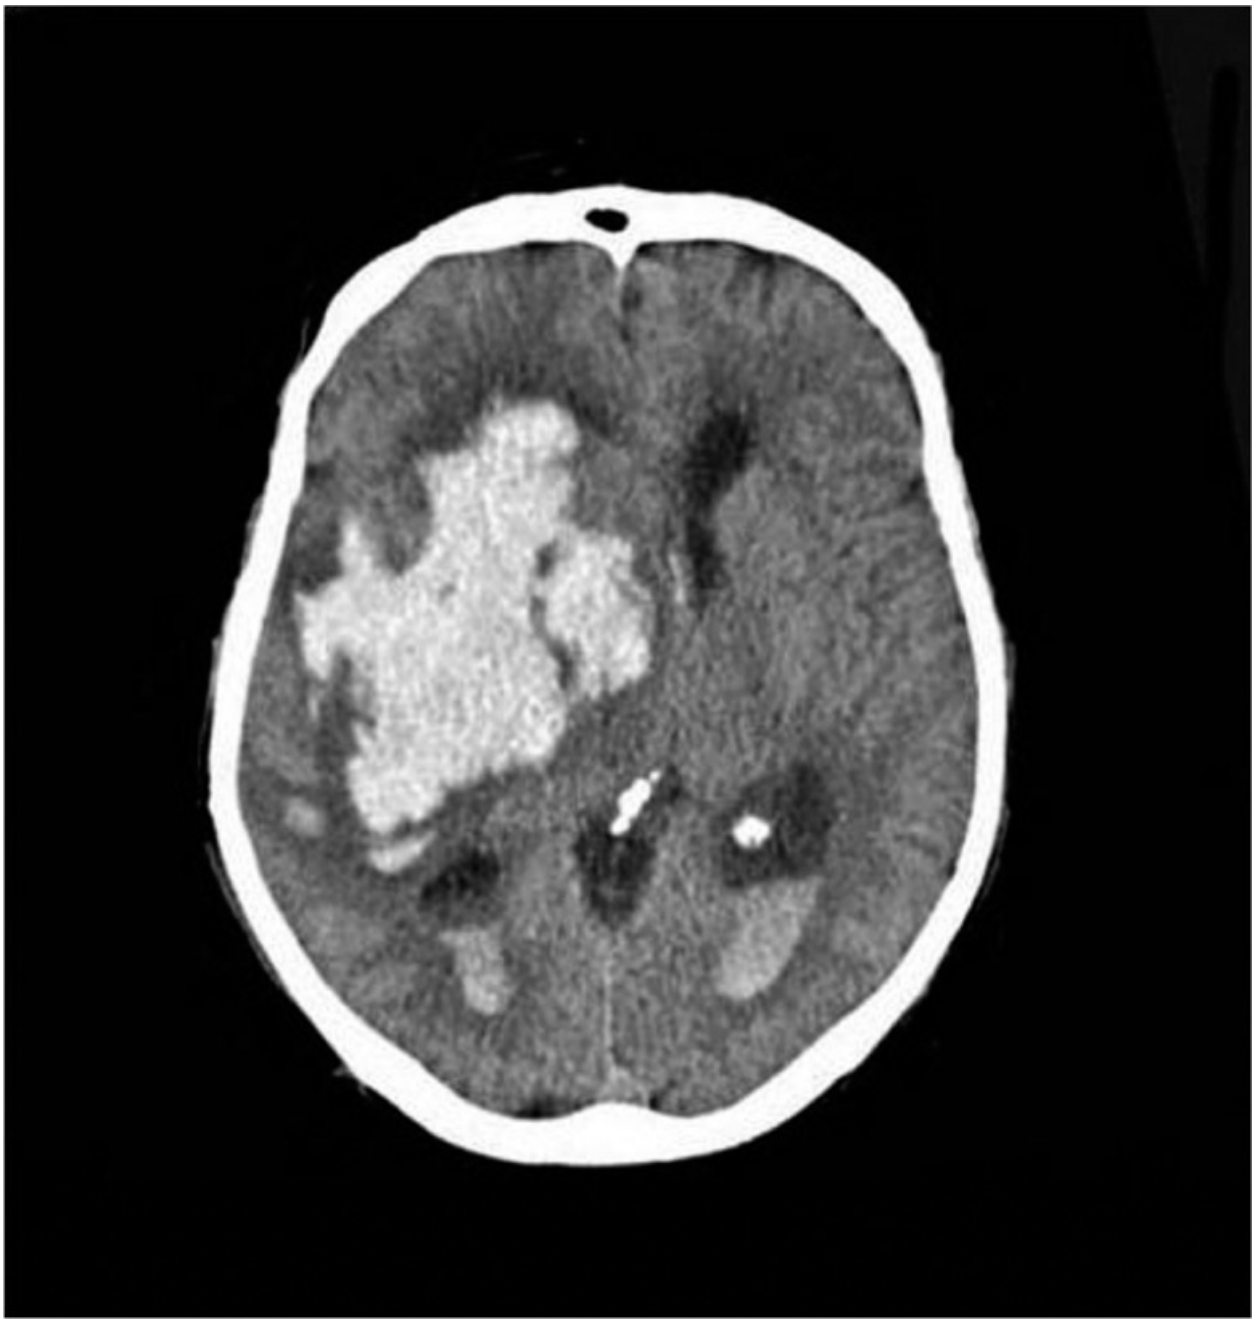

FIGURE 46.7 Large right basal ganglia intracerebral hemorrhage with intraventricular extension, hydrocephalus, and midline shift.

FIGURE 46.8 This axial noncontrasted head CT shows an acute right frontal intracerebral hemorrhage. CTA of the head was negative for any vascular pathology. The patient had uncontrolled hypertension and aspirin use as risk factors. He presented with acute left flaccid hemiplegia. CTA, computed tomography angiogram.

Initial workup and treatment for ICH parallels that of acute ischemic stroke.

Always remember to first evaluate the ABCs - airway, breathing, and circulation. A common cause of intubation in patients with acute neurologic injury is obtundation and inability to adequately maintain a patent airway and ventilation. Vital signs should be monitored every 5 to 15 minutes acutely, and once the patient is stabilized every 1 hour or as per ICU protocol. Generally in ICH, targeting the systolic blood pressure (SBP) to less than 140 mm Hg is thought to be safe and may improve functional outcomes.[16] Glucose should be normalized.

As in acute ischemic stroke, when the patient is being initially assessed, laboratory studies should be sent stat for chemistry, CBC, PT, and PTT. An arterial blood gas is indicated if the patient is obtunded or was recently intubated. Hypercarbia and hypoxia can exacerbate intracranial hypertension and so should be aggressively corrected.

The size and morphology of any intracranial hemorrhage is evaluated by noncontrast CT scan of the brain. For subdural hematomas, measure the maximum width of the hematoma, as well as any midline shift. For intraparenchymal hematomas, the size of the hemorrhage can be calculated by using measurements from the CT scan, using the ABC/2 formula:

$$\text{Volume of intraparenchymal hematoma (in cm}^3\text{ or mL)} = A \times B \times C/2$$

where A = maximum hematoma width in cm; B = maximum hematoma length perpendicular to A in cm; C = height in cm (number of [0.5 cm] CT cuts the hemorrhage is seen on)/2

Hematoma volume is directly related to outcome. Look for intraventricular hemorrhage, midline shift, uncal herniation, or crowding of the basal cisterns because these can cause rapid neurologic deterioration requiring life-saving interventions such as external ventricular drains (EVDs), emergency hematoma evacuation, or hyperosmotic therapy. The ICH score (**Table 46.8**) is a useful prognostic tool that may help in medical decision making.[17]

TABLE 46.8 The ICH Score

	POINTS
Glasgow Coma Score: 13–15 5–12 3–4	0 1 2
ICH volume: < 30 mL ≥ 30 mL	0 1

IVH: no Yes	0 1
Infratentorial location: no Yes	0 1
Age: < 80 y ≥ 80 y	0 1

The ICH score predicts historic mortality in ICH.
0 = 0%, 1 = 13%, 2 = 26%, 3 = 72%, 4 = 97%, 5 = 100%.
ICH, intracerebral hemorrhage; IVH, intraventricular hemorrhage.

TREATMENT OF INTRACRANIAL HEMORRHAGE

Reversal of Coagulopathies

The most common coagulopathies in the CCU are from medications. Medications that can cause or contribute to pathologic bleeding include heparin, low-molecular-weight heparins such as enoxaparin, warfarin, NOACs, aspirin, and other antiplatelet agents. Other causes of coagulopathy should also be considered, such as uremia and failure of synthetic liver function. We now review the reversal of common medication-induced coagulopathies[18] (**Table 46.9**).

TABLE 46.9 Anticoagulants and Their Reversal Agents

Heparin	Protamine Maximum dose 50 mg, maximum infusion rate 5 mg/min Based on the units of heparin in the previous 2 to 3 h Time since heparin: 0 to 30 min: 1 mg protamine IV/100 units heparin 31 to 60 min: 0.75 mg protamine/100 units heparin 61 to 120 min: 0.5 mg protamine/100 units heparin >120 min: 0.4 mg protamine/100 units heparin	Immediate reversal Monitor for anaphylaxis, hypotension
Low-molecular-weight heparins	Protamine Time since enoxaparin: Less than 8 h: 1 mg protamine per 1 mg enoxaparin Greater than 8 h: 0.5 mg protamine per 1 mg enoxaparin Dalteparin: 1 mg protamine per each 100 units of dalteparin	Reverses 60%–75%
Warfarin	Vitamin K 10 mg IV PCCs OR fresh frozen plasma	May need repeated doses over hours to days
Dabigatran (Pradaxa)	Idarucizumab (Praxbind) 5 mg IV	
	PCC 50 IU/kg (Pending FDA Approval)	

Factor Xa inhibitors Rivaroxaban (Xarelto) Apixaban (Eliquis)	Andexanet IV bolus over 15–30 min, then 2 h infusion If factor Xa inhibitor taken > 7 h ago: 400 mg bolus, 480 mg infusion If factor Xa inhibitor taken ≤ 7 h ago, or unknown: 800 mg bolus, 960 mg infusion	Andexanet is pending FDA approval.
Antiplatelet agents	DDAVP 0.3 μg/kg IV once Platelet transfusion (one apheresis unit) only if neurosurgical intervention	

IV, intravenous; FDA, US food and drug administration; PCC, prothrombin complex concentrates.

Heparin is used for a wide variety of indications in the CCU, including acute myocardial infarction, stroke prevention in atrial fibrillation, deep vein thrombosis, and left ventricular thrombus. If a patient has sudden focal neurologic deficits, any anticoagulant drip or medication should be held and a stat PT/PTT drawn. A noncontrast head CT should be obtained emergently. If an ischemic stroke without hemorrhagic transformation is discovered, no emergency reversal is necessary: whether to continue heparin would be based on a patient's specific case. If the patient has an intracranial hemorrhage and the PTT is elevated from heparin, then protamine should be given. Protamine dosing is based on the amount of heparin given and the time since the last administration of heparin. Patients are monitored for hypotension or anaphylaxis, and epinephrine should be available. Low molecular weight heparins can be reversed 60% to 75% with protamine. The factor Xa inhibitor reversal agent (andexanet alfa) being developed may play a future role in reversal of low-molecular-weight heparins.

Patients receiving warfarin and with an elevated INR should be immediately reversed, because hematoma expansion can continue for up to 72 hours in patients with vitamin K antagonist use. There are three steps to reversal of warfarin: discontinuation of warfarin, administration of vitamin K, and immediate replacement of coagulation factors with prothrombin complex concentrates (PCCs) or fresh frozen plasma (FFP). Vitamin K should be given at a dose of 10 mg IV over 10 minutes. PCCs have come into favor over FFP for immediate coagulation factor replacement. PCCs have either three factors (II, IX, and X) or four factors (II, VII, IX, and X). The United States has three brands approved by the FDA: Bebulin, Profilnine SD, and Kcentra. PCCs have the following advantages over FFP: takes no time to thaw, short preparation time, significantly lower infusion volume, rapid INR reversal, and lower risk infection. Dosing is based on both body weight and INR (**Table 46.10**). The

PT/INR should be repeated 1 hour after the PCC dosing, and if it remains elevated, then PCC can be redosed. If PCC is not available, then FFP may be given at a dose of 15 mL/kg IV. Recombinant factor VIIa had previously been used and studied for the reversal of warfarin-associated coagulopathy, but it only replaces one of the factors depleted by warfarin use. With the approval of 4-factor PCC/Kcentra in the United States and high rate of thromboembolism, recombinant factor VIIa has fallen out of favor.[19]

TABLE 46.10 4-Factor Prothrombin Complex Concentrate (Kcentra) Dosing

PRETREATMENT INR	DOSE (units/kg)	MAXIMUM DOSE (units)
2–4	25	2500
4–6	35	3500
>6	50	5000

INR, international normalized ratio.

The only new oral anticoagulant agent currently with an antidote is the direct thrombin inhibitor dabigatran (Pradaxa). Idarucizumab (Praxbind) is a monoclonal antibody fragment that specifically binds dabigatran. A total of 5 mg IV is given in two doses of 2.5 mg IV no more than 15 minutes apart. Idarucizumab quickly and completely reverses the effects of dabigatran.[20] If dabigatran was taken in the preceding 2 hours, also give 50 g activated charcoal.

The oral factor Xa inhibitors currently approved by FDA in the United States and in common use are rivaroxaban (Xarelto) and apixaban (Eliquis). Andexanet alfa was developed as an antidote to the factor Xa inhibitors, and is currently pending FDA approval. With major bleeding, good or excellent clinical hemostasis is achieved in approximately 80% of patients. It should be noted that there is an 18% rate of thrombotic events at 30 days with patients who received the drug.[21] Until andexanet alfa is available, PCCs at a dose of 50 U/kg should be strongly considered because this reverses laboratory abnormalities from rivaroxaban in nonbleeding humans.[22] If a direct factor Xa inhibitor was ingested in the preceding 2 hours, then 50 g of activated charcoal should be given.

Finally, many patients in the CCU are on antiplatelet agents. Traditionally, patients on aspirin, clopidogrel, or other antiplatelet agents were given DDAVP

0.3 μg/kg IV once (maximum dose of 20 μg) and transfused with platelets, despite lack of evidence supporting transfusion. A recent randomized trial showed that platelet transfusion in the setting of spontaneous ICH was potentially harmful, with the group receiving platelets having a statistically significant higher rate of disability than the group who did not receive platelets, and a trend toward higher mortality.[23] This study excluded patients who required neurosurgical intervention. One randomized study of patients undergoing craniectomy for hematoma evacuation after ICH showed a benefit of platelet transfusion in postoperative hemorrhage rate and volume, and in mortality, in those patients who showed aspirin-sensitivity on a platelet aggregation test.[24] Patients with thrombocytopenia and intracranial hemorrhage should be transfused platelets for a goal of greater than 70,000.

An excellent and complete review of reversal of all antithrombotic agents in the setting of intracranial hemorrhage was published in Neurocritical Care in 2016.[18]

Blood Pressure Control

Uncontrolled hypertension is a risk factor for ICH itself and for greater hematoma expansion, neurologic deterioration, dependency, and death. Current 2015 American Heart Association/American Stroke Association guidelines recommend reducing the SBP to < 140 mm Hg if the initial SBP was 150 to 220 mm Hg. This seems to be a safe target blood pressure, and may improve functional outcomes.[16] If the SBP is higher than 220 mm Hg on presentation, the goal may be adjusted. No particular agent is advantageous, although short-acting and titratable agents such as labetalol, nicardipine, or clevidipine are useful. Nitroprusside should be avoided due to a theoretical risk of increasing intracranial pressure.

Neurosurgical Intervention

Some intracranial hemorrhages may need neurosurgical intervention. Generally, symptomatic acute SDHs with mass effect or shift are evacuated. For ICH, evacuation is considered if the hematoma is large (greater than 30 mL), cortical, cerebellar, or the patient is young. New minimally invasive clot removal techniques have shown great promise, and some have even shown improvement in neurologic outcomes over medical controls. Suboccipital craniectomy is a life-saving procedure with cerebellar hemorrhages that have mass effect onto the

brainstem or cause hydrocephalus. Finally, EVD placement may be needed if the patient has hydrocephalus or is somnolent, as a way to measure and treat intracranial pressure. Ultimately, an expert in neurology, stroke, or neurosurgery should be involved early in the care of patients with ICH to guide treatment, including invasive measures.

Patient and Family Information for: STROKES

WHAT IS A STROKE?

A stroke occurs when there is sudden interruption of blood flow to a specific part of the brain. When this happens, those brain cells do not get enough blood. Blood carries oxygen. All cells need oxygen to live.

TYPES OF STROKE

There are two kinds of strokes: ischemic and hemorrhagic. An ***ischemic stroke*** is a “nonbleeding stroke” that happens when a blood vessel leading to the brain becomes blocked. This keeps the brain cells in that area from receiving blood and oxygen. A ***hemorrhagic stroke*** is a “bleeding stroke” that happens when a blood vessel in or near the brain bursts. The blood is released into the brain itself or into the space between the brain and the skull. The blood then presses on and irritates the surrounding brain and keeps the cells around it from working properly.

SYMPTOMS OF A STROKE

- Sudden numbness or weakness of the face, arm, or leg, especially on one side of the body;
- Sudden confusion, trouble speaking, or trouble understanding;
- Sudden trouble seeing in one or both eyes;
- Sudden trouble walking, dizziness, loss of balance, or loss of coordination;

- Sudden severe headache with no known cause.

If you experience any of these symptoms, **CALL 911 IMMEDIATELY.** Stroke is an emergency. Do not delay. Early treatment may be able to prevent or limit permanent disability or even death.

TESTS

These tests are done to see the location of the stroke and find out its type and cause:

- **CT scan:** This is a type of X ray that takes pictures of your brain. It shows if the stroke is ischemic or hemorrhagic.
- **CTA:** This is a special CT with dye given to light up the blood vessels going to the brain. The purpose is to show a blocked blood vessel that could possibly be opened up to make the stroke better. It can also show other abnormal blood vessels such as those that cause bleeding strokes.
- **MRI:** This test uses a giant magnet instead of X rays to take pictures of the brain. The pictures have more detail than a CT scan. Because the machine is narrow and loud, some patients get nervous and may need medicine to help relax. Patients with permanent pacemakers or implanted defibrillators often cannot have MRIs. Other metal in the body may or may not be safe for MRI. You will fill out a form to see if it is safe for you to have an MRI.
- **Magnetic resonance angiography (MRA):** This takes a picture of the blood vessels with the MRI. An MRA does not usually need dye.
- **Carotid Doppler:** This test uses sound waves (ultrasound) to make pictures of the blood vessels in the front of the neck that go to the brain.
- **Transesophageal echocardiogram (TEE):** For this test, the patient is given some medicine to help relax. The patient then swallows a small tube. The tube uses sound waves to make pictures of the heart and large blood vessels around the heart. This can show if there is a blood clot in the heart, a hole in the heart, or large plaque in the blood vessel just outside the heart. These types of problems can cause a stroke.

MEDICATIONS

Most people who have a stroke need several medicines. These medicines decrease the risk of having another stroke.

- Antiplatelet medications such as aspirin, clopidogrel (Plavix), and dipyridamole with aspirin (Aggrenox) are used to prevent new ischemic strokes in many patients.
- Anticoagulants are blood thinners. These are stronger than the antiplatelet drugs and are used to prevent new ischemic strokes from specific conditions like atrial fibrillation. There are now many anticoagulants, including warfarin (Coumadin), dabigatran (Pradaxa), rivaroxaban (Xarelto), and apixaban (Eliquis). The choice of medicine is based on your body and the specific reason you need blood thinners.
- Statin medications such as simvastatin (Zocor) or atorvastatin (Lipitor) lower the cholesterol level. They can help cholesterol plaques to become smaller and smoother. This makes the plaque less likely to cause a stroke.
- Keeping a normal blood pressure with blood pressure medicines helps to prevent new strokes.

REHABILITATION

Patients usually need rehabilitation after a stroke. Rehabilitation or “rehab” involves physical therapy, occupational therapy, and/or speech therapy. There are several types of rehabilitation programs.

- **Acute rehabilitation:** This is an intensive inpatient program (in a hospital or rehab center). Every patient must be able to do at least 3 hours per day of therapy. A patient can stay here a few weeks to a few months before returning home.
- **Skilled nursing facility with rehabilitation:** In this type of program, a patient participates in therapy for 1 to 2 hours per day. The patient can stay at this facility for several months. The patient then returns home or goes to a long-term care facility.
- **Outpatient rehabilitation center:** Here, the patient comes from home for therapy. Usually it is about 1 hour of therapy, three times per week. The patient then goes back home.
- **Home rehabilitation:** This is for patients who are unable to go from their

homes to an outpatient rehabilitation center. Therapy is provided in the patient’s home 2 or 3 times per week.

Gastrointestinal Emergencies in the Cardiac Care Unit

INTRODUCTION

Gastrointestinal (GI) consultation for patients in the Cardiac care unit (CCU) is common in modern inpatient medicine. GI bleeding, anemia, abdominal pain, abdominal distention, nausea and vomiting, and abnormal liver function tests all occur in patients with serious cardiac diseases.

Preparation for writing this chapter began with a review of cardiology textbooks, including old texts, plus the modern GI and cardiac literature. There is not a large literature on GI emergencies in the CCU. The older literature that exists largely focuses on surgery and the cardiologist's role. Little information is given about the nature of GI complications themselves, which confounds planning.

This chapter aims to review the general principles of evaluation and management of patients with serious cardiac disease from the GI perspective, as well as the common reasons for GI consultation, using case material from our institution. The impact of anticoagulation and antiplatelet therapies on management are analyzed in detail. The safety of GI procedures in cardiac patients is also discussed.

GENERAL PRINCIPLES

Charles Friedberg captured the essence of the gastroenterologists' and cardiologists' dilemmas in approaching a GI emergency in the CCU in his discussion of surgical procedures on the cardiac patient in his textbook *Diseases of the Heart.*[1] He wrote, "In general, it may be stated that the cogency of the surgical indication is more important than the cardiac status in determining whether an operation should be performed." The first task for the gastroenterologist is to assess the acuity of the presenting problem in relation to the acuity of the cardiac disease. Three examples should suffice.

Case 1: A 78-year-old female presented with 1 day of chest pain. She was found to have a ST-elevation myocardial infarction plus congestive heart failure (CHF). Evaluation revealed multivessel coronary artery disease (CAD) plus a right ventricular thrombus and a pericardial effusion, and she underwent emergency coronary artery bypass graft (CABG). She remained in cardiogenic shock after surgery, requiring multiple pressors, and developed renal failure. GI consultation was requested on postoperative day 10 because of a rapid rise in liver function tests, including hyperbilirubinemia, which was ascribed to shock liver. Absent bowel sounds and diffuse abdominal tenderness were noted on physical examination. Laboratory analysis revealed marked white blood cell (WBC) elevation plus persistent lactic acidosis. Noncontrast imaging studies were nondiagnostic. Because of a strong concern of bowel infarction, flexible sigmoidoscopy was performed and showed disruption of the bowel at the level of the sigmoid colon. Emergency laparotomy was performed and demonstrated infarction of the sigmoid colon and terminal ileum. The patient survived to leave the hospital 1 month later, though with very poor cardiac function.

Case 2: A 73-year-old man was transferred from another institution with hypotension and acute coronary syndrome. Cardiac catheterization revealed triple vessel disease. The patient had a history of ulcerative colitis. An intra-aortic balloon pump was placed to maintain cardiac output. The patient then developed bloody diarrhea without abdominal pain or increase in WBC count. Bowel sounds were audible. GI consultation was requested and the consultant opined that the patient had a flare of colitis rather than intestinal infarction or ischemic disease secondary to low cardiac output. Flexible sigmoidoscopy was performed while continuing ventricular assistance with the intra-aortic balloon pump, a diagnosis of active colitis was made, corticosteroids were given, the

patient responded promptly, and CABG was successfully performed 5 days later. Corticosteroids were tapered relatively rapidly and replaced by other antiinflammatory therapies after surgery to facilitate healing from the thoracotomy.

Case 3: A 60-year-old male presented with an acute coronary syndrome. Cardiac catheterization showed severe stenoses and the patient underwent coronary bypass grafting. He experienced bright red rectal bleeding on the second postoperative day. The bleeding was clinically mild, without hemodynamic changes or a fall in hematocrit. The patient had a history of prostate cancer, which had been treated with radiation. A presumptive diagnosis of radiation proctitis was made, the patient was treated with stool softeners without other evaluation until the day of discharge, when flexible sigmoidoscopy was performed and documented radiation proctitis. Plans for cauterization of the rectal lesions as an outpatient were made.

In the first case, the clinical impression of an abdominal catastrophe with a 100% morality rate, if untreated, mandated the performance of an endoscopic procedure without colonic preparation as well as emergency laparotomy, despite the patient's tenuous hemodynamic state. In the second case, the patient's history and the possible deleterious effect of a serious flare of ulcerative colitis on surgical outcomes also mandated the diagnostic procedure and treatment despite clear signs of hemodynamic instability, while the need to promote postoperative healing led to a more rapid tapering of the corticosteroids than is usually done. In the third case, the blood loss appeared trivial and not immediately threatening and the patient already had undergone cardiac operation; so the GI evaluation could be safely delayed until discharge. In some cases, evaluation can even be done after discharge. In all three cases, management was aided by repeated and effective communication and collaboration between the cardiologists and gastroenterologists.

Management of GI emergencies in the CCU has evolved greatly over the past generation. In the past, noncardiac evaluations and interventions were kept to an absolute minimum. The situation changed, at least from the gastroenterologist's point of view, when a publication in the GI literature more than 20 years ago demonstrated the safety and clinical efficacy of performing endoscopy in the presence of an acute coronary syndrome.[2] A second major development has been the widespread application of anticlotting therapies in cardiac patients, both anticoagulants and antiplatelet agents. This development has brought tremendous benefits in terms of decreasing morbidity and mortality from

thromboses and emboli. However, the therapies increase the risk of hemorrhage, especially in the GI tract.

The risks and benefits of anticlotting therapies follow a U-shaped curve. A greater degree of anticlotting therapy leads to a greater risk of bleeding but a lesser risk of thrombosis/embolism. Conversely, a lower degree of anticlotting therapy leads to a lesser risk of bleeding but a higher risk of thrombosis/embolism. The specific coefficients of increased or decreased risk are not entirely clear, especially with newer, short-acting agents. There are no data at all about combined antiplatelet/anticoagulant use, for example, in a patient with atrial fibrillation and an acute coronary syndrome. However, increased bleeding can be managed promptly by transfusion over the course of several hours, while thrombosis or embolism evolves over a much shorter time frame, which provides an advantage for anticlotting therapies. In addition, endoscopic or radiologic localization of a bleeding lesion may allow direct intervention for example, placing a hemostatic clip on a bleeding vessel or embolizing the bleeding vessel by interventional radiologists, which immediately reduces the risks of bleeding or rebleeding. For these reasons, gastroenterologists must learn to live with iatrogenic bleeding risks for patients in the CCU and those managing such patients must accept the attendant increased need for transfusions and invasive noncardiac therapies.

GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding (GIB) potentially is a life-threatening condition affecting approximately 102 patients per 100,000 hospitalizations, with significant morbidity.[3,4] While the severity of GI hemorrhage varies greatly, anticoagulation or antiplatelet therapies complicate the situation. Around 2% of the world population is said to be on vitamin K antagonist therapy and there is increased use of direct oral anticoagulants (DOACs) inhibiting thrombin or factor Xa in the coagulation cascade.[5] Warfarin-related major hemorrhage (irrespective of the site) is around 1% to 9% per person year, the results for newer DOACs are similar or lower than for warfarin.[6–9] On the other hand, there was an overall incidence of GI bleeding after a percutaneous coronary intervention (PCI) of 1.04% over an 8-year period, with an underlying GI malignancy being a strong predictor of such events.[10]

Although the incidence of major bleeding is low in cardiac patients, several

factors are to be considered when GI bleeding is suspected: (a) the severity of bleeding; (b) antiplatelet therapy/anticoagulation type and its possible reversal; (c) potential sites and types of lesions; and (d) continuation or the timing of reintroduction of anticoagulants with careful and ongoing assessment of thrombotic risk. There are no specific guidelines on when to reverse anticoagulation effects and the optimal time for endoscopy if a lesion is suspected.

SEVERITY OF BLEEDING

Although the Glasgow-Blatchford and Rockall scoring systems, when negative, play a vital role in avoiding endoscopic intervention, the HAS-BLED scoring system attempts to estimate risk of major bleeding in patients with atrial fibrillation who are placed on anticoagulation. HAS-BLED, which includes risk factors of hypertension, abnormal renal or hepatic functional status, stroke, bleeding predilection, labile international normalized ratio (INR), age over 64 years, drugs and alcohol history, was first proposed in 2010, then introduced into guidelines. The risk stratification as low, moderate, and high risk (depending on the scores of 0, 1 to 2, and greater than 2, respectively) has been validated and found to be superior to other scoring systems ($HEMORR_2HAGES$, ATRIA, or CHA_2DS_2-VASc scores). Similarly, CRUSADE score (Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes with Early Implementation of the ACC/AHA Guidelines) has been used to stratify patients who undergo PCI in the setting of ST-elevation and non-ST elevation myocardial infarctions. The stratification is as follows: very low risk with score less than or equal to 20 has a 3.1% risk of major bleeding; low risk with score between 21 and 30 has a risk of 5.5%; moderate risk with score 31 to 40 has a bleeding risk of 8.5%; high risk defined as score of 41 to 50 has bleeding risk of 11.9%; and very high risk with scores above 50 has a bleeding risk of 19.5%.

While these scoring systems can help stratify some patients *prior to medical treatment*, they are, in fact, futile when a patient is in the cardiac intensive care unit with evidence of bleeding. These scoring systems do emphasize the importance of hemodynamics: blood pressure and heart rate. These two parameters can help guide medical care in patients with suspected bleeding for prompt resuscitation prior to any endoscopic intervention. Resting tachycardia, while difficult to interpret in patients with atrial fibrillation, implies mild to moderate hypovolemia, while any signs of hypotension suggest intravascular

volume loss greater than 15% (if orthostatic) and 40% (if supine). Fortunately, the latter situations are infrequently seen, particularly after starting anticoagulation or antiplatelet therapy.

ANTIPLATELET THERAPY/ANTICOAGULATION

A variety of anticoagulants are used for (a) treatment of venous thromboembolism (VTE); (b) stroke prevention in patients with atrial fibrillation; and (c) prosthetic heart valves. These medications include both vitamin K antagonists (warfarin) and DOACs (rivaroxaban, apixaban, dabigatran, and edoxaban). In the setting of GI hemorrhage, the question of when to reverse anticoagulation often is difficult to answer. No specific guidelines exist for when and how to reverse the effects of anticoagulation, particularly in hemodynamically stable patients with a complicated clinical picture requiring intensive care.

In a massive bleeding emergency, vitamin K based anticoagulation can be reversed during a clinical emergency with vitamin K, fresh frozen plasma, or protein complex concentrates (clotting factors II, VII, IX, and X). Postprocedure assessment can be done with laboratory tests to confirm restoration of normal anticoagulation. However, reversing the effects of DOACs is not as straightforward. The bleeding risk profile of DOACs as compared to warfarin was assessed in various studies: Randomized Evaluation of Long Term Anticoagulation Therapy (RELY); Rivaroxaban Once-Daily, Oral, Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF), and Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE). Both dabigatran 150 mg twice daily and rivaroxaban 20 mg once daily were associated with higher incidence of massive GI bleeding compared with warfarin, while apixaban had a similar bleeding risk as warfarin. Nevertheless, in several Meta analyses of randomized controlled trials, the relative risk of massive GI bleeding was higher with DOACs compared to warfarin.[11] While the initial studies seem to convey a bleak picture, international prospective registries provide evidence of more efficacy and safety, with one study showing half the bleeding complication rate of using rivaroxaban compared to the data presented in ROCKET-AF.[12] Protein complex concentrates have been shown to attenuate the effects of the newer DOAC regimens in small studies and animal models; however, the intended correction may overshoot the

“normal” target to confer a “procoagulant” environment while the additional clotting factors remain in the vasculature. Additionally, there is no laboratory support to confirm the reversal of the effects of DOACs. However, in dire life-threatening emergencies, these protein complex concentrates have been recommended as first-line agents. Nonetheless, specific drug therapies are being developed. Recently approved in the United States, idarucizumab, a monoclonal antibody therapy, binds specifically to dabigatran and rapidly neutralizes its effects in over 90% patients without any safety concerns.[13] Given the high costs, logistical issues, hospital protocols, and reimbursements, implementation is likely to lag. Additional reversal agents are in the pipeline, like andexanet alfa, for direct factor Xa inhibitors.

In the more likely scenario of nonemergent, non–life-threatening situations, DOACs fare better in reversal because they are short lived with normal restoration of coagulation profile within 12 to 24 hours after the last dose in patients without any renal compromise. Conversely, the effects of vitamin K antagonists are longer lasting and known to be effective for up to 3 days. However, the optimal timing for reversing anticoagulants’ effects in nonemergent settings is not known. Given the rapid clearance of DOAC in patients with normal drug clearance, the need to use reversing agents may be unnecessary, because the drug effects dissipate within hours.

To complicate matters further, many patients have CAD requiring vascular intervention and atrial fibrillation, necessitating the use of antiplatelet along with anticoagulation therapy in an attempt to reduce their risk of both ischemic heart disease *and* stroke. Overall, the benefits from reducing adverse events with these medications is not higher than the augmented risks of bleeding, and therefore these medications are not recommended.[14] However, the concomitant use of antiplatelet therapy in patients using anticoagulation increases the risk of GI bleeding over time, which is worse with dual antiplatelet therapy and in the elderly. The risk was assessed in the APPRAISE-2 trial, and additional trials are underway to assess the risk further with other DOACs.

Nonetheless, it is important to remember that most cases of GI hemorrhage are not life-threatening. In addition, many studies mentioned earlier (ie, RELY, ROCKET-AF) have looked at outcomes to assess morbidity and mortality (including but not limited to need for reversal use, use of blood products, death after bleeding), showing a noninferior profile of DOACs when compared to older vitamin K antagonists.

LOCALIZATION: UPPER VERSUS LOWER

Whether the source of bleeding is the upper or lower GI tract is a question often faced by the critical care team. By definition, any lesion seen above the ligament of Treitz (proximal to the jejunum) is considered an upper GIB, whereas a lesion in the rest of the GI tract is considered a lower GIB. While the definitions may be clear, the attempt to localize may yield no definite source, or multiple potential sources with possible ascertainment bias. Trends in population-based evidence show that there has been a significant increase in lower sources and a decreasing trend in upper sources of GIB.[15] This is likely due to more "gut surface area" distal to the ligament of Treitz, the fact that a negative upper endoscopy will automatically characterize a bleeding episode as a lower GIB, and to the widespread use of proton pump inhibitors.[9] Although the data for DOACs are sparse, data regarding the actual source of GIBs shows 18.9% of patients have peptic ulcer disease, of which 7.2% cases required endoscopic intervention, while 9.5% of the 57.1% patients who underwent colonoscopy had lower GI findings that needed intervention endoscopically.[16] It is important to reiterate that localizing a site of bleeding may allow direct intervention, such as placement of hemostatic clips, application of a heater probe, or vascular embolization by an interventional radiologist, with abrupt cessation of bleeding and the ability to restate anticlotting therapy. In many cases, endoscopy and other studies do not reveal the source of bleeding, which is then characterized as being obscure GIB.

TIMING OF ENDOSCOPY

No evidence or guidelines exist to determine when patients on anticoagulation should/can undergo endoscopy. However, the gastroenterologists' general practice tends to be based on the clinical situation and presenting symptoms. During active bleeding, particularly when hemodynamic instability is noted (tachycardia, hypotension, bloody emesis), prompt endoscopy within 12 hours usually is performed. The use of proton pump inhibitors may reduce the yield of high-risk lesions and the need for direct intervention during endoscopy. While medical management is as important as endoscopy, urgent endoscopy (within a few hours of presentation) has not shown to improve morbidity or mortality in the general population. To complicate matters further, with anticoagulation use, iatrogenic injury to the GI tract is a valid concern; so waiting for reversal of the medication effects prior to endoscopy may be prudent.

In all cases, endoscopy should be pursued in patients who are anticoagulated as long as hemodynamic stability has been achieved, though the critical care and the gastroenterology teams must be prepared to accept a negative upper endoscopy and a negative colonoscopy during a bleeding episode (which may have resolved at this point of the work up). Although the next logical step for the bleeding work up is capsule endoscopy to assess the small bowel (the largest area of the GI tract), the procedure often is not performed in an inpatient setting. Thus, resumption of anticoagulation is often discussed prior to the completion of GI evaluation.

RESTARTING ANTICOAGULANTS/ANTIPLATELET THERAPY

Resuming anticoagulation and antiplatelet therapy after a GIB episode involves balancing the benefits of the therapy and the risks of rebleeding. Expert guidelines generally recommend that anticoagulation therapy should be resumed for stroke/systemic embolism prevention as soon as possible after a bleeding site has been treated and "stable hemostasis" has been achieved. As one strategy, warfarin could be started the day of the procedure as the effects of anticoagulation reach therapeutic values in 72 hours, while one would have to wait 48 to 72 hours before resuming shorter-acting agents. However, the situation is more complicated if the source is obscure or resolves without any intervention. Therefore, the risks of rebleeding are not often fully known in many cases. Clinical experience indicates that bleeding from peptic ulcer disease typically occurs within 72 hours of the initial bleeding episode in the absence of definitive therapy, which guides the intensity of patient follow-up.[17] The variety of difficult situations that arise, particularly in the CCU, mandates evaluating and reevaluating the risks and benefits of therapy on a daily basis or even more frequently.

Case 1: A 50-year-old man with a past medical history of atrial fibrillation, on warfarin, and chronic heart failure presented to the hospital with signs of fluid overload and melena. He underwent diuresis and upper endoscopy revealed a clean-based ulcer that needed no endoscopic intervention (ie, hemostatic clip, epinephrine injections, or electrocautery).

Case 2: A 50-year-old man with a past medical history of atrial fibrillation, on warfarin, and chronic heart failure presented to the hospital with signs of fluid overload and melena. He underwent diuresis and upper endoscopy revealed an ulcer with a visible vessel that required a hemostatic clip (which was placed adequately).

Case 3: A 50-year-old man with a past medical history of atrial fibrillation, on warfarin, and chronic heart failure presented to the hospital with signs of fluid overload and melena. He underwent diuresis and upper endoscopy revealed an ulcer with a visible vessel that required a hemostatic clip (which was placed possibly inadequately).

Although the three cases present similarly, the outcome of endoscopy can help the critical care team decide to restart anticoagulation promptly (ie, the first two cases), whereas the third case required a brief delay in restarting anticoagulation therapy. Although the use of proton pump inhibitors reduces the need for endoscopic intervention on high-risk lesions during an acute event, there is no evidence of it preventing upper GI bleeding/rebleeding when used concomitantly with anticoagulation and antiplatelet therapy.

As it is impossible to delineate all the possible scenarios of GIB episodes in patients with anticoagulation, ongoing multidisciplinary discussions in these cases is imperative. A team-based approach to help address the risks and benefits on case-by-case basis will allow stratification of patients based on their hemodynamic stability, clinical presentation, anticoagulation status and possible reversal, the benefits of endoscopy, and possibly resumption of therapy around the time of the GIB episode.

ANTICOAGULATION IN CIRRHOSIS

Cirrhotics, particularly the decompensated patients, have a higher bleeding risk profile often complicated by bleeding esophageal varices. Anticoagulation in these patients may be considered for various reasons, including portal vein thrombosis and atrial fibrillation. It is important to remember that coagulopathy from liver disease is not equivalent to medication-induced anticoagulation. While current clinical management supports use of vitamin K antagonists and low molecular weight heparin in selected compensated patients (lack of ascites, bleeding varices, encephalopathy, and hepatorenal syndrome), the use of DOACs is unclear. Those patients were excluded from the pivotal trials.

In summary, most cases of GIB in anticoagulated patients are nonlethal and do not lead to long-term adverse effects. Endoscopy should be pursued in patients who are anticoagulated or on antiplatelet therapy at a time when hemodynamic stability has been achieved, knowing that no lesion may be found or no endoscopic intervention may be pursued.

The risks and benefits should be assessed daily and the decision to resume or restart antiplatelet/anticoagulation therapy should be a team-based decision.

ANEMIA WITHOUT GASTROINTESTINAL BLEEDING

A common scenario that cardiologists are faced with in the CCU is unexplained anemia, particularly in a patient on anticoagulation or antiplatelet therapy. Clinically occult GIB is high on the list in the differential diagnosis. Although this may be the case in certain situations, having a healthy differential is prudent, especially when no overt signs of bleeding have been noted (ie, melena, hematemesis, or hematochezia). Blood in the GI tract acts like a cathartic and often presents with multiple bowel movements rather than constipation. With no clinical signs of GIB, endoscopy may not be warranted. For example, retroperitoneal bleeding or a postcatheterization hematoma in the leg may be associated with a sudden fall in hematocrit as can sepsis and disseminated intravascular coagulation.

INTESTINAL ISCHEMIA

Intestinal ischemia is an uncommon disease, particularly in cardiac patients, and may be due either to embolic or atherosclerotic disease. Intestinal ischemia encompasses acute mesenteric ischemia, nonocclusive mesenteric ischemia, and chronic mesenteric ischemia. Similar to its varied presentation from acute or chronic, the progression also embodies a large spectrum from being reversible to fatal. For example, in the acute setting of mesenteric ischemia (from embolism originating from atrial fibrillation or thrombosis from atherosclerotic disease in the superior mesenteric artery), mortality in the absence of treatment can reach up to 93% while the nonocclusive mesenteric ischemia during low-flow states can be from 50% to 90%.[18] Risk factors include history of vascular disease from smoking, diabetes, hypertension, and hyperlipidemia (similar to the risks presented in patients with CAD), as well as history of cardiomyopathies, myocardial infarctions, cardiac arrhythmias including atrial fibrillation, hypotension, recent CABG, among others.

PATHOPHYSIOLOGY

Anatomically, three major vessels supply the vasculature of the intestines: arteries from the celiac axis (supplies stomach and duodenum), superior mesenteric artery (rest of small intestine up to the splenic flexure), and inferior mesenteric artery (splenic flexure to the rectum). Although extensive collaterals

help prevent ischemia in the gut, there are certain areas that are more vulnerable to injury, often labelled as watershed areas. These areas include classically the splenic flexure (Griffiths point) and the rectosigmoid region (Sudeck point).

DIAGNOSIS

Clinical presentation can vary and particularly in a cardiac patient, both acute and chronic abdominal pain should raise the possibility of “gut angina” to “gut ischemia” to “gut infarction” (similar to the workings of the heart). In textbooks, acute pain out of proportion that precedes voluminous diarrhea with or without blood noted subsequently is classic for an ischemic event. It can however present with abdominal distention (discussed later), nausea, and vomiting. Selective angiography is the most sensitive means of making a diagnosis of arterial disease and allows for the direct instillation of vasodilators.[19] Computed tomography (CT) angiography also has high sensitivity for the diagnosis of arterial disease but does not allow for therapeutic intervention. It is important to note that early diagnosis is imperative because it improves survival. If there are any signs of inflammation of the bowel wall or colitis noted on imaging, comprehensive work up to rule out infections like *Clostridium difficile* must be done.

MANAGEMENT

As with any bleeding or emergency, hemodynamic status needs to be optimized. Additionally, in intestinal ischemia, broad-spectrum antibiotics (eg, ciprofloxacin and metronidazole) need to be initiated to prevent bacterial translocation. All attempts to stop vasoactive drugs or vasoconstrictors should be made. While some data exists on use of thrombolytics on embolic events, it is not recommend given the increased risk of hemorrhage. Nonetheless, a prompt surgical consultation is necessary to remove the damaged bowel, particularly in acute mesenteric ischemia. Vasodilators like papaverine (a phosphodiesterase inhibitor) can be used particularly in nonocclusive mesenteric ischemia and chronic mesenteric ischemia. Colonoscopy can be safely done in stable patients with ischemic colitis to differentiate from other types of colitis of infectious and inflammatory origin.

ABNORMAL LIVER FUNCTION TESTS

Gastroenterologic or hepatologic consultation in the CCU may be related either to the condition that prompted CCU admission or to the same causes of liver dysfunction that might afflict anyone, such as acute or acute on chronic hepatitis, decompensated cirrhosis, cholecystitis, etc. In the latter instances, the presentation does not differ from that in the noncardiac patient and the major clinical problem is managing the disease in the face of cardiac dysfunction. In some cases, such as cholecystitis or perforation of a duodenal ulcer into the gastrohepatic ligament, the symptoms may mimic acute cardiac disease and may even cause ECG abnormalities. Drug-induced liver disease (DILI) may occur in cardiac patients, and may be caused by drugs used in the CCU. However, it is more common for GI consultation to involve circulatory failure.

CIRCULATORY FAILURE

Though the liver comprises 2.5% of body weight, it receives around 25% of cardiac output, two-thirds from the portal system and one-third from the hepatic artery. Within the liver, the pericentral areas (zone 3) are most prone to injury because of a low oxygen tension under normal circumstances. The liver is partially protected from ischemic injury because of its dual blood supply—arterial and portal venous. However, the biliary system is supplied only by the hepatic artery. Heart failure can lead to hepatic dysfunction via two mechanisms, hepatic congestion related to increased venous pressure or ischemic injury related to decreased blood flow (**Table 47.1**). Passive congestion from increased central venous pressure occurs as a result of right-sided heart failure and may be chronic or acute, the latter in the case of pulmonary embolism, especially a saddle embolus. Hepatic dysfunction from right-sided heart failure may result from constrictive pericarditis, severe pulmonary arterial hypertension, mitral stenosis, tricuspid regurgitation, cor pulmonale, or cardiomyopathy. Right ventricular dysfunction with increased hepatic venous pressure can lead to atrophy of hepatocytes and perisinusoidal edema. Chronic right-sided heart failure may lead to hepatic fibrosis, previously termed “nutmeg cirrhosis.” Rheumatic heart disease was a very common cause of nutmeg cirrhosis in the past. Mortality in this condition usually was related to the severity of the heart disease, rather than the liver disease. Although the condition is termed cirrhosis, portal hypertension typically is not seen.

TABLE 47.1 **Causes of Hepatic Ischemia**

Heart failure[a]
- Right-sided heart failure
  - Right-sided myocardial infarction
  - Pulmonary embolism
  - Pulmonary hypertension
- Left-sided heart failure
  - Myocardial infarction
  - Cardiomyopathy
  - Valvular disease

Hypovolemia
  - Hemorrhage
  - Dehydration

Hypoxemia
Sepsis
Heat stroke

This is not a complete list but rather conditions that one might encounter in a CCU.
[a]In the presence or absence of cardiogenic shock.
CCU, coronary care unit.

Right-sided heart failure in the absence of left-sided heart failure usually presents with edema, ascites, and hepatomegaly. Jaundice may be noted on physical examination. Rarely, patients can present with severe hepatomegaly and right upper quadrant pain, which is due to stretching of Glisson capsule. The liver may be pulsatile if there is tricuspid insufficiency. The liver edge typically is smooth, and hepatojugular reflux may be elicited. When present, ascites classically has elevated protein content (>2.5 g/L) and a low serum-to-ascites albumin gradient, which is different from cirrhosis secondary to alcoholic liver disease or chronic viral hepatitis. Left-sided heart failure usually does not present with these symptoms, but with symptoms of dyspnea. Mild elevations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH), gamma-glutamyl transpeptidase, and alkaline phosphatase (ALP) typically are seen in right-sided heart failure, with elevations of up to 2 to 3 times the upper limit of normal. Bilirubin typically remains below 3 mg/dL with an elevated unconjugated fraction, but may be higher in patients with chronic, severe CHF. The rise in transaminases is greater with more acute presentations and in the presence of systemic hypotension, and may resemble acute hepatitis.

Hepatic dysfunction also may arise from low cardiac output leading to decreased perfusion and the predisposing conditions are similar to those discussed earlier. While oxygen delivery to the liver is related to both blood flow and Pa_{O_2}, hypoxemia alone rarely is sufficient to cause tissue injury. If affected by hypoxemia, the areas around the central veins are most vulnerable, because oxygen tensions are lowest under normal circumstances. Virtually any cause of

hypotensive shock can result in hepatic injury, including hemorrhage, burns, heat stroke, toxic shock, sepsis, acute CHF, trauma, crush injuries, pulmonary embolism, etc. In addition to hepatic artery thrombosis and embolism, hepatic artery occlusion also may occur from sickle cell crisis, cocaine-induced arterial spasm, aortic dissection, vasculitis, hypercoagulable states, hepatic artery aneurysms, toxemia of pregnancy, embolism from tumor, endocarditis, and others (**Table 47.2**). The vulnerability of the liver to ischemic disease is greater in the presence of cirrhosis because of portosystemic shunting or portal vein thrombosis, and in CHF because of the inability of the heart to compensate for the decreased hepatic blood flow. The liver also is susceptible because of the relatively high metabolic activity of the hepatocytes. Furthermore, the liver may suffer from reperfusion injury with reactive oxygen species and lipid peroxidation as well as superoxides and hydrogen peroxide.

Hepatic injury usually is acute, but may be recognized well after the inciting event has occurred.

TABLE 47.2 Causes of Hepatic Infarction

Hepatic artery thrombosis
- Atherosclerosis
- Hypercoagulable states

Hepatic artery embolism
- Endocarditis
- Tumor emboli
- Therapeutic embolization

Hepatic artery aneurysm
Aortic dissection
Vasculitis involving the hepatic artery
Sickle cell disease
Vasospasm—cocaine ingestion

This is not a complete list but rather conditions that one might encounter in a CCU.
CCU, Cardiac care unit.

The diagnosis typically is made on clinical grounds. In severe episodes of hypotension, shock liver can occur in which there is a profound elevation in serum alanine aminotransferase and aspartate aminotransferase, and prolonged prothrombin time. The diagnosis of hepatic infarction can be made radiographically, with demonstration of a wedge-shaped or other defect, especially on a contrast CT study. Laboratory abnormalities in ischemic hepatitis usually peak after 1 to 3 days and normalize after 5 to 10 days. Diagnosis is typically clinical when liver tests are found to be abnormal 1 to 3 days after the episode of hypotension though the condition may mimic acute hepatitis,

especially if the inciting event was missed, for example, hypotension associated with a tachyarrhythmia in an outpatient setting. There may also be concomitant elevations in creatinine from acute tubular necrosis. In these episodes of severe hypotension leading to elevated liver tests, patients usually present with serum bilirubin elevations up to 20 mg/dL and AST more than 10 times the upper limit of normal. LDH typically rises and an ALT/LDH ratio of less than 1.5 can help differentiate ischemic liver damage from viral hepatitis. In addition, the transaminases tend to fall rapidly because of the acute, reversible inciting event, as opposed to viral hepatitis in which transaminase elevations are much more prolonged, lasting for a few weeks. Most cases resolve with supportive care, though hepatic decompensation may occur, especially in the presence of chronic liver disease. There is no specific therapy for ischemic injury.

The following case is an example of an acute ischemic injury to the liver.

A 36-year-old man presented to the emergency room with severe chest pain, with onset while returning from an overseas trip. CT angiogram showed no evidence of pulmonary embolism but did show aneurysmal dilatation of the ascending aorta. Transthoracic echocardiogram showed a flap in the ascending aorta plus severe aortic insufficiency. He underwent emergent aortic root replacement with reconstruction and reimplantation of coronary buttons and hemiarch replacement, with 16 minutes of circulatory arrest and a cross clamp time of 192 minutes. GI consultation was requested for marked transaminase elevations (AST, 9736 and ALT, 5731) on postoperative day 3, plus coagulopathy (INR, 3.3). Transfer to a liver transplantation center was sought but was denied due to the need for multiple pressors and other postoperative care. Continuous venovenous hemoperfusion followed by hemodialysis was started because of acute kidney injury. Doppler examination showed blood flow to both kidneys. The transaminases peaked on postoperative day 4, while the total bilirubin continued to rise until postoperative day 8. Renal recovery was noted on postoperative day 11. At discharge on postoperative day 15, both liver and kidney function tests were improving and the patient was no longer receiving hemodialysis.

DRUG-INDUCED LIVER INJURY

Medications are also a common cause of hepatic dysfunction, which may present as asymptomatic liver test elevations or even fulminant liver failure. DILI may be nonidiosyncratic or idiosyncratic. Acetaminophen is a classic nonidiosyncratic etiology of DILI because high doses of acetaminophen can lead

to DILI in anyone. However, many medications cause idiosyncratic DILI. In fact, it is estimated that 20 new cases of DILI per 100,000 persons occur each year and that idiosyncratic DILI causes 11% of the cases of acute liver failure in the United States. DILI is classified as hepatic, cholestatic, or mixed based on the abnormalities in alanine aminotransferases and ALP. It mostly presents within 6 months of drug exposure, but can occur within days or up to a year after starting the offending agent.

There are many medications used in the CCU that may contribute to elevated liver tests (**Table 47.3**). These include, but are not limited to, aspirin, amiodarone, angiotensin converting enzyme inhibitors, angiotensin receptor blockers, statins, clopidogrel, hydralazine, and diltiazem. Liver function abnormalities during statin therapy have been widely publicized but usually are not a problem in the CCU, though they could be present on admission in a patient recently started on high dose therapy, especially simvastatin or lovastatin, and in the presence of drug–drug interactions, with agents that are CYP3A4 inhibitors. Liver function abnormalities occur less frequently than muscle injury.

TABLE 47.3 Drug-induced Liver Injury

MEDICATIONS[a]	COMMENTS
ACE inhibitors	Associated with low rate of elevated serum aminotransferases (< 2%)
Alpha blockers	Associated with minimal rate of elevated serum aminotransferases (0.2%–2%)
Angiotensin II receptor antagonists	Associated with minimal rate of elevated serum aminotransferases (0.2%–2%)
Antiarrthymics	Amiodarone is associated with elevation of serum aminotransferases in 15%–50% on long-term therapy. It is recommended to have ALT and AST values checked at baseline and every 6 mo, with discontinuation of amiodarone if over twice the upper limit of normal. Using the medication intravenously may cause severe liver injury, including liver failure, with elevations in enzymes by 10–100 fold.
Hydralazine	Can cause delayed liver injury in a lupuslike syndrome or acute liver injury
Methyldopa	Chronic use is associated with mild elevation in serum aminotransferases in 5%–35% of patients. More rarely do patients present with acute liver injury.
Fibrates	Mild-to-moderate serum transaminase elevations
Niacin	Doses above 500 mg daily cause elevation >3 times ULN of transaminases. Sustained release forms may cause serious hepatotoxicity.

Statins	Associated with mild-to-moderate serum transaminase elevations. Very rarely causes acute liver failure.
Ezetimibe	Associated with transaminase elevations in 0.5%–1.5%
Aspirin	May cause elevated transaminase levels with high-dose therapy. Can have mild increase in alkaline phosphatase and bilirubin.
Clopidogrel	Associated with serum enzyme elevations in 1%–3% of patients
Prasugrel	Similar to clopidogrel
Ticlopidine	Associated with serum transaminase elevations in 4%
Dabigatran	Associated with moderate ALT elevations of >3 times ULN in 1.5%–3% in chronic use
Fondaparinux	Associated with enzyme elevation >3 times normal in 1%–3% patients
Rivaroxaban	Associated with ALT elevation of >3 times normal in 1.5%–3% patients
Apixaban	Associated with serum transaminase elevations >3 times normal in 1%–2% patients
Edoxaban	Associated with serum transaminase elevations >3 times normal in 2%–5% patients
Heparin	Associated with elevated serum transaminase 10%–60% patients
Beta-blockers	Rarely cause elevations in serum transaminase levels
Calcium channel blockers	Associated with elevated serum transaminase levels
Tolvaptan	Studies mixed: some demonstrate no hepatic damage; some show worsened outcomes in cirrhotic patients.
Sidenafil	Associated with hepatocellular and cholestatic injury
Endothelin receptor antagonists	Associated with serum transaminase elevations

[a]This is not a complete list but rather a list of medications that might be used in the CCU.
ACE, angiotensin converting enzyme; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ULN, upper limit of normal.
From https://livertox.nih.gov/.

Diagnosis is usually made by careful medication history and by eliminating other etiologies of abnormal liver tests with laboratory testing for viral hepatitis, autoimmune hepatitis, etc, and imaging to rule out obstruction. The ultimate diagnosis can be made by liver biopsy, but is not required. Liver tests should

normalize with discontinuation of the offending agent. In some cases, the drug-induced injury is chronic. In these cases, improvement is slower, but clinical experience indicates that the transaminases will fall by at least 50% within 2 weeks of drug discontinuation.

INTESTINAL DISTENTION

Intestinal distention is a rather frequent cause of GI consultation for patients in the CCU, especially after open heart surgery. The causes may be mechanical (obstructive) or functional (nonobstructive). The major causes of mechanical obstruction are extrinsic compression, tumor, hernia, adhesion, stricture, volvulus (torsion), and intussusception, and usually are not related to the problems prompting CCU admission. In contrast, intestinal distention after cardiac surgery or myocardial infarction is more likely to be nonobstructive in nature, that is, ileus. The first task when seeing someone with intestinal distention is to differentiate obstruction from ileus. Ileus usually is reversible with treatment of the underlying causes/exacerbating factors, whereas obstruction may require surgery, sometimes on an urgent basis. The reason for this is that ischemia/infarction occurs when intraluminal and tissue pressures are higher than mean arterial pressure, and pressures are higher in obstruction than in ileus, so that strangulation with ischemia/infarction is more likely with obstruction.

PATHOPHYSIOLOGY

The pathophysiology of ileus is incompletely understood. Historically, ileus was felt to be related to paralysis from toxins, such as in patients with peritonitis. However, experimental studies demonstrated that removal of the distended bowel and rinsing with sterile solution allowed for peristalsis to return spontaneously. Thus, ileus began to be seen as inhibited motility. Toxic megacolon is a special circumstance associated with severe, transmural inflammation, associated with ulcerative colitis or infectious colitis, such as *C. difficile*-associated colitis, which includes systemic toxicity in addition to peritoneal irritation/inflammation.

The mechanisms controlling intestinal motility include neurogenic, myogenic, and humoral factors. Intestinal motility is stimulated by cholinergic impulses and inhibited by adrenergic impulses. Ileus is related either to increased inhibition,

decreased excitation, or both. Altered sympathetic/parasympathetic balance due to exaggerated sympathetic tone from retroperitoneal stimulation of thoracic sympathetic ganglia, for example, by blood products in or adjacent to the posterior peritoneum is felt to promote ileus in the small intestine (**Figure 47.1A**). The situation undoubtedly is more complicated because motility also is related to the presence of inflammatory cytokines, perhaps mediated through the activity of nitric oxide and prostaglandins.[20,21] The effects of inflammatory and other mediators are abetted by electrolyte imbalances, particularly calcium, magnesium, and phosphate, acid–base disorders, as well as by the pharmacologic effects of opiates, calcium channel blockers, and anticholinergics. Vomiting promotes loss of potassium and hydrogen ions. Intraluminal accumulation of fluid leads to losses from the intra- and extravascular compartments, while abdominal distention may limit respiration. Gaseous distention is caused, in large part, by swallowed air, which provides a rationale for nasogastric tube decompression.

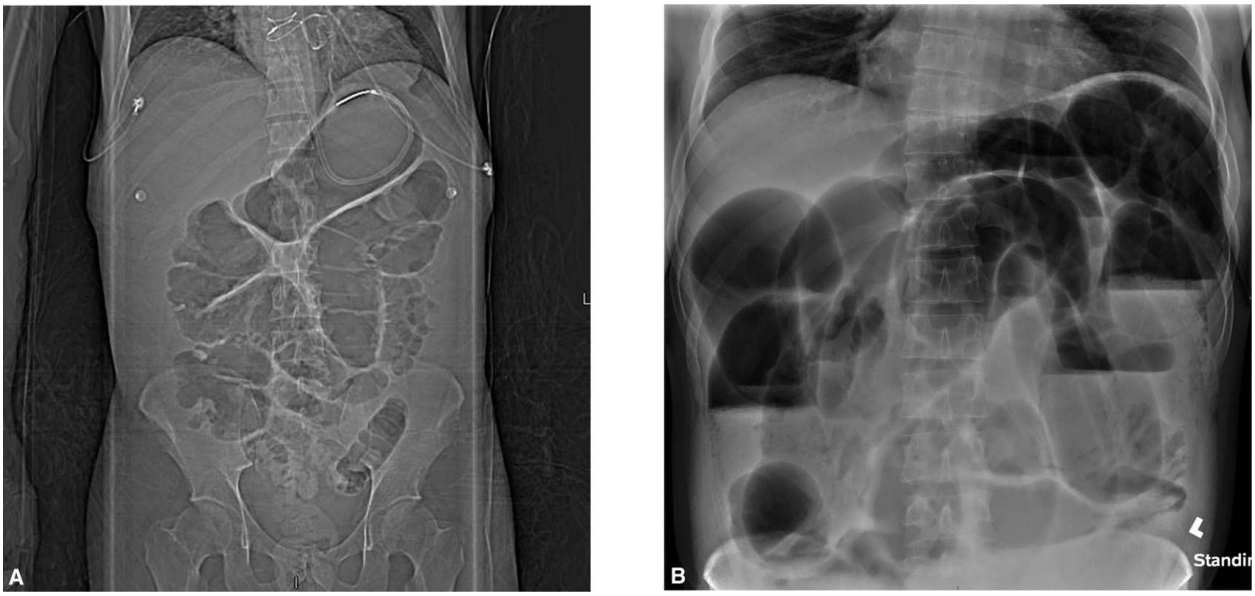

FIGURE 47.1 A, Supine abdominal film in a patient with ileus. Gaseous distention is limited to the small intestine. In this case, ileus was related to a mycotic aneurysm in a branch of the superior mesenteric artery in a patient with infective endocarditis. B, Upright plain film of the abdomen in a patient with organic obstruction, in this case volvulus associated with congenital malrotation. Note the air fluid is at different levels, which is typical for organic obstruction, as opposed to ileus.

Ileus may involve the small bowel or the colon, or both sites (**Table 47.4**). The small bowel is preferentially affected by retroperitoneal processes in the

thoracolumbar region, whereas the colon is preferentially affected by retroperitoneal processes in the sacral region. Of note, Ogilvie syndrome, or isolated colonic ileus, was originally related to retroperitoneal malignancies.

TABLE 47.4 Causes of Ileus

Infectious/inflammatory
- Severe sepsis
- Bacterial peritonitis
- Appendicitis
- Diverticulitis
- Cholecystitis
- Pancreatitis
- Pneumonia
- Pulmonary embolism
- Intraperitoneal hemorrhage

Ischemic
- Arterial thrombosis/embolism
- Venous thrombosis
- Nonobstructive mesenteric ischemia
- Mesenteric arteritis
- Strangulation/volvulus

Retroperitoneal processes
- Pyelonephritis
- Retroperitoneal hemorrhage
- Retroperitoneal abscess
- Retroperitoneal malignancy
- Ureteropelvic lithiasis

Drug-induced
- Opiates
- Anticholinergics
- Psychiatric medications

Metabolic
- Electrolyte imbalance—Sodium, potassium, calcium, magnesium, phosphate
- Uremia
- Acidosis

Other
- Laparotomy
- Perforated viscus
- Chronic obstructive pulmonary disease
- Sickle cell disease

This is not a complete list but rather conditions that one might encounter in a CCU.
CCU, Cardiac care unit.

DIAGNOSIS

A careful history, physical examination, and review of the medical records are important to uncover historical clues suggestive of obstructive disorders or ileus; prior abdominal surgery, prior episodes of obstruction, evidence of inguinal or abdominal hernias, prior intestinal cancer or polyps, prior radiation, inflammatory bowel diseases, gallstones, ulcers, and a history of gallstones all

raise the possibility of an obstructing lesion. On the other hand, a psychiatric history, certain medications (opiates, psychiatric medications, etc), and endocrine problems such as hypothyroidism may suggest ileus. Fever, rigors, leukocytosis, or hyperlactatemia suggest infection.

It is important to remember that mesenteric ischemia can mimic ileus radiologically as well as symptomatically. Mesenteric ischemia may be arterial or venous in origin and due to atherosclerosis, embolism, or vasculitis.[22] The colon is more vulnerable than the small intestine due to a less rich collateral circulation. Increasingly severe and steady pain in the presence of abdominal distention suggests intestinal infarction, but this is a late sign; a high index of suspicion is needed to lead to a correct diagnosis before infarction occurs. Elevations in serum amylase, ALP, creatine phosphokinase, ALT, AST, and lactate dehydrogenase suggest ischemia or infarction, with enzyme leakage from damaged cells.

Radiologic studies can suggest the etiology of intestinal distention as well as its severity. Air fluid at different levels on an upright film suggests organic obstruction (**Figure 47.1B**). A jejunal diameter of > 3.5 cm is considered worrisome. The diameter of the colon to be considered worrisome is uncertain. Classically, a diameter of > 12 cm is of concern, though patients with chronic distention, such as some patients on chronic psychiatric medications, have greater diameters and are asymptomatic. On the other hand, a rapid increase in diameter is worrisome no matter what the precise diameter is. Cross-sectional studies are helpful in detecting retroperitoneal pathology such as hemorrhage or infection, which may complicate thoracic as well as abdominal surgeries.

MANAGEMENT

For the treatment of organic obstruction, the reader is referred to GI or surgical texts. For the treatment of ileus, supportive care is key, with replacement of fluids and electrolytes as necessary, and the discontinuation of agents that inhibit motility. One should consider nasogastric decompression, especially in the presence of vomiting. One may consider colonic decompression for Ogilvie syndrome if it does not respond to conservative measures with placement of a rectal tube to maintain decompression. A cecostomy should be considered for recurrence of colonic ileus or failure of colonoscopic decompression. It should be emphasized that small intestinal ileus responds to conservative measures in most cases. Endoscopy rarely is needed in patients with ileus, though it may be helpful in patients with proximal obstruction of the small bowel or distal

obstruction of the large bowel. If endoscopy is performed, instilling as little air as possible is recommended so as not to exacerbate the situation and to use carbon dioxide for insufflation rather than room air, because it is resorbed much more rapidly.[23]

GASTROINTESTINAL COMPLICATIONS AFTER LEFT VENTRICULAR ASSIST DEVICE IMPLANTATION

GIB rate in patients with left ventricular assist device (LVAD) is frequent and estimated to be 18% to 44%.[24] The causes for GIB may be from use of antithrombotic agents, impaired platelet aggregation, acquired von Willebrand syndrome, and mostly commonly arteriovenous malformations (AVMs) or angiodysplasias in patients who suffer from chronic heart failure. Though the same lessons as described earlier apply to LVAD patients as well, additional precautions need to be taken with special attention to hemodynamics in this cohort. The possibility of obscure sources of GIB should be considered in these patients and a team-based approach is required to navigate these situations.

Patient and Family Information for: GASTROINTESTINAL EMERGENCIES IN THE CARDIAC CARE UNIT

Being in the cardiac care unit can be an overwhelming time for both patients and their families. This can be escalated by other conditions and medical problems that present during a hospitalization. The key to understanding GI and liver diseases in a cardiac patient is to first understand that it involves interdisciplinary care and discussion among the cardiologists and gastroenterologists, with a plan individualized for each patient.

Gastro-Intestinal bleeding (GIB) can occur in any individual. This can be bleeding anywhere in the intestinal tract from the esophagus down to the rectum. Bleeding can be from the upper GI tract, which includes the esophagus, stomach, or first part of the intestines, or from the rest of the intestines, which is considered the lower GI tract. Patients may present with passing blood per rectum, black stools, or coffee-colored or bloody vomitus. If it is severe, it can cause shock with lowered blood pressure and a fast heart rate. Many different conditions can cause bleeding, ranging from an ulcer to a tear in the intestinal lining, hemorrhoids, a bleeding mass, irregular blood vessels called AVMs, to diverticulosis, which is an outpouching in the lining of the intestines. The treatment of the cause of bleed depends on the severity of the bleeding (ie, how much the blood counts drop, how much the blood pressure or heart rate changes, and how quickly blood is being lost). In some instances, it can be treated supportively with fluids, blood products, and certain medications to decrease acid secretion from the stomach. In other situations, patients may require direct visualization with endoscopy or colonoscopy, or CT studies to analyze the blood

vessels. In either case, direct treatments may be used to stop the bleeding.

Some patients are at higher risk for bleeding than others. These include sick patients in an intensive care setting, and patients on blood thinners such as most patients with cardiac conditions. Although the incidence of major bleed is low in cardiac patients, it can be life threatening. The gastroenterologists and cardiologists need to assess the severity of bleeding, the potential site that the patient is bleeding from, the type of blood thinners the patient is on, and whether blood thinners can be continued or not. It is a risk and benefit conversation that will have to be individualized based on the patient. If a bleed is severe enough to cause patients to be unstable, then regardless of their cardiac status they may require an invasive procedure. The biggest discussion will be held after the bleeding is controlled about the risks and benefits of using blood thinners in somebody with a recent bleed because blood thinners increase the risk of bleeding further. Again this will be individualized for each patient with discussions among the cardiologist, gastroenterologist, and the patient.

Another problem that arises in patients in the cardiac care unit is abnormal liver function tests. This can be for a few reasons. One is mainly caused by the fact that both the heart and liver work simultaneously to help blood flow throughout the body. Many patients in the cardiac care unit have heart failure. If you can imagine, this can present in two ways. If the heart is failing to pump out blood effectively enough, then there is a lack of blood flow to all organs, including the liver. This results in less oxygen being delivered to the liver and presents as damage to the liver. On the other hand, if the heart cannot fill properly with blood, the blood will back up to all of the organs, including the liver. The liver then becomes congested with blood and can become damaged. These conditions present with elevated liver function tests and should improve with improvement of the heart failure. If heart failure is long standing and not improving, there is a chance that it can lead to liver failure and cirrhosis.

Another situation is when patients have episodes of extremely low blood pressure and decreased blood flow from the heart, which causes less oxygen to be delivered to the liver, resulting in liver damage. The treatment for this is supportive with management of the blood pressure. It will slowly resolve over time and usually does not result in liver failure.

Certain medications, both cardiac and noncardiac medications, can cause elevations in liver tests as well. Usually this is diagnosed when the liver tests get elevated after starting certain medications and after elimination of all other types of liver disease, for example, viral hepatitis. It should resolve with stopping the

offending medication. The condition usually is not life threatening, but sometimes can cause chronic problems with the liver. In these instances with elevated liver tests, it is a matter of watching the laboratory values to see if they are improving and if not, patients may require a liver biopsy.

Many patients in the cardiac care unit also do not get out of bed and risk getting distension of the intestines. This differs from patients who have an actual obstruction (from a tumor, scar tissue, hernia, etc) and have a blockage in their intestines. If a patient gets distension of his or her intestines, basic radiologic workup will be done including an X-ray or a CT scan. After that, the treatment depends on whether or not the physicians believe there is an actual obstruction in the intestines. If so, the patient may require surgical intervention, because it can become life threatening. If not, the care is supportive with fluids, ensuring movement (which may be as simple as the nurse turning the patient, or walking), sometimes stopping medications that can induce distension (ie, opiate pain medications), and making sure the patient’s potassium and magnesium levels are normal.

Line Access in the CCU

INTRODUCTION

Obtaining vascular access in the cardiac care unit (CCU) patient is a potentially lifesaving intervention and an important practical skill for physicians in training to acquire during their critical care rotations. Vascular access is essential for providing lifesaving medications, therapeutic interventions, and also hemodynamic monitoring. Determining the type of catheter needed, appropriate indications, contraindications, and the various considerations for the insertion, maintenance, and timely removal of arterial and venous catheters is important to prevent complications. Knowledge of vascular anatomy, familiarity with the equipment, and competency with the use of ultrasonography (US) are prerequisites for successful insertion of the catheter.

A central venous catheter (CVC) or central line (CL) is defined as a venous intravascular catheter that terminates at or close to the heart or in one of the great vessels. A CVC can be used to provide infusions of vasoactive and other medications, blood products, and also for hemodynamic monitoring. An arterial line (A-line) is an intraarterial catheter placed in a peripheral or central artery and is used for hemodynamic monitoring or for vascular access for procedures such as coronary angiography. The placement of CVCs and A-lines is routine CCU procedure, often performed at the bedside under sterile technique. Vascular

access devices (VAD) that may be encountered in the CCU patient include peripheral intravenous (PIV) catheters, triple lumen catheter (TLC), introducer catheter, tunneled and nontunneled hemodialysis catheters, peripherally inserted central catheter (PICC), Swan-Ganz or pulmonary artery catheter (PAC), A-lines, and venous and arterial sheaths.

Not every CCU patient requires a CVC or A-line. The decision to place a line and the choice of site of insertion should be based on a thoughtful assessment by the operator and the CCU team of the patient's anatomy, clinical status, and coagulation profile. All lines should be placed under aseptic technique using a "bundle" or "checklist" as per institutional policy. Real-time ultrasound guidance is recommended for CVC placement in sites such as internal jugular vein (IJV) or femoral vein (FV), as well as any difficult-to-access sites. Once a VAD has been placed, there should be a daily thoughtful assessment of the need for continued use of the catheter. The best way to avoid complications of VAD is to avoid unnecessary placement and remove them as soon as they are no longer necessary.[1]

Although the authors believe that there is no substitute for bedside hands-on learning, we hope this chapter serves as a fundamental quick reference guide for physicians, nurses, physician assistants, nurse practitioners, and other health care practitioners for "frequently asked questions" about VAD encountered in the CCU.

BASIC PRINCIPLES

MATERIAL

Most catheters in the CCU, including PIVs and CVCs, are polyurethane-based catheters, which provide some rigidity to the flexible catheter and prevent kinking. The main adverse effect of these catheters is the risk of vessel perforation, namely that of the superior vena cava (SVC) from a left-sided CVC. Silicone-based catheters are more pliable and have a lower risk of vessel injury, hence are placed for long-term venous access. These catheters need a sheath introducer or an inner dilator or stylet for percutaneous insertion. Examples of silicone-based catheters encountered in the CCU include PICC and some silicone-coated sheath introducers.

SIZE

Catheter size is classified in either gauge (G) or French (F) units. In general, needles or single lumen catheters are sized by gauge and multilumen catheters are measured by French size. Whereas French size and catheter diameter are directly related (the higher the French, the larger the diameter), gauge and size are inversely related (lower gauge indicates larger diameter). The size specifications are generally indicated on the outer packet or insert.[2]

FLOW RATES

A working knowledge of the relationship between catheter size, length, and flow rates is essential in choosing the appropriate catheter for the CCU patient. The rate of flow (***Q***) across a catheter is directly proportional to the pressure gradient (ΔP) and inversely proportional to the resistance (***R***) to flow:

$$Q = \Delta P \times \frac{1}{R} \qquad \text{(Eq. 1)}$$

Resistance is directly proportional to the length of the catheter and viscosity (μ) and inversely proportional to the radius (***r***): $R = 8\mu \times \text{length}/\pi r^4$. Hence the rate of flow is directly proportional to the inner radius of the catheter and the pressure gradient, and inversely proportional to the length of the catheter and the viscosity of the fluid or blood product being infused. This is based on Poiseuille's law:

$$Q = \frac{\pi r^4 \times \Delta P}{8\mu \times \text{length}} \qquad \text{(Eq. 2)}$$

This concept is important in the resuscitation of the CCU patient, whether it is for hypovolemia or hemorrhage. Flow rates improve exponentially (r^4) with larger radius catheters, pressure bag application, and with shorter catheters. A large bore catheter that is short is optimal for volume resuscitation. **Table 48.1** lists the flow rates achieved with various devices commonly used in the CCU. So if a patient in the CCU has a major bleeding complication (eg, from femoral arterial sheath removal or gastrointestinal bleeding from antithrombotic agents), a 16-gauge antecubital peripheral IV or an introducer catheter is preferred over a long triple lumen catheter (TLC) or PICC.[3]

TABLE 48.1 Flow Rates and Catheter Size

Catheter gauge and length	Flow Rate (mL/min)

24G × 0.75″	25
22G × 1.00″	35
20G × 1.00″	65
20G × 1.88″	55

PICC, peripherally inserted central catheter; TLC, triple lumen catheter.

PERIPHERAL VENOUS CATHETERS

Any patient admitted to the CCU would be considered a critically ill patient and hence needs at least one peripheral intravenous (IV) catheter. This can be

potentially lifesaving when the previously stable cardiac patient becomes unstable, whether it is from a bradyarrhythmia, tachyarrhythmia, or cardiac arrest. Infusates with a pH between 5 and 9 and osmolality < 600 mOsm/L can be delivered via a peripheral catheter. Even vasopressors can be administered emergently through a properly placed peripheral catheter until central venous access is obtained. Due to increased risk of phlebitis with catheter dwell time,[4] most institutions have policies requiring change of peripheral catheters every 72 to 96 hours.[1] A recent randomized controlled study from Australia however showed no difference in adverse outcomes such as phlebitis when peripheral catheters were changed only as clinically indicated.[5]

Most institutions have one of two types of catheters: an over-the-needle cannula (ie, angiocatheter or “angiocath”) or a winged catheter set (ie, butterfly) (**Figure 48.1A** and **B**). **Table 48.2** lists a step-by-step approach to placing a PIV. **Figure 48.2** illustrates the venous anatomy of the upper extremity. A proximal site is preferred if the patient is at risk for hemorrhage. In general, an 18G or 20G is preferable because it provides an adequate size for rapid infusion of medications or of contrast if the patient needs a computed tomography (CT) angiogram. Note that catheters in the antecubital fossa (eg, median cubital vein) may kink when the patient bends his or her arm, thus interfering with medication administration. If ultrasound guidance is used to cannulate the basilic or cephalic veins (**Figure 48.2**), a longer angiocatheter is preferred. Avoid sites that may appear injured or infected (ie, cellulitis). Complications include phlebitis (irritation), cellulitis, and bacteremia leading to sepsis. Hematoma, thrombus formation, and nerve injury can occur from multiple unsuccessful attempts. Infiltration of fluid around the IV site is not uncommon; however, extravasation of medications such as vasopressors and vesicants can lead to localized swelling and vascular compromise. Any early signs of minor or major complications should lead to removal of the catheter. Warm compresses and arm elevation can be used to treat phlebitis and extravasation.

FIGURE 48.1 A, Winged peripheral IV catheter system. B, Over-the-needle angiocatheter with retractable needle.

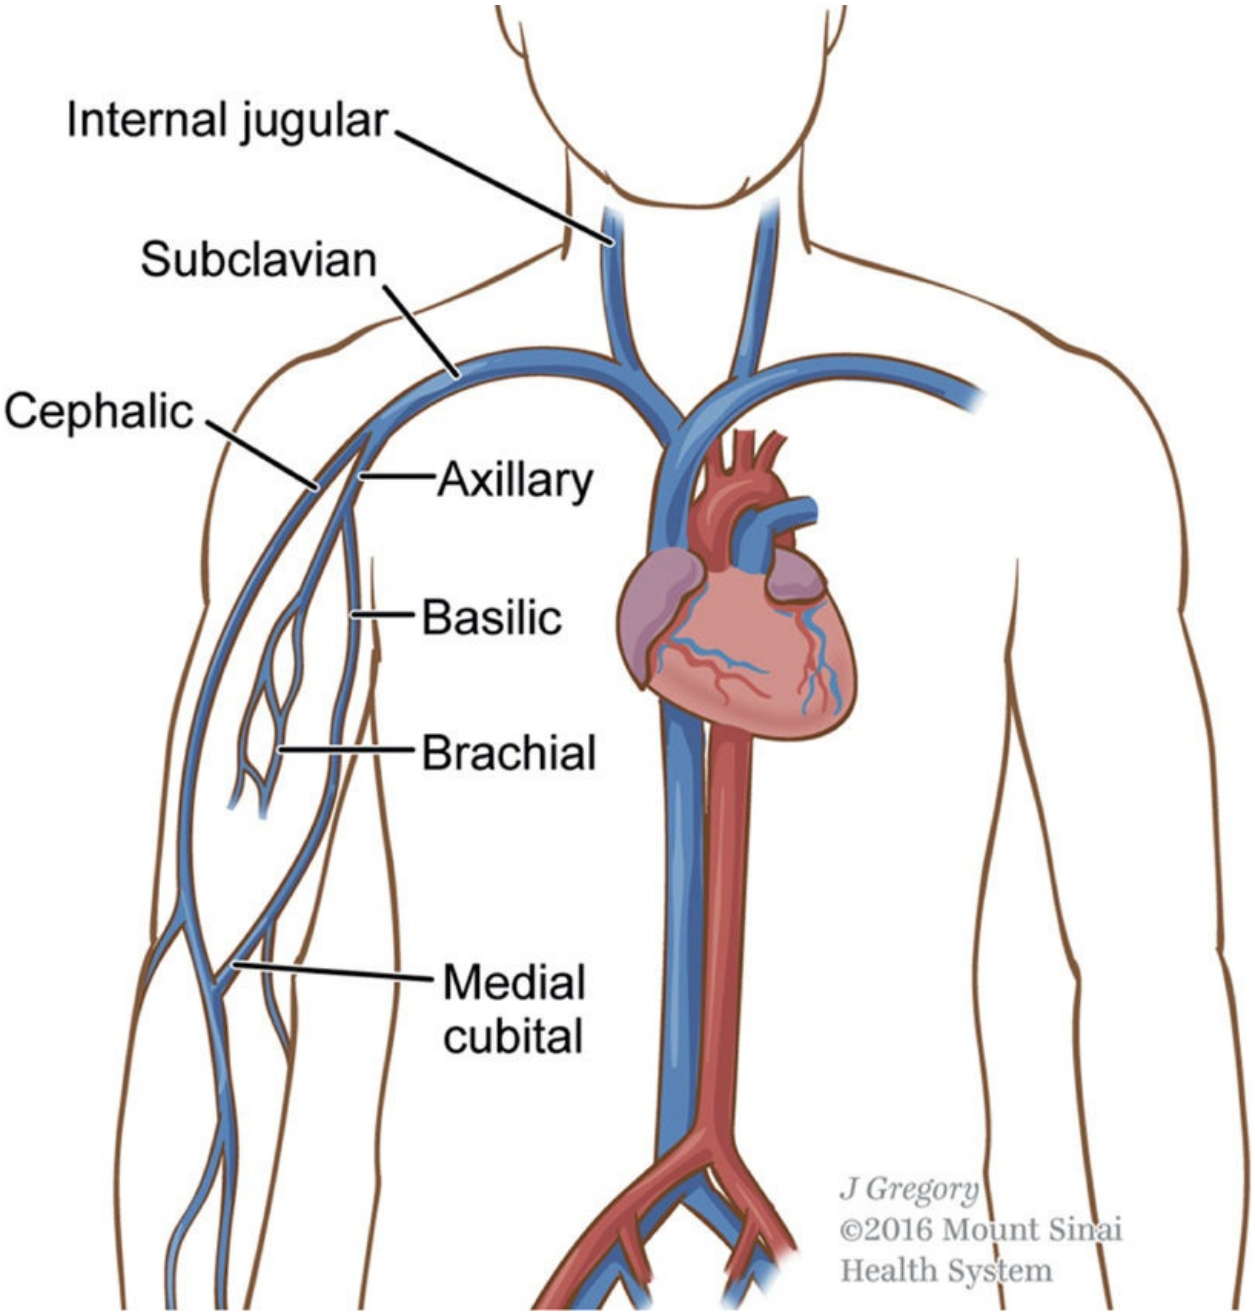

FIGURE 48.2 Venous anatomy of the neck and upper extremity.

TABLE 48.2 Peripheral IV Insertion Procedural Checklist

STEP	DESCRIPTION
1	Perform hand hygiene and organize equipment.
2	Explain procedure to patient.
3	Apply tourniquet on selected arm, 3 to 5 inches above the elbow.

4	Ask patient to open and close hand or hang arm to gravity.
5	Inspect arm for veins with largest diameter and fewest branch points.
6	Sterilize insertion site with chlorhexidine, alcohol, or povidone iodine.
7	Stabilize vein with nondominant hand by holding skin taut.
8	**Winged catheter system (butterfly)**
	a. Hold the system with thumb and forefinger on the finger grips.
	b. Access the vessel at a low 10 to 30 degrees angle.
	c. Visualize blood return along the catheter, then up the extension tube.
	d. Lower needle and advance the entire catheter and needle unit.
	e. Stabilize the system and pull back until the push-tab component releases from the device.
	f. Discard shielded needle into sharps container.
9	**Over-the-needle (angiocatheter)**
	a. Hold device by ribbed needle housing using dominant hand.
	b. Insert catheter using dominant hand with bevel up at 10 to 30 degrees angle in direction of vein.
	c. Observe for blood return through flashback chamber.
	d. Advance 2 to 3 mm and lower needle until flush with skin.
	e. Gently advance catheter into vein until hub rests at puncture site.
	f. Stabilize cannula and release tourniquet with nondominant hand.
	g. Use one finger to apply pressure over catheter tip to stop blood flow.
	h. Slide off needle or press safety button to retract needle.
	i. Dispose needle in sharps container.
10	Attach extension set and flush with normal saline.
11	Secure catheter with tape and transparent occlusive dressing.
12	Ensure that sterility is maintained throughout the procedure.

IV, intravenous.

CENTRAL VENOUS CATHETERS

OVERVIEW

A CVC is defined as a venous intravascular catheter that terminates at or close to the heart, in one of the great vessels. In the United States the Centers for Disease Control and Prevention (CDC) estimates that over 5 million CVCs are placed each year leading to 15 million central line days per year.[1] A CVC can be used for administration of select medications and blood products, central venous pressure (CVP) monitoring, and sampling of central venous blood. Additionally, in the CCU, an introducer catheter can allow introduction of a transvenous pacer (TVP) or a Swan-Ganz catheter. The vessels that are commonly cannulated for obtaining central venous access are the IJV, the subclavian vein (SCV) (**Figure 48.2**), and the FV. CVCs can also be used for hemodialysis, plasmapheresis, chemotherapy, and parenteral nutrition.

CVCs are available with antimicrobial impregnation (eg, chlorhexidine-silver sulfadiazine, minocycline-rifampin) and these are used when the anticipated use is over 5 days. Studies have shown a lower incidence of bacterial colonization and lower rate of central line-associated blood stream infection (CLABSI) when antimicrobial-coated CVCs are used.[6] A working knowledge of the indications and contraindications for CVC placement, as well as the principles for its insertion, maintenance, and removal is essential.

TYPES OF CENTRAL VENOUS CATHETERS

In the CCU, there are five main types of catheters that are used for central access. The most commonly used line is the TLC because it provides multiple lumens for infusion of medications and fluids (**Figure 48.3A and B**). Nontunneled hemodialysis catheters (**Figure 48.3C**) are often placed in the CCU for intermittent hemodialysis or continuous renal replacement therapy. Sheath introducers (**Figure 48.3D**) are usually single lumen and can be placed in the venous or arterial system. These can be used for insertion of a temporary pacemaker (venous circulation) and are also often left in place after left heart catheterization (arterial circulation). The Swan-Ganz catheter (**Figure 48.3E**) or PAC can be placed through a sheath introducer into the pulmonary artery. See Chapter 49 for a full discussion of invasive hemodynamic monitoring including CVP and pulmonary artery catheterization. PICC lines are often placed in the CCU patient for long-term vascular access for medications such as antibiotics. A

PICC line is considered a central line as the tip ends in the SVC. Intravascular cooling catheters (**Figure 48.3F**) may be used to induce therapeutic hypothermia in the CCU patient who is post cardiac arrest. Other central catheters one may encounter in the CCU patient include long-term VADs such as tunneled hemodialysis catheters, Hickman catheters, and Ports, which are not discussed in this chapter.

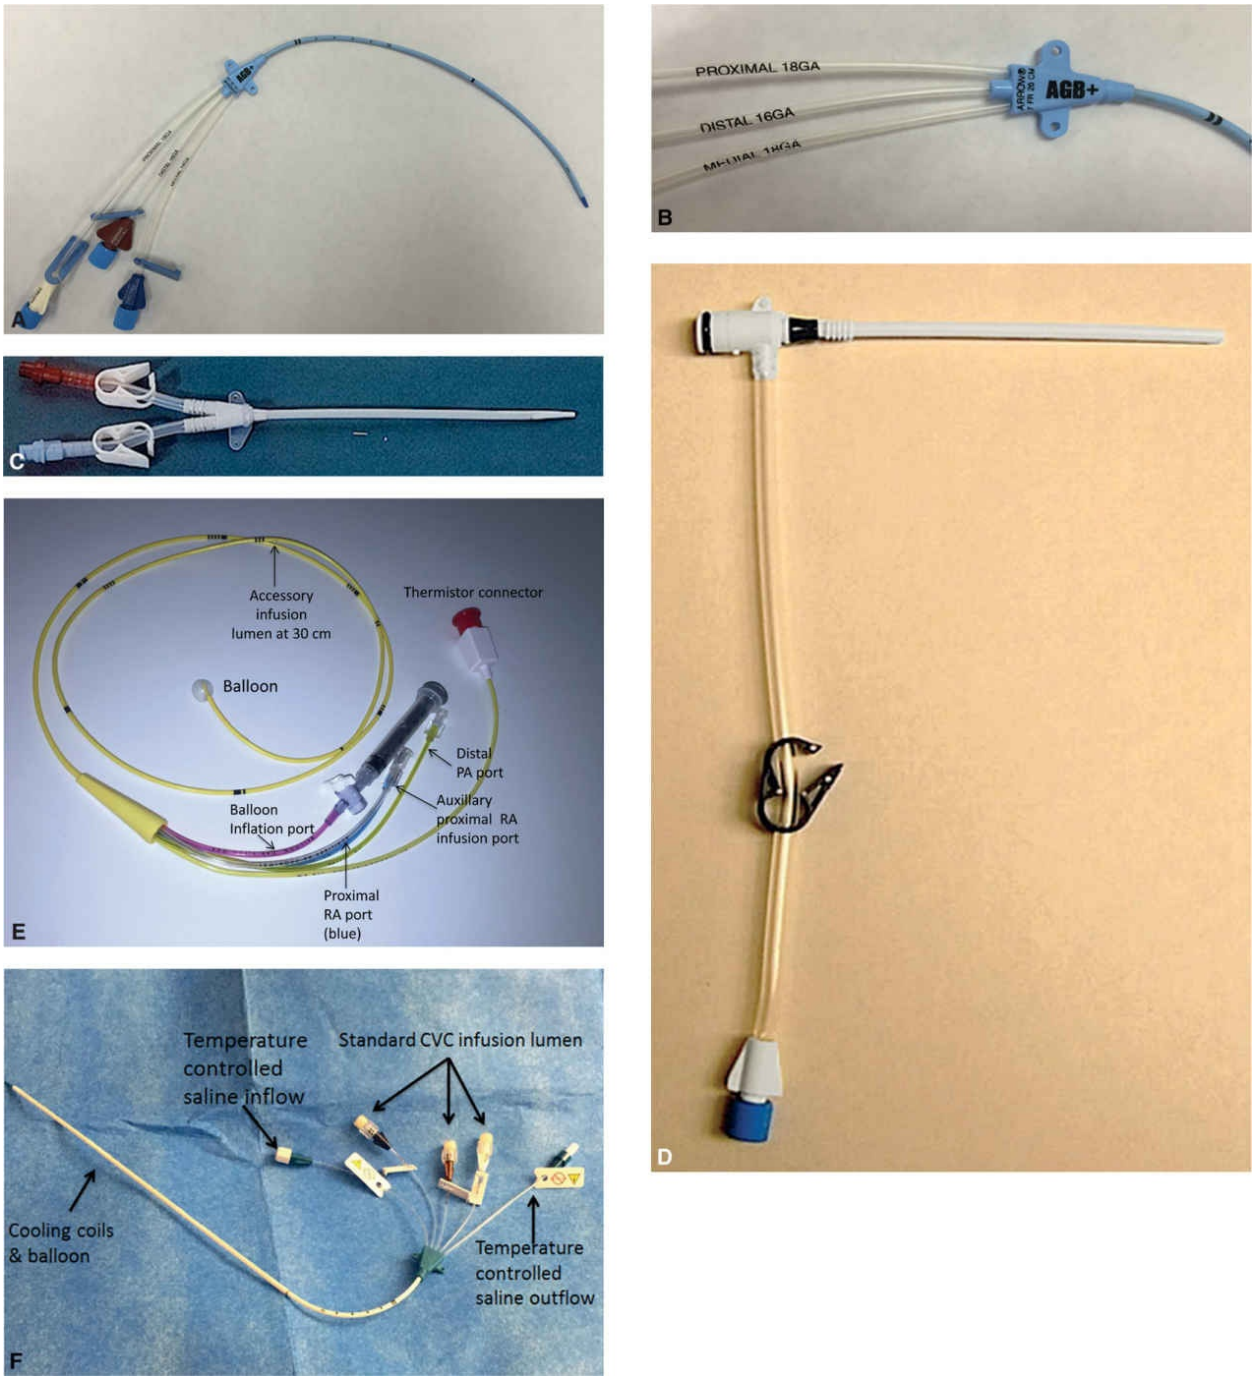

FIGURE 48.3 A, Triple lumen catheter. B, Three ports of the triple lumen catheter. C, Nontunneled hemodialysis catheter. D, Sheath introducer. E, Swan-Ganz or pulmonary artery catheter. F, Cooling catheter. CVC, central venous catheter. RA, Right atrium; PA, Pulmonary artery.

Triple Lumen Catheter

The TLC has three ports: proximal (white, 18G), medial (blue, 18G), and distal (brown, 16G) in relation to the site where the line enters the patient (**Figure**

48.3B). **Table 48.3** summarizes their basic characteristics. The catheter is easily inserted at the bedside either electively or during emergencies. It is sutured at an appropriate length based on the patient's height and insertion site (see section on technique). The catheter is typically made of polyurethane and is radiopaque so the tip can be easily visualized on a chest radiograph. The tip should be in the SVC, at the junction of the SVC, and the right atrium (RA). The three lumens allow infusion of multiple, even incompatible solutions, at the same time. The distal port (brown, 16G) has the fastest flow rate and is used for resuscitation fluids and blood products, as well as for monitoring CVP because it gives the most accurate waveform. The distal port should also be used for venous blood sampling such as measurement of central venous oxygen saturation ($Scvo_2$), as it has the fastest flow rate and is closest to the pulmonary artery. The $Scvo_2$ is a surrogate for mixed venous O_2 saturation (Svo_2). TLCs with continuous measurement of $Scvo_2$ are available as well (PreSep catheter, Edwards). If hyperalimentation or total parenteral nutrition (TPN) is anticipated, the medial lumen should be dedicated solely for this purpose in order to limit risk of infection.

TABLE 48.3 Port Characteristics of the Triple Lumen Catheter

LUMEN	COLOR	GAUGE	LOCATION	RECOMMENDED USES
Distal	Brown	16	Catheter tip	1. Central venous pressure monitoring
				2. Administration of viscous, high volume of fluids, or blood products
				3. Medication administration
				4. Blood sampling
Medial	Blue	18	2.2 cm from distal	1. TPN or cap for future TPN use
				2. Medication administration (if TPN is not anticipated)
Proximal	White	18	2.2 cm from medial	1. Medication administration
				2. Blood administration

The colors may vary depending on the manufacturer.
TPN, total parenteral nutrition.

Nontunneled Hemodialysis Catheter

These are double lumen catheters (**Figure 48.3C**) for hemodialysis access with internal diameter of approximately 12G to accommodate high flow rates needed for hemodialysis or plasmapheresis. The catheters typically have a brown port and a blue port. The blue is the distal port from which the wire appears. Blood is drawn from the brown port into the dialyzer machine and the dialyzed blood is returned via the blue port. The ports should be reserved only for hemodialysis, except in a life-threatening emergency. Hemodialysis catheters are placed in either the IJV or CFV; the SCV is avoided due to the risk of SCV stenosis or thrombosis, especially if arteriovenous fistula (AVF) creation is anticipated for long-term access.

Sheath Introducer

An introducer is an "L-shaped" single lumen, large bore (>8F) VAD with a port, which can be used to insert various devices and catheters (**Figure 48.3D**). The short length and large diameter make it an ideal catheter for large volume resuscitation. When an introducer is used with a pressurized system, liters of fluids and blood products can be infused within minutes. Since it has one lumen, additional incompatible medications cannot be infused through the same lumen. Double and triple lumen introducers are available and have the advantage of additional ports for medication infusion, however at the expense of a lower flow rate. Additionally, in an emergency, a TLC can be potentially inserted through an introducer for additional lumen, provided sterility is maintained. When placed in the venous system, it serves as a conduit for introduction of devices and catheters, like a TVP or PAC for right heart catheterization (RHC). When placed in the arterial system, introducers are used for procedures such as left heart catheterization. Accidental removal of sheath introducers, especially arterial sheaths, is potentially fatal. Only an experienced operator should remove arterial sheaths because it carries a high risk of hemorrhage and death.

Pulmonary Artery Catheter

The PAC or Swan-Ganz catheter is a long quadruple lumen thermodilution catheter used for invasive hemodynamic monitoring (**Figure 48.3E**). It is inserted through a sheath introducer under sterile technique and the balloon inflated before advancing into the pulmonary artery. It provides measurements of right atrial, right ventricular, pulmonary artery, and pulmonary artery occlusion

pressures (PAOP), and allows measurement of cardiac output and oxygenation (Svo_2). Although the PAC provides extremely useful information about the hemodynamic status of the patient, its role has diminished as studies show it does not change clinical outcomes. Nevertheless, the PAC does provide useful information and is still utilized in CCUs and cardiothoracic ICUs, both for diagnosis and monitoring of shock states, as well as postoperative management of the cardiac surgery patient. The PAC is reviewed in detail in Chapter 49.

Intravascular Cooling Catheter

With the advent of therapeutic hypothermia after cardiac arrest, targeted temperature management of post cardiac arrest patients is often performed in the CCU. Intravascular cooling catheters can have a built-in temperature sensor that allows for precise control. It controls the temperature of saline circulating through catheter balloons via remote sensing of the patient's temperature (Zoll IVTM Catheters, Chelmsford, MA). The catheters can come with additional lumens that can be used for vascular access. The patient is cooled or warmed as venous blood passes over each balloon, exchanging heat without infusing saline into the patient. This allows for cooling to targeted temperature for the induction of hypothermia and precise temperature control during the rewarming and maintenance phase of therapeutic hypothermia.

ECMO Catheter

Extracorporeal membrane oxygenation (ECMO) is being increasingly used for prolonged mechanical cardiopulmonary support and is often delivered in the CCU or cardiothoracic ICU. Venoarterial (VA) ECMO is used for patients with cardiac failure and venovenous (VV) ECMO is used for severe acute respiratory failure. ECMO catheters are much larger (13F to 31F) and usually placed percutaneously by surgeons, typically by a modified Seldinger technique, using serial dilators to accommodate the large size. The major complications to monitor for are bleeding and limb ischemia.

Peripherally Inserted Central Catheter and Midline Catheters

PICC lines are placed for long-term venous access for intravenous medications and other therapeutics. They are usually placed in the interventional radiology (IR) suite by the IR service or at the bedside by a PICC service or an intensivist. They are inserted using ultrasound guidance into the basilic, cephalic, or brachial

vein (**Figure 48.2**) through a small introducer. PICCs come with single, double, or even triple lumen and are sometimes placed in lieu of a TLC because they carry a lower risk of complications. Vasoactive agents, TPN, and caustic medications can be administered through a PICC; however, it is not an optimal line for resuscitation in a critically ill patient, especially if it is single lumen. In the CCU, they are inserted in patients with poor venous access or in patients who are being transferred to medical floor who need long-term vascular access (ie, antibiotics for endocarditis).

Midline catheters are long catheters (3 to 8 inches) that are placed in the brachial, basilic, or cephalic vein, however these are NOT considered central lines. These can remain in place for up to 30 days and often obviate the need for a central line. The infection risk with midline catheters is low and comparable to a peripheral IV.[7]

INDICATIONS FOR CENTRAL ACCESS IN THE CCU

Vascular access is crucial in the CCU patient and can often be challenging in the setting of difficult venous access, prior IV drug use, or in the context of a deteriorating patient or one in cardiac arrest. **Table 48.4** lists common indications for central access in the CCU patient. In general terms, cannulation of a central vein allows for five main scenarios:

1. Medication administration: Administration of medications contraindicated for peripheral access or when the latter is unobtainable (**Table 48.5**).
2. Hemodynamic monitoring: Measurement of parameters such as CVP and $scvo_2$. PAC allows for measurement of cardiac output and PAOP, which can be used to guide treatment.
3. Extracorporeal therapies: Central access is needed for hemodialysis and other forms of renal replacement therapy, plasmapheresis, and ECMO.
4. Introduction of catheters: An introducer is necessary for advanced procedures performed in the CCU such as pulmonary artery catheterization and transvenous cardiac pacing.
5. Volume loading: Although fluid resuscitation is not an indication for central access, large bore introducers are very helpful in massive resuscitation with fluids or multiple blood products. Patients often are in shock and need vasoactive agents as well; hence central access is preferred.

TABLE 48.4 Indications for Central Access in the CCU

THERAPEUTIC PURPOSES
Administration of vasoactive medications: vasopressors, inotropes
Administration of blood products
Aspiration for venous air embolism
Hemodialysis
Plasmapheresis
INVASIVE MONITORING
Hemodynamic monitoring
Central venous pressure monitoring
Central venous oxygen saturation ($Scvo_2$)
Pulmonary artery catheterization
Transvenous cardiac pacing
Intra-aortic balloon pump
Left ventricular assist device
MEDICATION ADMINISTRATION
Drugs with a pH < 5 and > 9
Venous irritants regardless of pH or concentration
Nutritional support (total parenteral nutrition)
VASCULAR ACCESS
Emergency venous access
Lack of peripheral access
Massive transfusion

CCU, cardiac care unit.

TABLE 48.5 Medications to be Infused Through a Central Line

DRUG	CLASS	COMMENT
Amiodarone (Cordarone)	Antiarrhythmic	Central line preferred if concentration >2 mg/mL
Calcium chloride	Electrolyte	Standard concentration (1 g/50 mL) contains three times more elemental calcium than calcium gluconate; at risk for precipitation, so CVC recommended except in case of cardiac arrest.
Dextrose in water	Nutrition/fluid	CVC preferred in high concentrations (>10%)
Dobutamine (Dobutrex)	Inotrope	Inotrope used to improve CO. Low fixed doses can be given temporarily via peripheral IV depending on institutional policy.
Dopamine (Intropin)	Adrenergic agent	Low fixed doses can be given via peripheral access depending on institutional policy.
Epinephrine (Adrenalin)	Adrenergic agent	Potent vasoconstrictor; concern for extravasation. Cardiac arrest dose (1 mg of 1:10,000) can be given peripherally.
Esmolol (Brevibloc)	Beta blocker	Short-acting beta blocker infusion; central access preferred but can be given peripherally.
Milrinone (Primacor)	Inotrope/vasodilator	Central access preferred but can be given peripherally.
Nicardipine (Cardene)	Calcium channel blocker	Venous irritant; can be infused through large peripheral IV but change site every 12 h.
Nitroglycerin	Vasodilator	Central access preferred but can be given peripherally.
Norepinephrine (Levophed)	Adrenergic agent	Potent alpha adrenergic agent, vasoconstrictor; concern for extravasation.
Phenylephrine (Neo-Synephrine)	Adrenergic agent	Works mainly on alpha adrenergic receptors. Low-dose boluses and low fixed-dose infusion can be given temporarily via peripheral access depending on institutional policy.
Potassium chloride (KC1)	Electrolyte	High concentrations (20 mEq/50 mL) infused via CVC
Sodium chloride (NaCl)	Electrolyte	Hypertonic solutions (≥ 3%) given via central line
Vasopressin (Pitressin)	Vasopressor	Vasoconstrictor; concern for extravasation

This is a limited list of medications that may be encountered in the CCU. Check your institutional policy for medications that have to be infused through a central line.

Exceptions may be made during emergencies.
CCU, cardiac care unit; CO, cardiac output; CVC, central venous catheter.

PRECAUTIONS AND CONTRAINDICATIONS

Once the patient meets criteria of appropriateness for central line placement, it is the clinician's duty to assess for contraindications specific to each potential site. As CCU patients are all critically ill, contraindications are all relative. The operator must balance the risks and benefits to truly assess the need for the CVC. **Tables 48.6 and 48.7** summarize some absolute and relative contraindications, as well as site-specific relative contraindications for central line placement. Absolute contraindications at a particular site include distorted anatomy or trauma, infected skin or soft tissue, thrombosis, existing lines or devices, and vascular injury at that site. Relative contraindications include coagulopathy and bleeding disorders; however, these patients may need emergent vascular access so the benefits must be weighed against the risks. Examples include the patient with thrombotic thrombocytopenic purpura who needs plasmapheresis or the patient on aspirin, clopidogrel, and warfarin presenting with cardiogenic shock. Efforts should be made to correct major coagulopathy; however, emergent central venous access can be potentially lifesaving and should not be delayed as a result.[8]

TABLE 48.6 Contraindications and Considerations for Central Line Placement

ABSOLUTE CONTRAINDICATIONS
Patient refuses
Uncooperative patient
Site specific:
• Skin or soft tissue infection
• Venous thrombosis
• Prior radiation or sclerosing agent
• Vascular injury
Superior vena cava or inferior vena cava injury or thrombosis
Expected risk outweighs any benefit

Presence of line, pacemaker, or defibrillator on the same side
Presence of fistula on the same side
RELATIVE CONTRAINDICATIONS
Moderate to severe thrombocytopenia
Uncorrected coagulopathy
Suspected stenosis of the target vein (hemodialysis patients)
Presence of arteriovenous Fistula
Multiple failed attempts (>2 attempts)
Patient cannot tolerate or has contraindication to Trendelenburg position (ie, stroke or intracranial hemorrhage with elevated intracranial pressure)
Mechanical ventilation on patient on high positive end-expiratory pressure (PEEP)
Hemothorax or pneumothorax on the contralateral side
Whole lung atelectasis or pneumonia in contralateral side
CONSIDERATIONS FOR AVOIDANCE OF CENTRAL ACCESS IN HOMONYMOUS SIDE
Anticipated need for limb alert in patient who will require long-term dialysis
Anticipated need for limb alert in patient who will require long-term implantable cardioverter defibrillator/permanent pacemaker
Lymphadenectomy in homonymous side after mastectomy or radiation therapy

TABLE 48.7 Site-specific Relative Contraindications for Central Line Placement

SUBCLAVIAN VEIN
Severe chronic obstructive pulmonary disease
Contralateral pneumothorax
Whole lung atelectasis or pneumonia in contralateral side
Mechanical ventilation with high positive end-expiratory pressure or oxygenation requirements
Morbid obesity or extreme cachexia

Major coagulopathy or bleeding risk—noncompressible site
Fracture of ipsilateral clavicle or anterior proximal ribs
Inability to lie in Trendelenburg position
Left bundle branch block—guide wire can potentially induce complete heart block
INTERNAL JUGULAR VEIN
Cervical spine immobilization
History of intravenous drug use
Inability to lie in Trendelenburg position
Whole lung atelectasis or pneumonia in contralateral side
Left bundle branch block—guide wire can potentially induce complete heart block
FEMORAL VEIN
Avoid site if possible, especially if patient is ambulatory
Ipsilateral deep vein thrombosis
Large pannus
Fungal skin infection

Laboratory results and use of US may alleviate some of these contraindications. The use of ultrasound imaging is an important tool for identifying preexisting thrombus formation and anatomic variations in the IJV location, and allows for a safer and more successful line placement.[9] Additionally, operator experience is a major factor with regard to overcoming relative contraindications and limiting risk of complications. Simulation-based training has been shown to improve success rates and decrease both infectious and mechanical complications rates among trainees.[10–12]

SITE SELECTION IN THE CCU PATIENT

The operator must have an individualized approach to the CCU patient, performing a thoughtful assessment to determine the safest location of insertion, the safest method, and the appropriate periprocedural care. This will depend

mostly on the experience and skill of the operator. **Figure 48.4** illustrates site-specific considerations when choosing the insertion site for central line placement. **Table 48.8** lists the anatomic landmarks to identify for each site and also the advantages, disadvantages, and complications associated with each site.

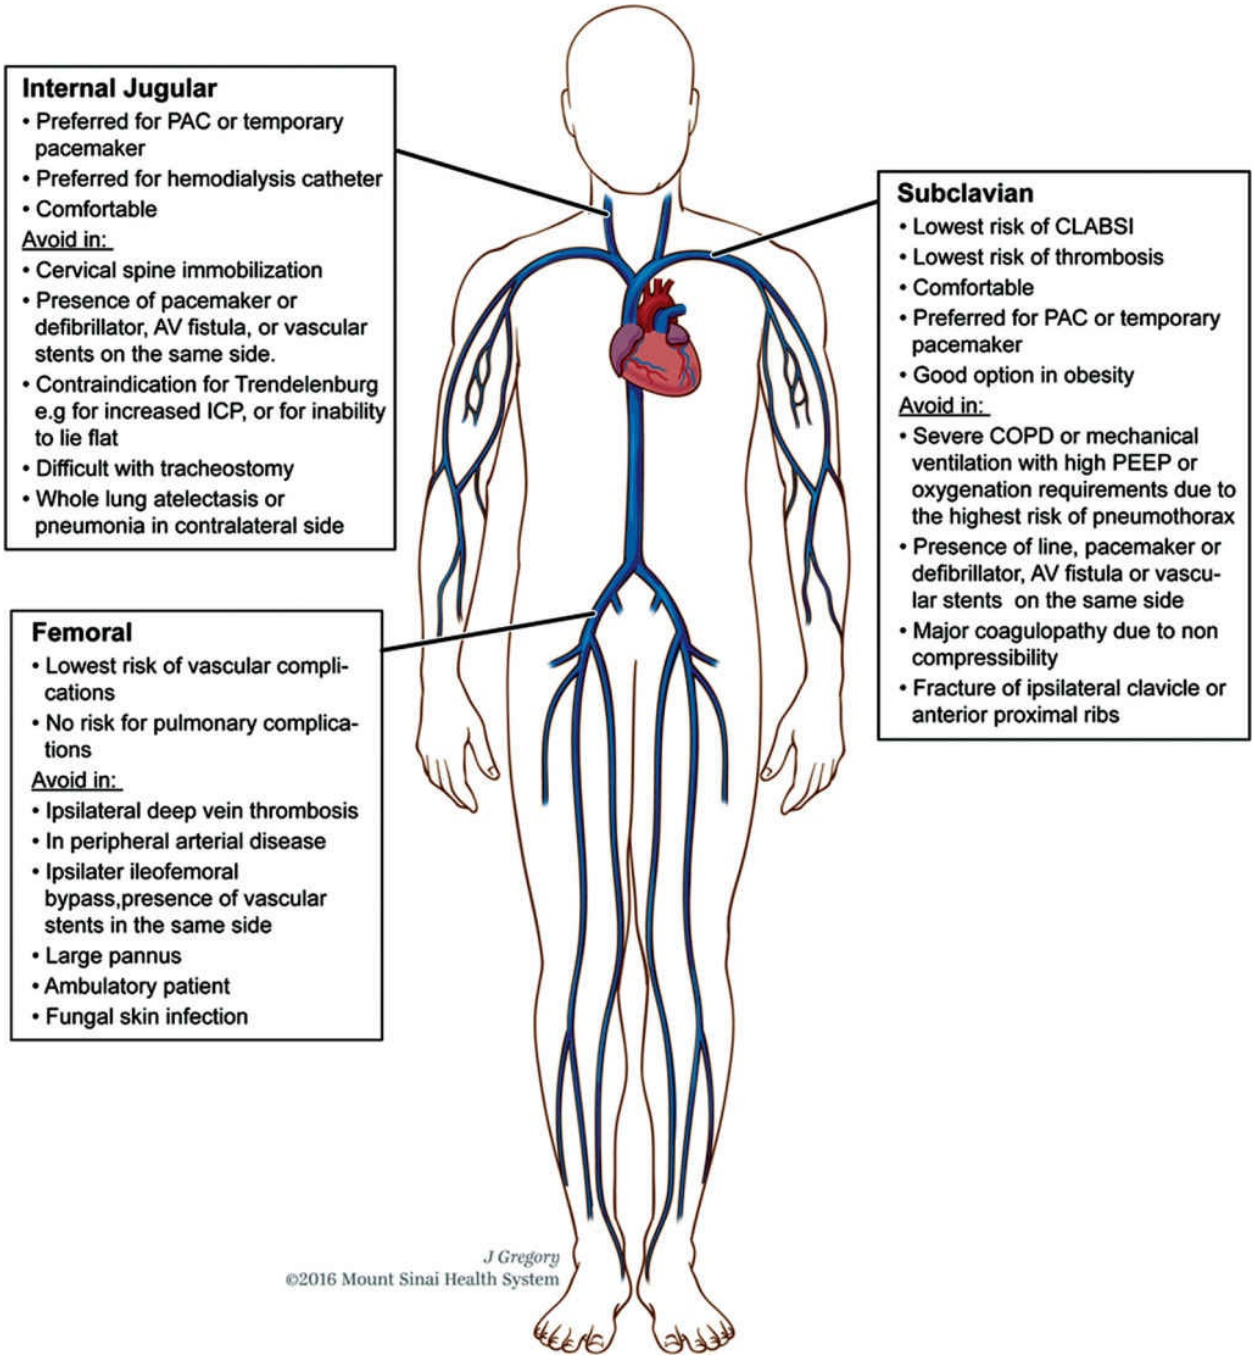

FIGURE 48.4 Site-specific considerations for central line placement. AV, arteriovenous; CLABSI, central line-associated blood stream infection; COPD, chronic obstructive pulmonary disease; ICP, intracranial pressure; PAC, pulmonary artery catheterization; PEEP, positive end-expiratory pressure.

TABLE 48.8 Site-specific Landmarks, Advantages, Disadvantages, and Complications

SITE	LANDMARKS	ADVANTAGES	DISADVANTAGES	COMPLICATIONS

Internal jugular vein	Mandibular angle Heads of sternocleidomastoid (SCM) Clavicle	Easy to locate, especially with US Straight path to superior vena cava Low complication rate Low maintenance from nursing standpoint Preferred site for pulmonary artery catheter (PAC) Low risk for malposition Lower risk of pneumothorax	Easily collapsible Proximity to: • Carotid artery • Lung apex • Thoracic duct • Phrenic/vagus nerve Higher infection rate Not preferred for short neck Difficult access during emergencies Need chest X-ray confirmation Dressings hard to maintain	Carotid puncture Infection Thrombosis Pneumothorax Arrhythmia Pleural effusion Chylothorax Brachial plexus injury Air embolism
Subclavian vein	Clavicle Suprasternal notch Manubriosternal junction 2 portions of SCM	Low infection rate Low risk for thrombosis Easily maintained Patient comfort Bony landmarks, even in obesity	Noncompressible site if bleeding Avoid in coagulopathy, cachexia, high PEEP Proximity to lung apex, thoracic duct High risk for malposition (crossing to contralateral subclavian or ipsilateral internal jugular vein) Need chest X-ray confirmation	Arterial puncture Pneumothorax Hemothorax Infection Thrombosis Arrhythmia Air embolism Chylothorax Pleural effusion Subclavian stenosis
Femoral vein	Inguinal ligament Laterally to pubic tubercle **VAN** (from medial to lateral: *vein, artery, nerve*)	Fast, easily accessed High success rate Can be used immediately Preferred for emergencies/cardiac arrest Preferred for patient in respiratory distress or on high PEEP	Highest risk for infection Highest risk for thrombosis Proximity to femoral artery No central venous pressure monitoring $scvo_2$ less reliable Prevents mobility	Infection Thrombosis Arterial puncture Retroperitoneal hematoma Arteriovenous fistula Pseudoaneurysm Inferior vena cava

	No risk of pneumothorax	Dressing changes take longer	filter dislodgement Air embolism

GENERAL RULES

As with any procedure, the operator should always weigh the risks and benefits of placing a central line at a particular site in order to avoid a high-risk complication. The operator should only attempt at a site where he or she is comfortable placing the CVC. With the popularity of US, many junior operators are very comfortable with US-guided CVC and may not feel as confident with SCV access. Always review the chest radiograph and attempt cannulation preferably on the same side as the lung pathology (ie, perform right IJV or subclavian CVC if the patient has pneumonia in the right lung). Causing a pneumothorax on the normal lung is potentially fatal. Always check a chest radiograph after unsuccessful attempts at IJV or subclavian CVC, prior to trying on the opposite side. Monitor for bleeding complications during and after CVC cannulation. A hematoma in the neck due to inadvertent puncture of the carotid artery can potentially lead to airway compromise by compressing the trachea. The subclavian site is noncompressible; so accidental cannulation of the subclavian artery may need intervention by a vascular surgeon. Similarly, bleeding in the FV or artery site can be very extensive before being recognized.

SITE-SPECIFIC CONSIDERATIONS

Subclavian Vein

The subclavian site is the most preferable site because it carries the lowest risk of CLABSI and thrombosis when compared to IJV or FV catheters; however, it has a higher risk of pneumothorax.[13] Additionally, once placed, it is a comfortable site for the patient and the catheter itself is tucked under the clavicle and less likely to be manipulated with patient movement. Accessing the SCV requires placement of the cannulation needle under the clavicle and near the apex of the lung, so it is not surprising that pneumothorax is a potential complication. Avoid SCV catheterization in patients with lung hyperinflation due to severe chronic obstructive pulmonary disease (COPD) or asthma, high F_{IO_2} and positive end-expiratory pressure while on mechanical ventilation, and patients with parenchymal lung disease and limited pulmonary reserve. Also avoid subclavian access in patients with chest wall deformities, cachexia, or

morbid obesity.

Internal Jugular Vein

This is a very popular site because it is easily accessed with ultrasonography.[9] The IJV is located under the sternocleidomastoid muscle (SCM) on either side of the neck. The right side of the neck is preferred because the vessels run a straight course to the RA. This side is preferred for PAC or temporary pacemaker placement, and hemodialysis catheter placement. IJV cannulation may be difficult in patients with tracheostomies because the tracheostomy holder often overlies the site. Additionally, oral and tracheal secretions from patients on mechanical ventilation often contaminate the IJV site, hence a transparent dressing is essential to secure the catheter and prevent CLABSI.

Femoral Vein

The FV site is associated with the fewest vascular and pulmonary complications; however it carries a higher infection rate and hence is discouraged by the CDC.[1] Interestingly, in a recent study comparing the three sites, there was no significant difference between the IJV and FV sites in rates of CLABSI; however, colonization rates were higher in the femoral site.[13] This site often limits the patient's ability to sit and walk, which can lead to deconditioning. Larger central catheters such as introducers and dialysis catheters are at risk for accidental displacement, which can potentially lead to massive hemorrhage. The FV is the choice of site for central venous catheterization during emergencies such as cardiac arrest (intraosseous access is another option) or in a patient who is in respiratory distress or agitated. It also has the added advantage in that placement does not have to be confirmed with a chest X-ray and so it can be used right away to administer lifesaving medications.

CATHETER-SPECIFIC CONSIDERATIONS

Introducer Catheter

An introducer for vascular access and resuscitation can be placed at any of three sites. If placing an introducer for insertion of PAC or temporary venous pacer in the CCU, right IJV access is preferred for direct access to the right heart. FV access for pulmonary artery catheterization is typically performed in the cardiac catheterization laboratory under fluoroscopic guidance.

Nontunneled Hemodialysis Catheter

A right IJV or FV catheter is preferred for central access for the initiation of hemodialysis in the CCU. The KDIGO guidelines for acute kidney injury (AKI) recommend (ungraded recommendation) in the order of preference: right IJV, followed by FV, then left IJV, and lastly, SCV with preference for the dominant side.[14] The subclavian and left IJV sites should ideally be avoided to limit risk of central venous stenosis. Although, the femoral site has been associated with increased risk of CLABSI, the CATHEDIA study demonstrated a lower catheter colonization rate in the FV site compared to IJV site in patients with body mass index (BMI) < 24.2 and a lower rate at the IJV site in patients with BMI > 28.4.[15]

CENTRAL VENOUS CATHETER PLACEMENT

Preparation and setup are key to successful CVC placement. Take time to optimize the setup by adjusting the height of the bed, procedure tray, and arrange the individual items in the order that they will be used. Always check the patient's platelet count, coagulation profile, and medication list (eg, anticoagulants, especially newer oral anticoagulants) prior to attempt.

STERILE TECHNIQUE

These catheters should be placed under the utmost sterile, operating room-like conditions. Always alert the CCU team including nursing and ancillary staff that a sterile procedure is going to be performed. Transit in and out of the room should be limited and anyone entering or leaving the room should wear a hat and a mask.

ULTRASOUND GUIDANCE

Numerous studies have shown that ultrasound guidance increases the first-attempt success rates and decreases mechanical and infectious complications.[9,11,16–18] The use of US for CVC placement is strongly advocated by various organizations such as the Agency for Health Care Research and Quality (AHRQ),[19] American Society of Anesthesiology,[20] American College of Surgeons,[21] American Society of Echocardiography, and Society of Cardiovascular Anesthesiologists.[22] Ultrasound guidance allows the operator to identify the target vessel and ensure that there is no thrombus within the vessel;

it allows for real-time visualization of the needle during the cannulation. Additionally, it allows confirmation of venous placement of the guide wire before dilation and placement of the catheter. Studies have shown significant variation in the size of the central vein and its position with respect to the artery (ie, deep to the artery or directly over the artery), allowing for the possibility of arterial puncture. Landmark methods lead to failure rates as high as 36%, even in experienced hands.[9,18]

US guidance is most useful for IJV and FV cannulation. Although US guidance can be used successfully for SCV access,[16] it has a steeper learning curve and should only be performed by experienced operators due to the risk of pneumothorax. Prior to inserting a central line using US guidance, the operator should perform a preprocedural scan. The portable US machine should be set to the "vascular" preset. A high-frequency linear array (ie, vascular) transducer or probe is used for this purpose because it images superficial structures well. The operator should hold the probe like a pencil with the hypothenar eminence steady on the patient's body. This allows for a steady image during the actual procedure. The marker on the transducer should always be "operator left" to match the marker on the upper left-hand corner of the screen of the US machine. Hence, the left side of the US probe corresponds to the left side of the screen. With this setup, in order to aim the needle left, one would advance the needle to the left, and vice versa. Ultrasound gel should be used as a medium to obtain the images. The depth should be adjusted such that the vessel of interest is in the center of the screen and the gain (brightness) should be optimized to ensure the image is not too bright and not too dark. Arteries have thick walls and are pulsatile, whereas veins have thin walls and are easily collapsible when pressure is applied over the vein. Bear in mind that in profound shock states, the artery may also be collapsible; however, it will still be pulsatile. Color Doppler or pulsed Doppler can be used to further confirm arterial versus venous flow.

In the short-axis or transverse plane, the vessels will appear as round circles (**Figure 48.5A**) as the ultrasound beam intersects the vessel in a cross section at a perpendicular angle.[23] In the long-axis or longitudinal view, the ultrasound beam is parallel to the vessels and the vessels will appear as long cylinders if the beam transects the vessel in the middle along its course (**Figure 48.5B**). Ensure the vein and artery are parallel to each other and not on top of each other. **Figure 48.6A and B** demonstrate examples of unsafe sites for cannulation as the carotid artery and IJV are not parallel to each other. Gentle side-to-side tilting of the transducer can often assist in optimizing the vessels such that they are parallel to

each other. Image the vein up and down in the transverse view to ensure patency. Do a compression maneuver by applying gentle pressure in at least three sites to ensure there is no thrombus (**Figure 48.7**). This is a leading cause of unsuccessful CVC placement; so avoid the site and order a comprehensive study through the radiology department. **Figure 48.8A and B** show examples of intraluminal thrombus detected prior to IJV CVC placement. This patient actually had left IJV thrombophlebitis due to *Fusobacterium necrophorum* sepsis with septic emboli to the lungs and other organs, also known as Lemierre syndrome. **Figure 48.9A and B** show the CT scan of the neck to correlate with the US findings. **Table 48.9** summarizes the steps for preprocedural ultrasound scan, which should always be done prior to US-guided line placement.

TABLE 48.9 Steps for Line Placement: Preprocedural Ultrasound Scan

STEP	DESCRIPTION
1	Set ultrasound machine in “vascular” preset mode.
2	Hold vascular probe like a pencil with hand resting on patient.
3	Ensure probe marker is “operator left.”
4	Identify vein and artery.

5	Optimize gain and depth, ensuring vein is in center of screen.
6	Scan up and down the vessel to ensure patency.
7	Do a compression maneuver at three sites along the vessel to ensure no thrombus.
8	Ensure vein and artery are parallel to each other.
9	Image both sides for optimal site selection.
10	Identify safest site for cannulation.

Once a safe site is identified, cannulation should be performed with the thin-walled introducer needle with the needle inserted at a steep angle (70 to 90 degrees) and directly beneath the center marker of the probe. The US probe is held steadily with the nondominant hand and the needle advanced with the dominant hand. The needle and syringe apparatus may have to be jiggled gently because it is being advanced in order to appreciate the needle on the screen. Once there is good blood flow, the angle should be decreased prior to inserting the guide wire. Alternatively, a lower angle (30 to 60 degrees) can be used with the ultrasound probe being advanced as the needle is being advanced, with gentle back-and-forth sweeping of the probe to identify and follow the tip of the introducer needle directly into the vein (**Figure 48.10**). US can also be used for confirmation that the guide wire is in the vein and not the artery. Once the guide wire is inserted, the needle should be removed and the vein imaged in both the transverse and longitudinal planes. The guide wire should be visualized in the longitudinal plane within the thin-walled vein, which will be compressible with gentle pressure (**Figure 48.11). Be careful not to confuse this with the artery, which is immediately adjacent but will be thick walled, noncompressible, and pulsatile. A sterile probe cover should always be used in central venous catheterization. We recommend dynamic real-time use of ultrasound guidance over static US, where the skin overlying the central vein is marked due to higher success rates.**[18]

LINE PLACEMENT

The following instructions apply for all central venous access sites:

Step 1: Consent

Explain the necessity and benefits of the procedure in layman terms to the patient or surrogate, as well as the risks as described earlier; convey that this is a routine and frequently performed procedure in the CCU. Assure that you will provide local anesthesia to limit pain during the procedure and that the patient will need to be under a sterile drape for an approximate period of 20 to 30 minutes. In life-threatening situations, consent may be deferred if the procedure

is critical (eg, CVC placement for shock states) to treatment.

Step 2: Review Chart

It is imperative that the operator reviews the patient's laboratory data, medications, and chest radiograph to assess the safety of the procedure and for site selection. Consider platelet transfusion or reversing coagulopathy with fresh frozen plasma in the appropriate setting, if time allows.

Step 3: Prepare Equipment

Depending on the manufacturer, the central line kit will contain the basic items necessary to perform central venous catheterization (**Figure 48.12**). Many institutions have prepackaged customized procedure kits or a central line cart, which contains all the additional items necessary for CVC placement (**Figure 48.13**). Essential items to bring to the bedside include the central line kit, procedure pack or cart, ultrasound machine, ultrasound probe cover, and a bedside procedure table. **Table 48.10** contains a checklist of items necessary for central line placement.

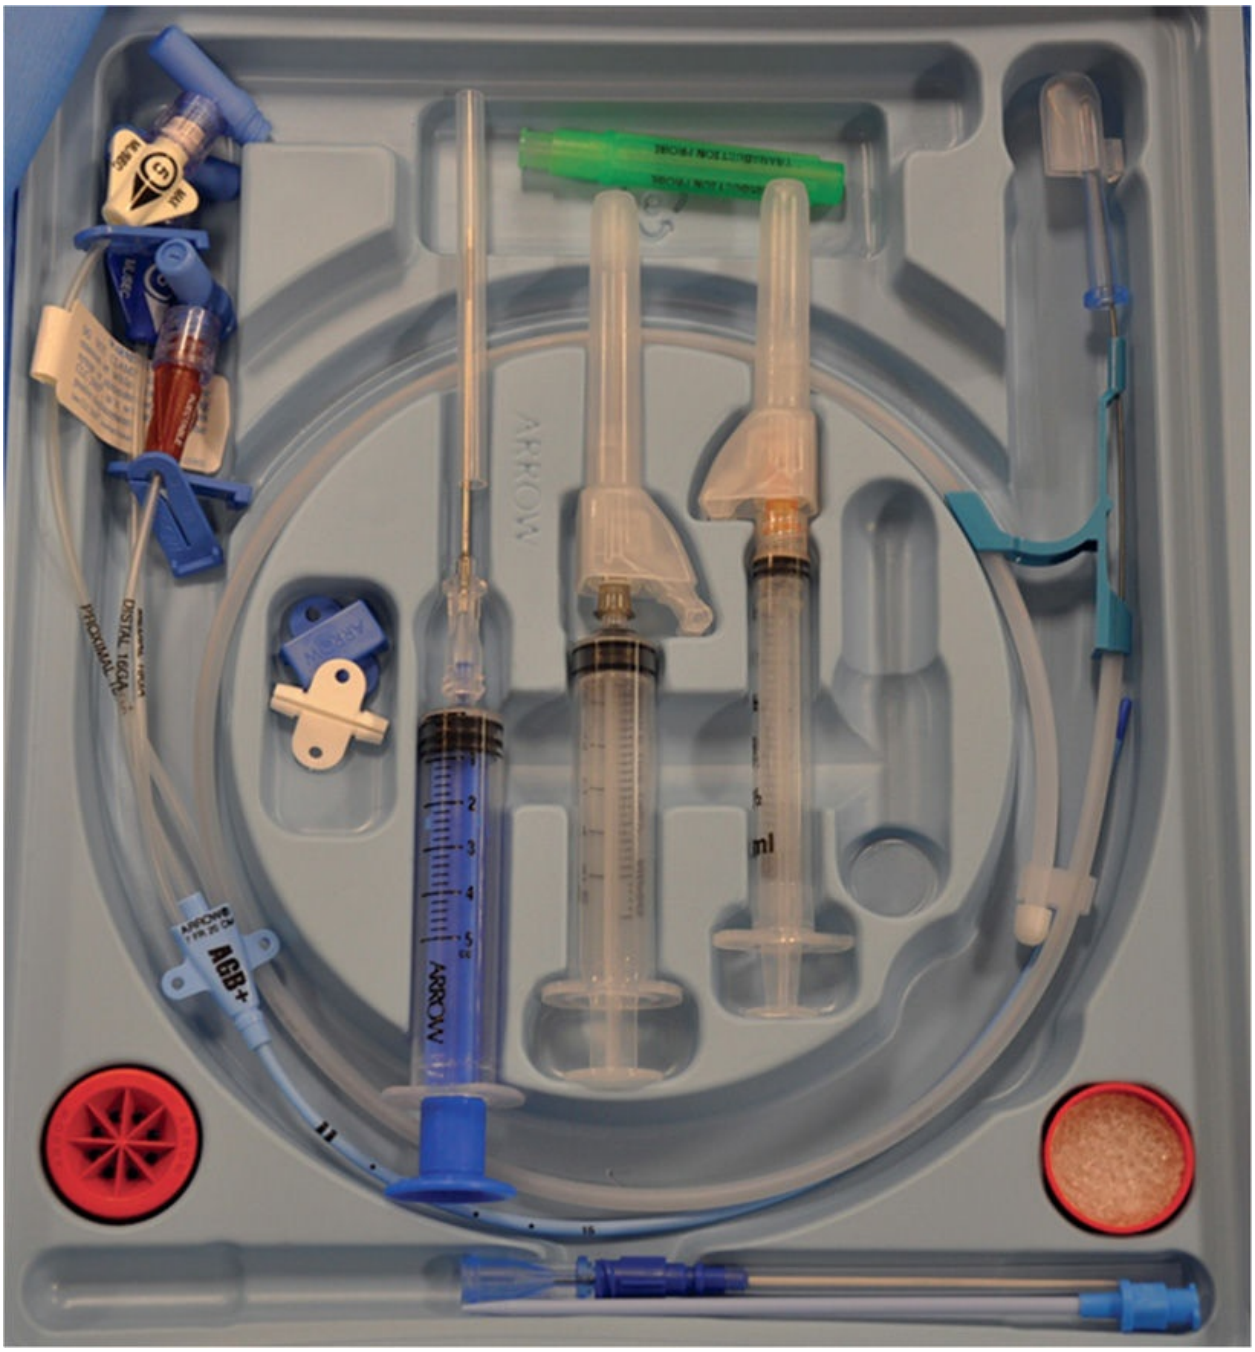

FIGURE 48.12 Central venous catheter kit.

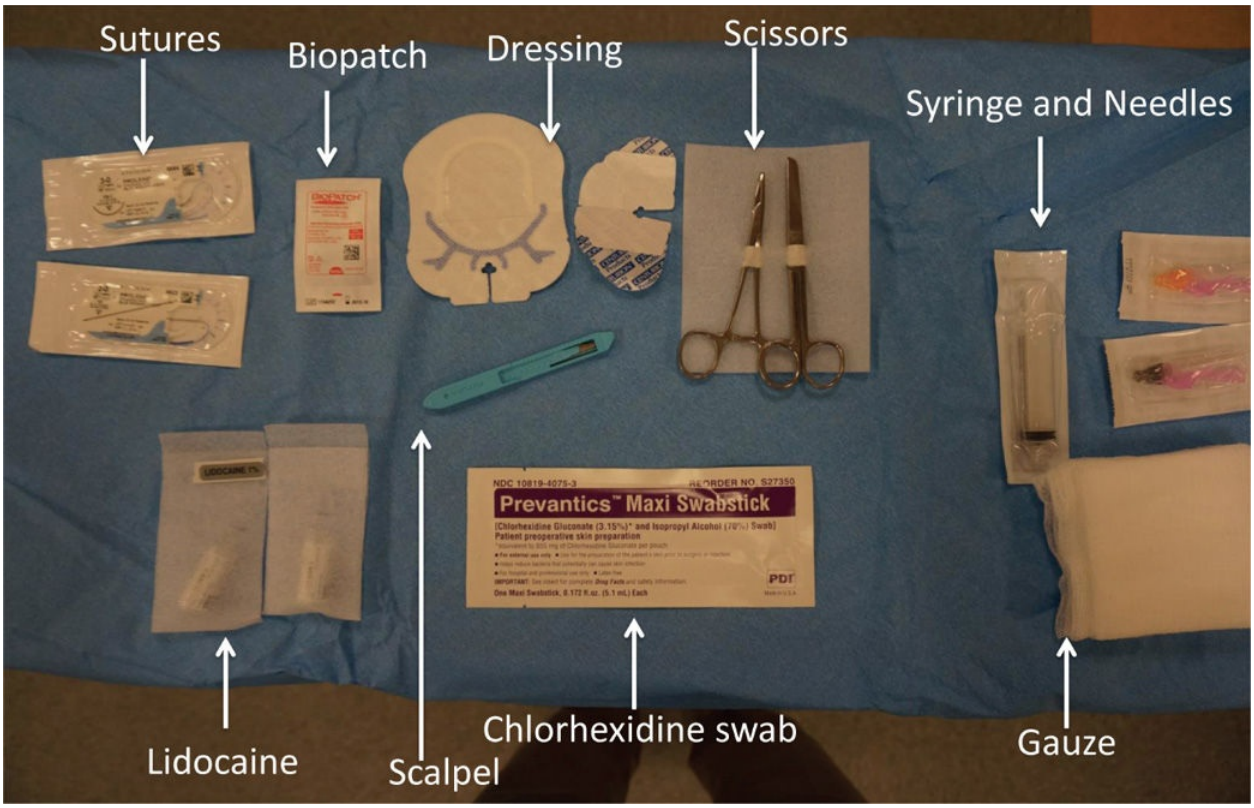

FIGURE 48.13 Additional items necessary for central line placement.

TABLE 48.10 Checklist of Items Necessary for Central Venous Catheterization

CENTRAL LINE KIT
Triple lumen catheter with Luer Lock caps
1% lidocaine 5 mL vial
25G × 1″ needle with 3 mL syringe for lidocaine administration
22G × 1.5″ “finder” needle with 5 mL syringe
18G × 2.5″ steel introducer needle with 5 mL Luer slip tip syringe
18G angiocatheter needle (in some kits)
GUIDE WIRE
Scalpel (#11)
Tissue dilator

Anchoring clips (clamp and fastener)
Needle holder
PROCEDURE CART OR PROCEDURE PACK ITEMS (IN ORDER OF USE)
2 surgical hair covers (one for assistant)
2 masks with eye shields (one for assistant)
Sterile gloves (for prepping) of appropriate size
2 chlorhexidine swabs/scrubs
Sterile gowns
Sterile gloves (for procedure) of appropriate size
Full-body fenestrated drape
3 sterile saline-filled syringes (or empty 10 mL syringe)
Medication label: 1% lidocaine
Sutures: 3.0 silk or nylon with curved or straight needle
Needle holder/driver for curved needle (if applicable)
Scissors (optional)
Gauze: 2″ × 2″ or 4″ × 4″ pads
Biopatch protective disk
Transparent, occlusive dressing
ADDITIONAL ITEMS
Portable ultrasound machine with linear array (vascular) probe
Sterile probe cover
Disposable underpad (blue Chux)

Step 4: Time-out

Prior to performing the actual procedure, it is important to engage the CCU nurse and any procedural assistants to conduct a preprocedural verification.

Perform and document a “Time-Out” as per your institution’s standardized protocol. All members should agree on the following:

1. Correct patient using two identifiers (name and date of birth or medical record number);
2. Correct procedure to be performed;
3. Correct site of insertion;
4. Ensure the procedural consent form is signed and dated.

Any concerns about procedural risks should be vocalized at this point. The assistant or any team member should be empowered to halt the procedure if inappropriate technique or break in sterility occurs.

Step 5: Patient Preparation

With an assistant’s help, optimize the position of the patient and the bed before sterile barrier precautions are in place. Once the site is prepped and draped, it is difficult and inconvenient to reposition the patient and optimize the procedural settings. Ensure the patient is on a monitor. Place the patient in Trendelenburg position, with the head of the bed tilted 15 degrees posteriorly. If US is being utilized, do a prescan of the venous anatomy on both sides and identify a safe site for venous access. A disposable underpad may be placed under the proposed insertion site to prevent blood contaminating the patient’s bed.

Internal Jugular Vein

Ensure the patient is in Trendelenburg position with the head slightly turned 45 degrees to the contralateral side from the intended insertion site. Anatomic landmarks for the IJV begin at the triangle formed by the heads of the SCMs and the clavicle (**Figure 48.14**). The surface projection of the IJV runs from the ear lobe to the medial clavicle, between the sternal and clavicular heads of the SCM. It increases in diameter as it descends to meet the SCV. Trendelenburg position and Valsava maneuver increase the size of the IJV. The IJV is easily collapsible and can often not be visualized due to excessive pressure by the ultrasound probe or the operator’s finger. Excessive head rotation can increase the overlap of the carotid artery over the IJV, increasing risk of arterial injury. Hence, US guidance is strongly recommended for IJV cannulation. The Trendelenburg position also minimizes risk and complications of venous air embolism. Caution is advised for patients with elevated intracranial pressure, congestive heart

failure, or other patients who cannot lay flat. These patients may be left in a comfortable position for most of the procedure (ie, prepping, draping) and then briefly placed in Trendelenburg position immediately before the cannulation portion.

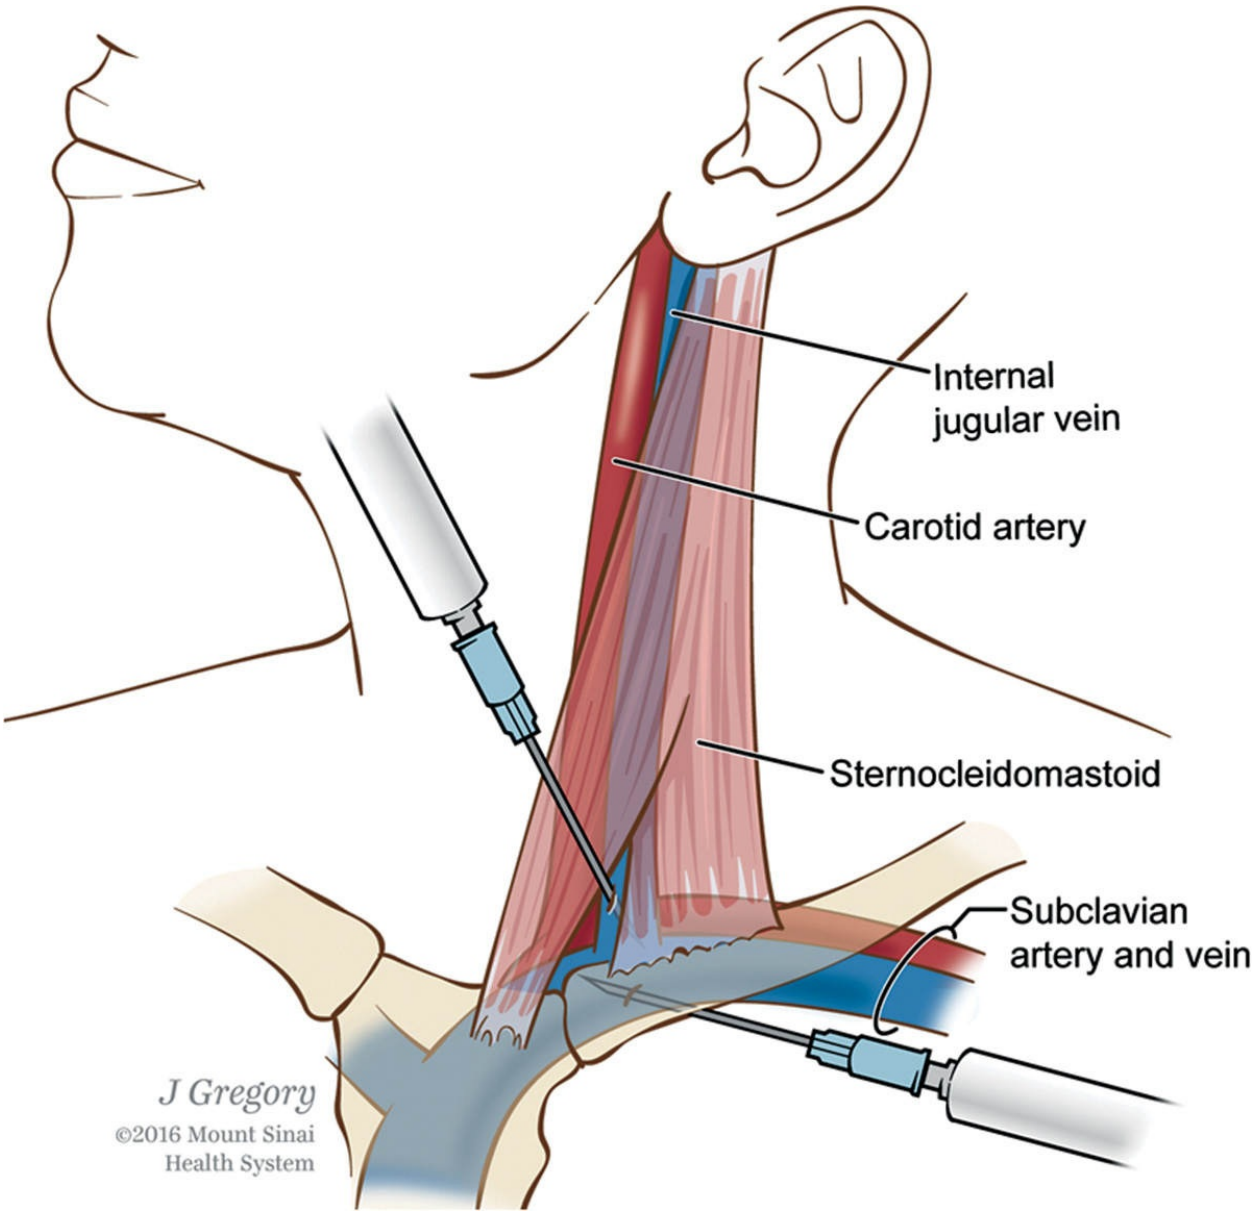

FIGURE 48.14 Internal jugular vein and subclavian vein anatomy.

Subclavian Vein

The SCV (**Figure 48.14**) is a continuation of the axillary vein and begins at the lateral edge of the first rib.[24] It courses anterior to the anterior scalene muscle, which separates it from the subclavian artery. It joins the IJV to form the brachiocephalic trunk. The pleural surface lies inferior and posterior to the SCV. The subclavian artery is immediately posterior to the vein. The SCV is usually not collapsible because it is tethered by fibrous connective tissue to the clavicle and first rib. This is especially helpful in the hypovolemic patient or during

cardiac arrest. The thoracic duct joins the left SCV at its junction with the IJV. Right SCV cannulation is preferred in order to avoid thoracic duct injury; however, it has also been shown to have higher mechanical complications such as malpositioning.[25]

Prior to cannulation, place the patient in a 15-degree Trendelenburg position and assess the anatomic landmarks, beginning with the middle third of the clavicle. Follow the clavicle laterally to the "bend" where it deviates superiorly from the proximal ribs. Just medial to this point, the SCV and IJV run inferior to the clavicle. The insertion site should be somewhat removed from the clavicle, so that the path of the needle stays parallel under the clavicle. The typical point is 2 cm lateral and 2 cm caudal to the middle third of the clavicle. Some operators place a rolled towel vertically under the spine to identify the external landmarks. Know that propping the shoulder or turning the head has been shown to decrease the size of veins. Although the traditional landmark approach is preferred by many, several articles suggest that US can increase the likelihood of success.[16,26]

Femoral Vein

For optimal exposure of the femoral region, place the patient in supine position, externally rotate and abduct the patient's leg away from midline.[27] The common FV lies medial to the common femoral artery as it runs distal to the inguinal ligament (**Figure 48.15**). The mnemonic "VAN" illustrates the contents of the femoral sheath (see **Figure 48.15**) from medial to lateral: femoral *v*ein, femoral *a*rtery, and femoral *n*erve. The femoral artery lies at the midpoint of a line connecting the pubic symphysis (PS) to the anterior superior iliac spine (ASIS). The FV lies 1 cm medial to the femoral artery. Localize the FV by palpating the artery or with US. The cannulation site must be inferior to the inguinal ligament. Reverse Trendelenburg position, with the feet tilted 15 degrees below the horizontal axis, can help engorge the FV and may aid in visualization.

Step 6: The Technique—The A to Z of Central Venous Catheterization

Dr. Seldinger developed the "Seldinger technique" in 1953.[28] More than 60 years later, the same technique is the gold standard for most vascular access procedures.[23,24] **Figure 48.16** illustrates the steps of the modified Seldinger technique where a needle is used to aspirate blood or fluid, a guide wire inserted through the needle, the tract dilated, and a catheter advanced into the vessel or desired space.

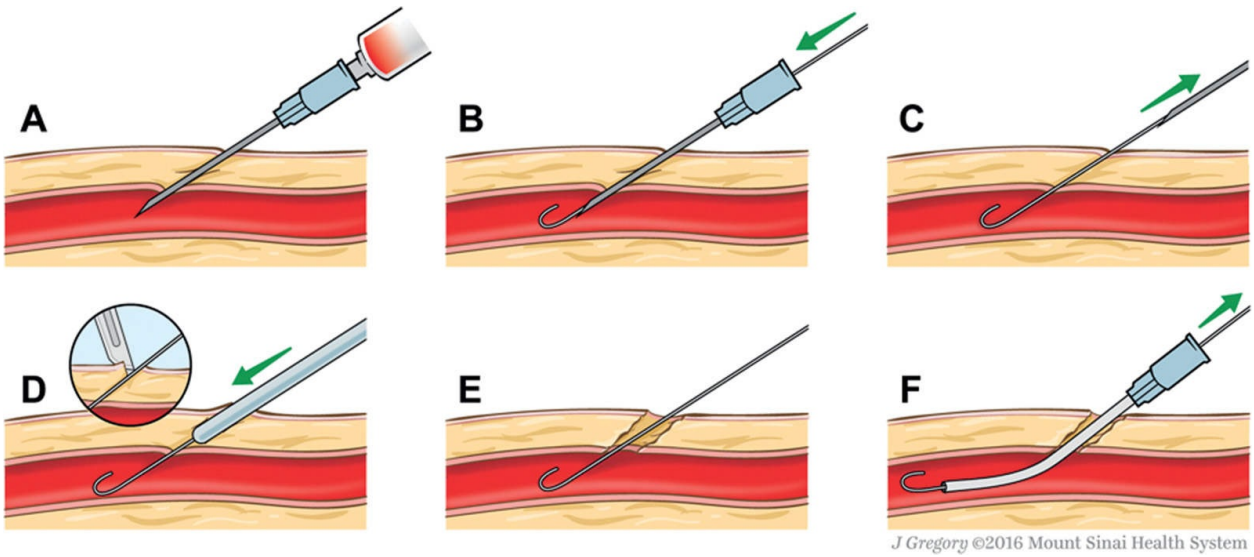

FIGURE 48.16 The Seldinger technique. A, Insert the needle into the vessel, advancing slowly until blood is aspirated. B, Stabilize the needle and insert the guide wire into the introducer needle. C, Remove the needle. D, Make a small skin incision and advance the dilator over the guide wire. E, Remove the dilator. F, Advance the catheter over the guide wire and then remove the guide wire.

The following is a list of steps for central venous catheterization using US guidance. Don a facemask with eye shield and a surgical hat ensuring all hair is tucked away. Jewelry or watches, which may be in the field, should be temporarily removed. Assistants and all personnel in the room should also wear a hat and mask.

A. Perform hand hygiene by washing hands for 30 seconds with soap and water or using an alcohol-based hand rub, taking care to cover areas such as the wrists, finger webs, and area under fingernails.

B. Don sterile gloves in sterile fashion. Open the wrapper widely, ensuring that

the sides of the wrapper do not fall back on the sterile gloves and contaminate it. Use care to touch only the inside of the glove with bare hands.

C. Prepare site using chlorhexidine-based swab or scrub with a back and forth motion for 30 seconds. Prepare a wide area and allow up to a minute for the solution to dry.

D. Deglove and perform hand hygiene once again.

E. Don sterile gown using correct technique. Put both hands into armholes and hold the gown away from the body allowing it to unfold completely. Minimize exposure of the hands outside the cuff. The assistant should pull the gown over the shoulder and tie the top portion and the inner belt of the gown, touching only the inside portion.

F. Don sterile gloves ensuring the cuffs of the gown are inside the sterile glove. Inspect the wrist to ensure that there is no exposed skin.

G. Grasp the belt card, wait, and hand it to the assistant. Make a counterclockwise turn and retrieve the outer belt from the assistant, who holds on to the belt card. Tie the outer belt firmly.

H. Hold the sterile full-body fenestrated drape and arrange it such that the head and feet match up with that of the patient. Remove the adhesive stickers and fold it gently like a book. Place the drape on the patient ensuring the fenestrated opening is directly on the insertion site. Pat down the drape to ensure it sticks to the body before opening. With one hand keeping the drape in place, gently open the sides of the drape like a book. The assistant can help extend the full-body drape by touching only the nonsterile edges of the drape. Be careful to avoid “drape creep,” whereby the drape is moved around, pulling material from the unprepped area to the sterile field.

I. The assistant should open the CVC kit and the operator should grasp the inside sterile cover and place the kit on the procedure table. Unfold the central line kit on the procedure table and position the contents at easy reach and in the order that you will use them. Take utmost care to ensure the contents do not get contaminated.

J. Prepare the TLC by placing Luer lock caps on the proximal (white) and medial (blue) ports, leaving the distal (brown) port open to allow exit of the guide wire. Flush the catheter lumens with sterile saline. If prepackaged sterile saline syringes are not available, three empty sterile syringes and a blunt needle can be used to aspirate sterile saline from a 50 mL saline bag with the assistant’s help. Alternatively, sterile saline can be spurted onto the

CVC kit from a prefilled 10 mL saline flush by the assistant. Prepare the guide wire by pulling back the J-shaped tip of the guide wire into the tapered hub.

K. Draw up 1% lidocaine local anesthetic using the 22G needle and syringe. Label the syringe with a lidocaine sticker. Note that the labeling is a requirement in the United States by the Joint Commission. This is done to ensure that the lidocaine is not confused with sterile saline and accidentally administered intravenously. Use a 25G needle for the initial injection over the skin.

L. If US is being utilized, drape the ultrasound probe with the sterile probe sheath. Hold the outside of the sterile cover and place sterile ultrasound gel (usually comes with the kit) inside the sheath. Have the assistant feed the nonsterile ultrasound probe into the inside of the sterile sheath, ensuring sterile gel is on the footprint of the probe. Grasp the sterile cover with the probe within and pull the sheath to cover the wire of the transducer. Do not touch the nonsterile probe or wire during this process. Place elastic bands or fasteners (comes with kit) to secure the outer cover so that it does not interfere with the procedure. Identify an area on the sterile field on which the probe can be placed when not in use. Be careful not to drag any uncovered parts of the wire into the sterile field.

M. Place gel onto the sterile probe and obtain a view where both the central vein and artery are visualized parallel to each other. The probe may need to be moved slightly up and down until the largest and safest site is identified. The assistant may need to further adjust the gain and depth to obtain an optimal view of the vein at the center of the screen.

N. Anesthetize the area over the insertion site, as well as the suture site, with 1% lidocaine. Make a wheal over the skin with the 25G needle and administer additional lidocaine in the soft tissue. Use the 22G needle if a longer needle is necessary, aspirating intermittently with the syringe to ensure a vessel is not entered. US guidance may be utilized to practice precise administration of the local anesthetic directly over the vein. Even in sedated patients, it may be wise to administer local anesthesia to ensure that they are not in pain and moving during the procedure.

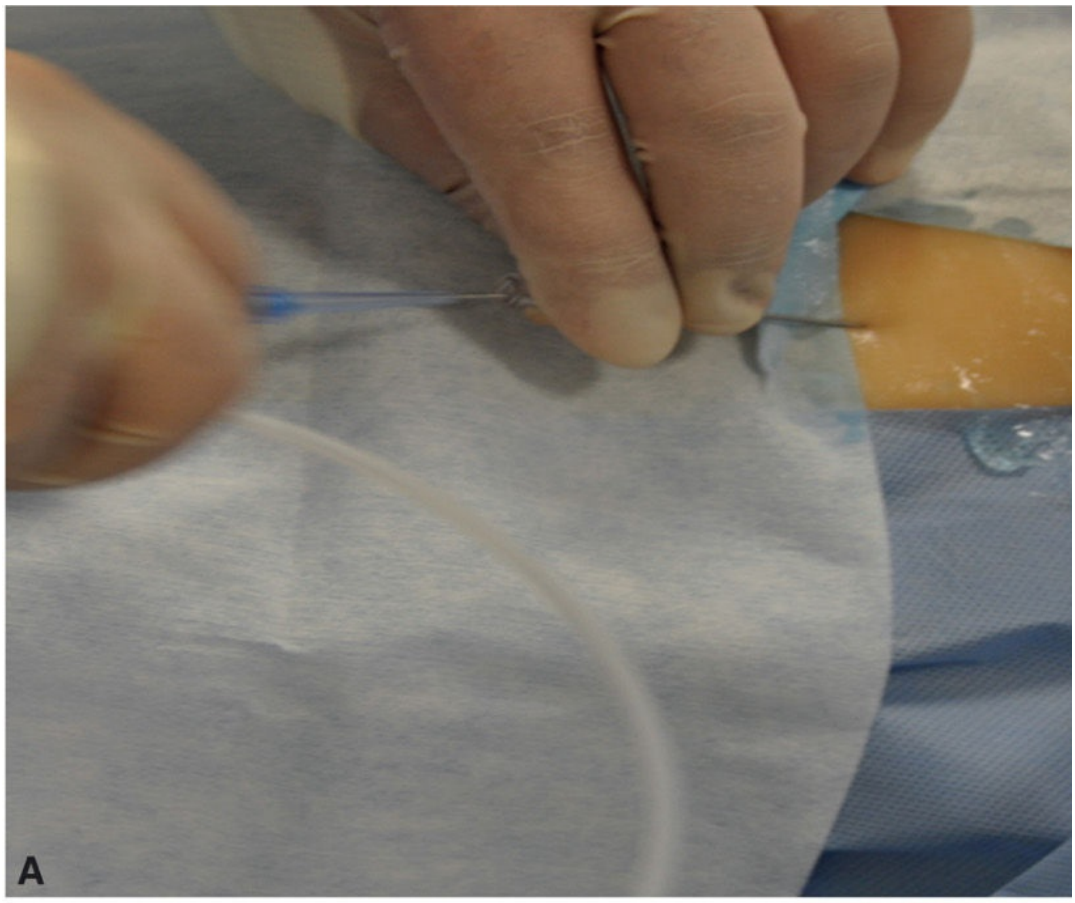
O. Prior to the actual central venous catheterization, arrange your equipment on the sterile procedure table in the order that you will use them: introducer needle, guide wire, gauze, scalpel, dilator, TLC, saline flushes. Scrambling to find these items during the procedure can often result in need for multiple

attempts.

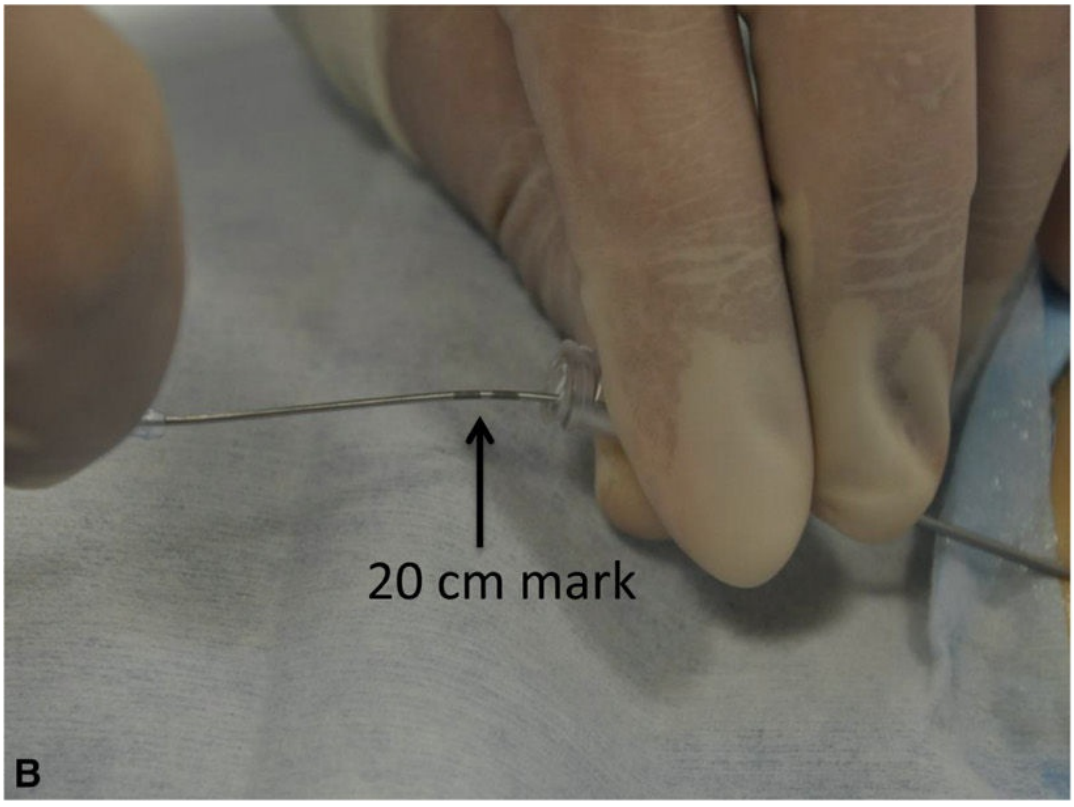
P. Hold the ultrasound probe with your nondominant hand, steadying it by resting it on the patient. Obtain a transverse view and ensure the vein is at the center of the screen. Identify the distance to the vessel by looking at the distance scale on the right-hand side of the US monitor. A needle cap or the dilator can be used to apply pressure onto the skin to ensure the proposed insertion site is directly over the vein. With the dominant hand, insert the needle and slip-tip syringe (bevel up) immediately proximal to the probe at the center marker. Insert the needle using a steep angle (70 to 90 degrees) and advance the needle slowly into the vein, applying gentle negative pressure on the syringe (**Figure 48.17**). The skin may need to be made taut and a quick jab may be needed initially to pierce through the skin. The needle may need to be jiggled to identify it on the screen of the US machine. Alternatively, a lower angle (30 to 60 degrees) may be used with back and forth sweeping of the probe to follow the needle tip into the vein (**Figure 48.10**). Once the needle tip is directly over the vein, a quick jab may be needed to pierce through the vessel wall.

FIGURE 48.17 Needle position at center of linear array probe.

Q. When blood is aspirated, stop advancing and decrease the angle of the needle, ensuring good venous blood flow with negative pressure. Stabilize the needle by holding the needle with your thumb and index finger, steadying the needle by resting your hand on the body (**Figure 48.18A**). Remove the syringe from the needle making sure not to displace the needle from the vessel. Once you remove the syringe, nonpulsatile dark red blood is expected to flow gently. Pulsatile or bright red blood may indicate arterial cannulation. Remove needle and hold pressure if this occurs.



A



20 cm mark
B

FIGURE 48.18 A, Stabilization of the needle and insertion of the J-shaped guide wire. B, Advancement of the guide wire 20 to 25 cm.

R. Insert the guide wire into the introducer needle and advance it to 20 to 25 cm (**Figure 48.18A** and **B**). Each black mark on the guide wire indicates 10 cm. Monitor for arrhythmias if IJV or SCV is being cannulated. If you meet resistance, DO NOT force the guide wire. Resistance may indicate that the introducer needle may be against the vessel wall or intersection or may have come out of the vessel altogether. If this occurs, try withdrawing the guide wire, rotating it slightly, and decreasing the angle before readvancing it. If there is resistance still, remove the guide wire and confirm again your position into the vessel with US until blood is aspirated again into the syringe.

S. Once the guide wire is in, always keep a firm grip on it, especially after dilation. Now remove the needle and confirm the position of the guide wire with US by visualizing it in the vein in both the transverse and longitudinal views (**Figure 48.11**). In the transverse view, back-and-forth sweeping of the probe may be needed to visualize the guide wire entering the vein. In the longitudinal view, do not confuse the vein (compressible) and artery (pulsates when compressed).

T. Keeping the skin taut, make a small 1 to 2 mm nick with the number 11 blade at the insertion site with the scalpel (**Figure 48.19**). With the skin taut, advance the dilator over the wire in a twisting motion and dilate the skin and subcutaneous tissue only (**Figure 48.20**). Once the tract is dilated, remove the dilator and use gauze to control any bleeding that occurs after dilation. Keep hold of the guide wire at all times, particularly after dilation, to avoid inadvertent insertion into the vessel.

FIGURE 48.19 Skin incision with dull side of scalpel.

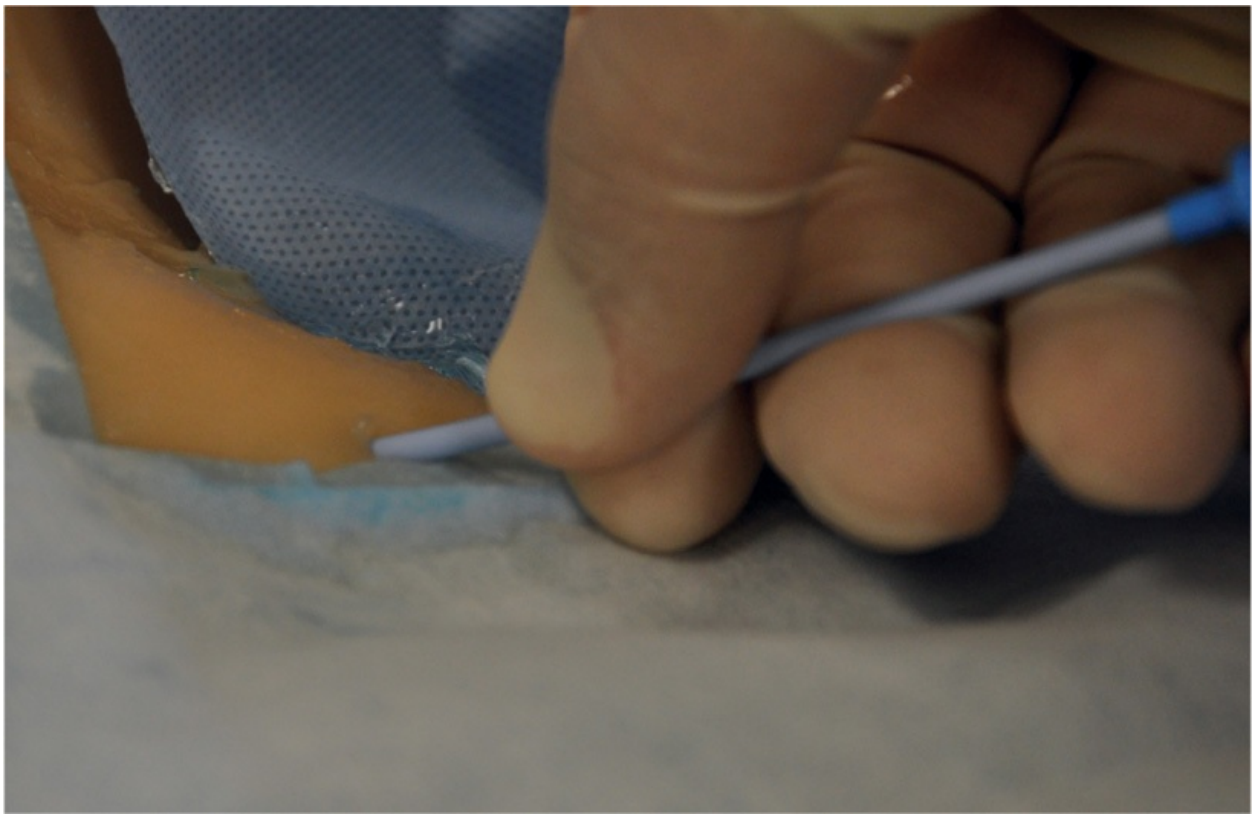


FIGURE 48.20 Dilation of the skin and soft tissue.

U. Thread the guide wire through the distal tip of the catheter until it comes out through the distal (brown) port of the TLC (**Figure 48.21A** and **B**). While holding the guide wire static with your nondominant hand, advance the catheter over the wire with your dominant hand to the desired depth (**Figure 48.21C**). Remove the guide wire and immediately cap the distal brown port. Confirm blood return from all ports and ensure all lumens flush without resistance. **Table 48.11** contains suggested depths to insert subclavian and IJV catheters. Depending on the height and gender of the patient, SCV and IJV CVCs can be advanced to the suggested depth. For IJV and SCV, the catheter tip should be in the SVC above its junction with the RA, with the distal tip parallel to the vessel wall. Femoral lines can generally be advanced all the way and secured.

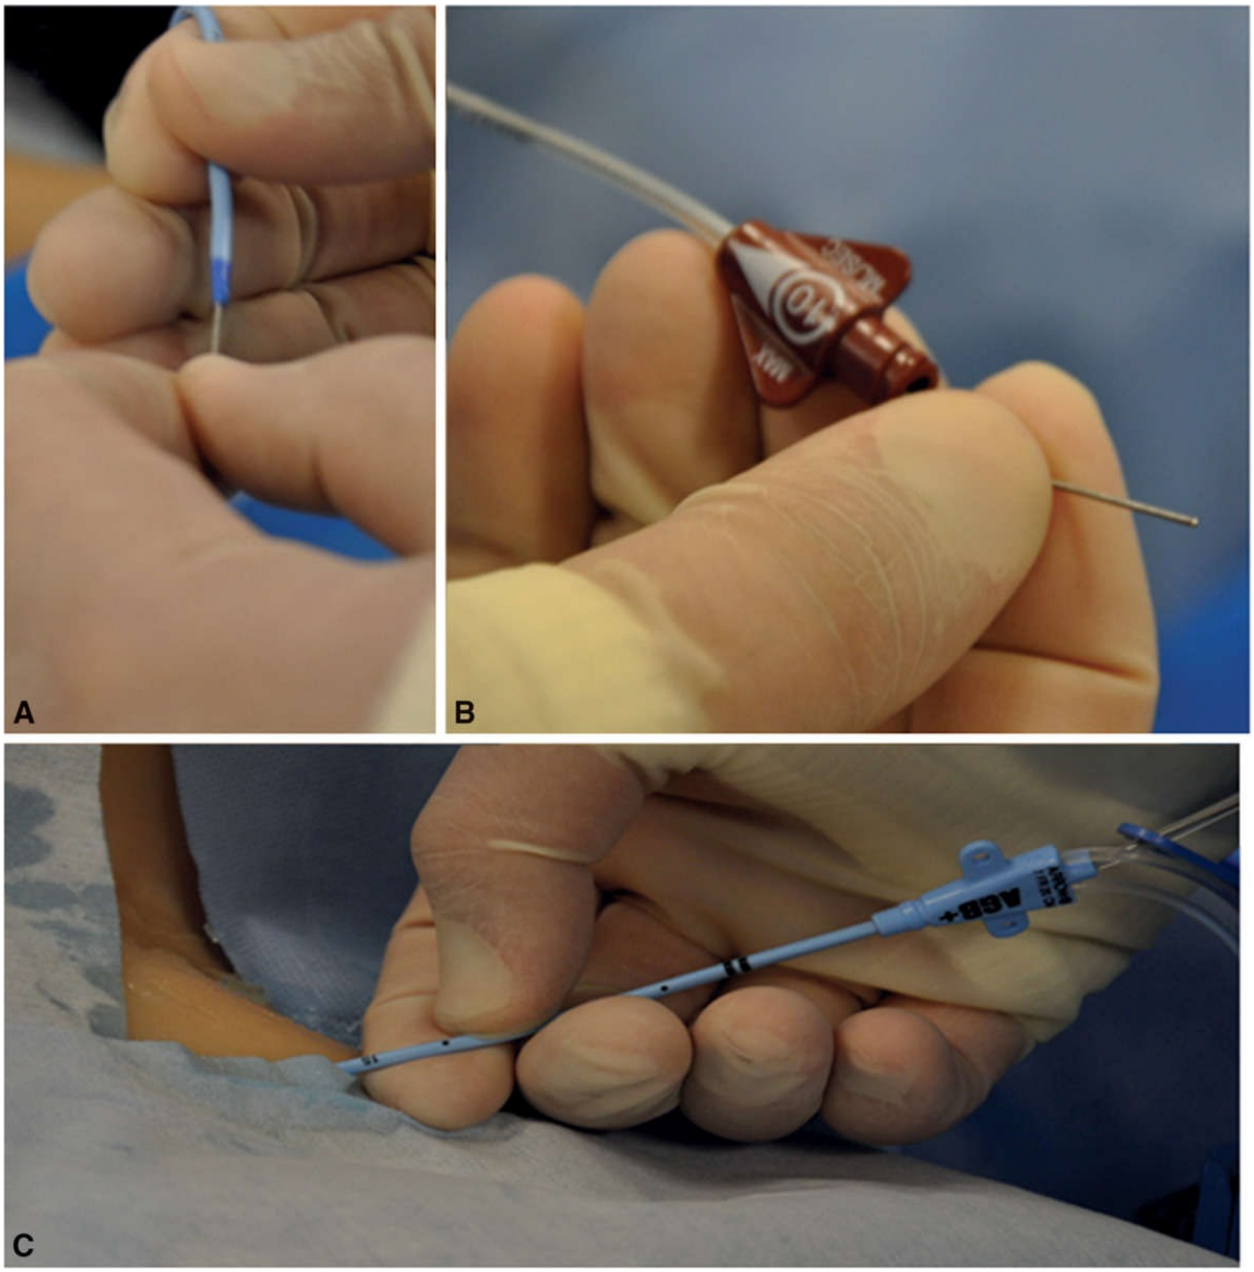

FIGURE 48.21 Advancement of the catheter over the guide wire. A, Insert the guide wire into the tip of the catheter. B, Thread the guide wire until it comes out through the distal port of the catheter and grasp the guide wire. C, Advance the catheter over the guide wire and then remove the guide wire.

TABLE 48.11 Depth of Central Venous Catheter Insertion

SITE	SUGGESTED DEPTH	FORMULA-BASED (HEIGHT IN CM)[a]
Right SCV	15–17 cm	(Height/10) – 2 cm
Right IJV	16–18 cm	Height/10

Left SCV	18–20 cm	(Height/10) + 2 cm
Left IJV	18–20 cm	(Height/10) + 4 cm

[a]There are no well-controlled studies of height-based formulas supporting their routine use.
IJV, internal jugular vein; SCV, superior vena cava.

V. Clean the site with alcohol or chlorhexidine and allow it to dry. Place the blue and white catheter anchoring clips over the catheter (SCV and IJV), and a Biopatch on the catheter at the insertion site (**Figure 48.22A**).

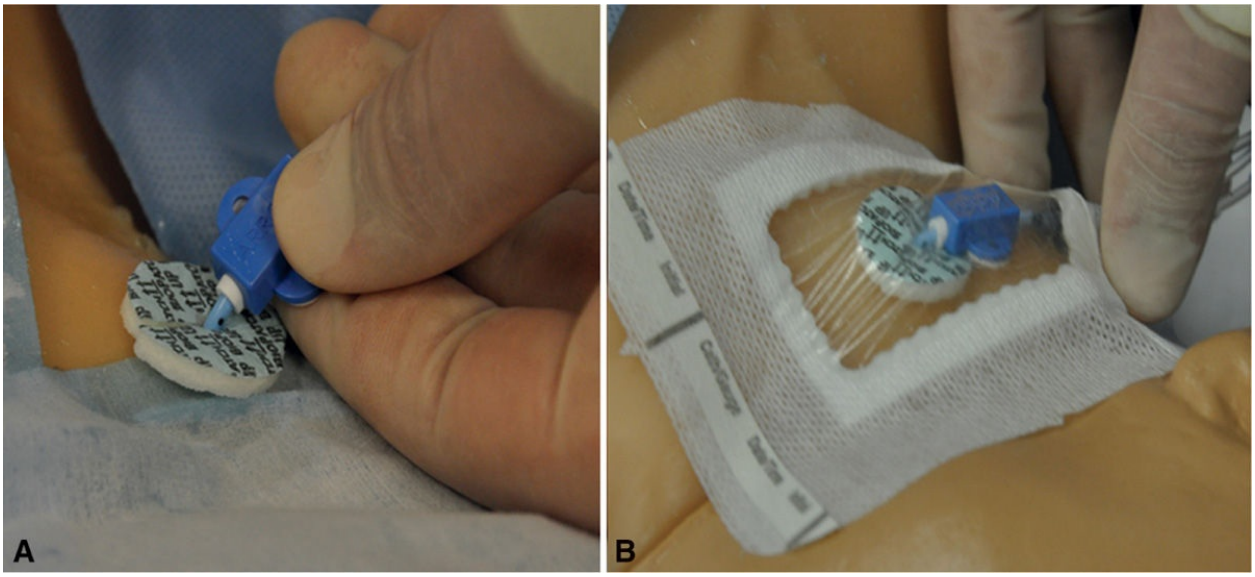

FIGURE 48.22 Securement of central venous catheter with anchoring clips, sutures, and transparent dressing.

W. Suture the line in place. Clean and apply a sterile, transparent, occlusive dressing (**Figure 48.22B**).

X. Uncover the patient, discard all the sharps in the sharps container and order a portable chest radiograph to confirm position.

Y. Write a procedure note.

Figure 48.23 delineates a step-by-step algorithm of central venous catheterization using the steps already described. Additional landmark approaches and site-specific techniques are described in later sections.

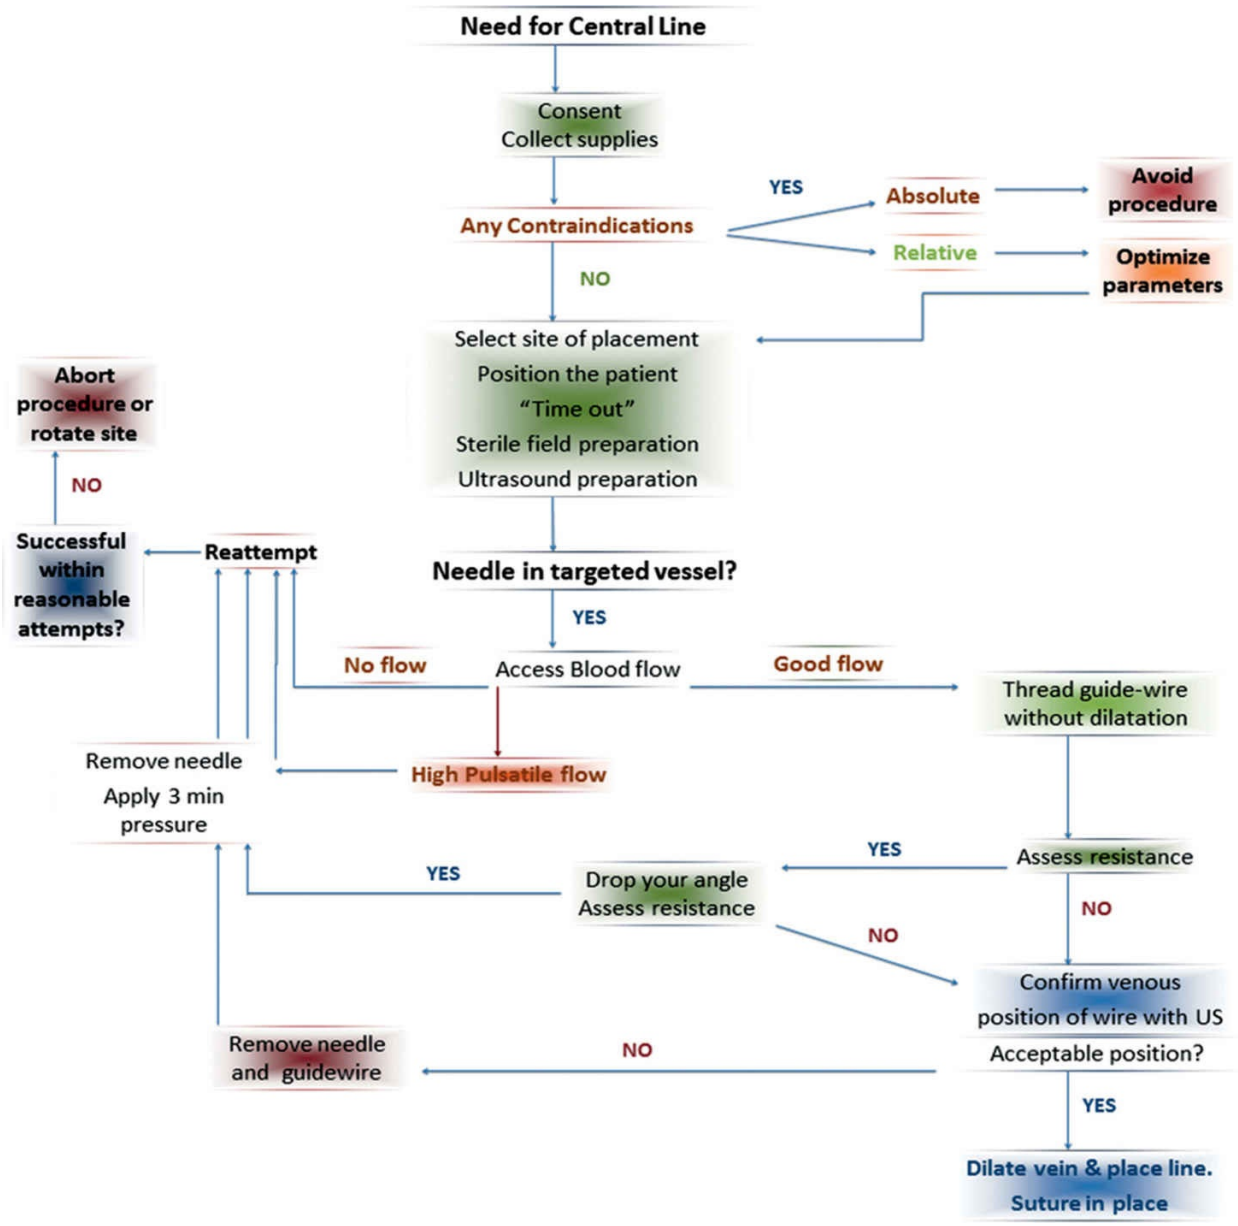

FIGURE 48.23 Central venous catheterization algorithm using Seldinger technique.

SITE-SPECIFIC LANDMARKS AND ULTRASOUND-GUIDED APPROACHES

Internal Jugular Vein

Anatomic landmarks for the central approach to IJV catheterization begin at the apex of the triangle formed by the sternal (medial) head and clavicular (lateral) head of the SCM and the clavicle (**Figure 48.14**). A confluence between the IJV and the brachiocephalic vein facilitates cannulation at this location. The head

should be rotated 45 degrees contralaterally, avoiding excessive rotation. With landmark approaches, a 21G or 22G “finder needle” attached to a 5 mL syringe is often used to locate the vein and estimate the distance and angle to the vein. The finder needle may be either removed or left in place for reference when the introducer needle is inserted.

Ultrasound-guided approach: This approach is the standard of care and preferred method to minimize mechanical and thrombotic complications. Do a preprocedural scan of the left and right IJV to select the best site. Place the ultrasound probe parallel and cephalad to the clavicle, at the apex of the triangle, with the probe marker “operator left.” Visualize the IJV and carotid artery in the transverse view. The carotid artery will be thick walled and pulsatile while the IJV will be thin walled and easily compressible (**Figure 48.5**). Identify a safe site for cannulation where the IJV is away from the carotid artery and not overlying it (**Figure 48.6**). Position the transducer and optimize the depth such that the vein is centered on the screen. Stay in the mid-neck and avoid the lower neck region above the clavicle, because there is a risk of puncturing the apex of the lung, even with US guidance. Use a high angle (70 to 90 degrees) and advance the needle into the IJV, maintaining negative pressure until the vein is punctured. Decrease the angle of the needle prior to feeding the guide wire.

Alternatively, a lower angle may be used but the operator must follow the tip of the needle into the vein using sweeping back-and-forth motions with the transducer to identify the needle tip as it is advanced into the IJV (**Figure 48.10**). Once the needle is inserted through the skin, slide or tilt the probe toward the needle tip until it is visualized on the screen. Be careful not to be confused by imaging the “shaft” of the needle, which will look similar to the tip. As the needle is advanced toward the vein, tilt the probe in the direction of the needle’s trajectory to ensure you can see the needle tip at all times. Periodically reposition the tip to confirm that it is directly above the vein. Make a small jab as the needle tip punctures the IJV and confirm good blood flow in the syringe prior to decreasing the angle and inserting the guide wire. Always confirm that the guide wire is in the vein prior to proceeding with the Seldinger technique (**Figure 48.24A** and **B**).

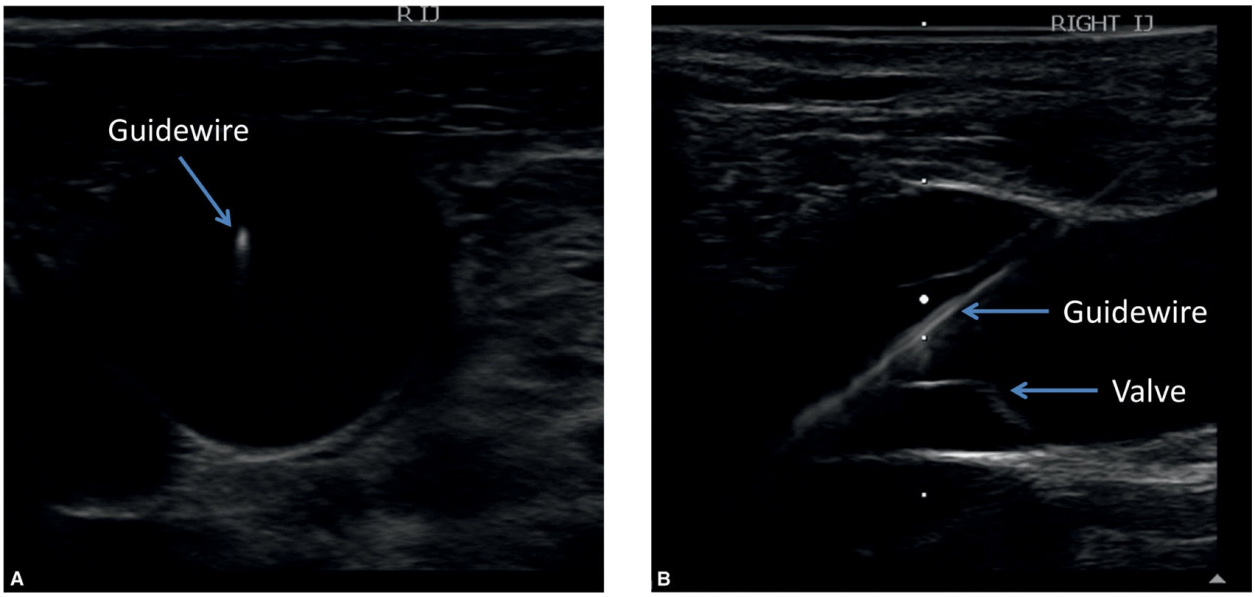

FIGURE 48.24 A, Guide wire in IJV. B, Longitudinal view of guide wire in internal jugular vein.

Landmark approach: The central approach is the most commonly used landmark approach. Place the index finger of the nondominant hand on the carotid artery pulse. Insert needle at apex of the triangle. The insertion point is just lateral to the carotid artery pulse. Use a 45 to 60 degrees angle and aim toward the ispsilateral nipple. The depth of the IJV using this technique is 3 to 5 cm. Sometimes the vessel will have been completely traversed by the needle with no blood return due to vessel collapse by hypovolemia or from pressure on the skin. Withdraw the needle to the subcutaneous plane and redirect the needle slightly medially.

Subclavian Vein

Landmark approach: The infraclavicular approach is most commonly used because it is quick and easy to perform, and obviates the need to set up the US machine. As part of setup, the clavicle should be divided into three parts: medial, middle, and lateral. Several different techniques and insertion sites are described in the literature:

- Insert the needle 2 cm caudal to the mid-clavicle.
- 2 cm lateral and caudal to the bend of the clavicle.
- 1 cm caudal to the junction of the medial and middle third of the clavicle.
- Inferior to the clavicle at the deltopectoral groove.

The needle should be inserted with the bevel facing the heart at a 10-degree angle toward the sternal notch. Matching up the numbers of the syringe with the bevel will allow you to know where the bevel is facing at all times. Starting 2 cm lateral to the bend of the clavicle and approximately 2 cm caudal (usually midclavicular), insert the catheterization needle through the skin and toward the sternal notch. Keep a low (<20 degrees) angle at all times. Once the needle is under the skin, keep the needle and syringe parallel and beneath the clavicle (**Figure 48.14**). Advance the needle toward the sternal notch until venous blood is aspirated.[24] Keep the middle finger of the nondominant hand on the sternal notch and use it as a landmark. Use the thumb of the nondominant hand to depress the soft tissue adjacent to the needle, so as to get beneath the clavicle and keep the needle flat at all times. Once blood is aspirated, advance the guide wire and follow the steps of the Seldinger technique(**Figure 48.16**).

Ultrasound-guided approach: Technically speaking, we are referring to US-guided axillary vein cannulation as the insertion point is lateral to the first rib. The brachial and basilic veins combine to form the axillary vein and the SCV is the anastomosis of the axillary and cephalic veins (**Figure 48.2**). Although US-guided SCV catheterization is safe, it requires expertise with vascular ultrasound. Using the linear array probe with the orientation marker left, scan along the inferior margin of the mid-clavicular region in a sagittal plane and slide the transducer laterally toward the axillary region. In the transverse or short-axis view, identify the axillary vein where it is most superficial and separate from the axillary artery. Stay within 4 cm of the mid-clavicle to avoid brachial plexus injury. Do a compression maneuver and use color Doppler to identify the vein from the artery. Identify the pleural line beneath the vessels. Now holding the base of the probe steady with the nondominant hand, turn the probe counterclockwise with the dominant hand and obtain a longitudinal view. Perform a compression maneuver and ensure the vessel is the vein and not the artery. While holding the probe steady with the nondominant hand resting on the body, insert the needle at the midpoint of the transducer at 45 to 70 degrees and follow the needle as it punctures the midpoint of the vein (**Figure 48.25**). Consider decreasing the angle to facilitate advancing the guide wire and the remaining steps.

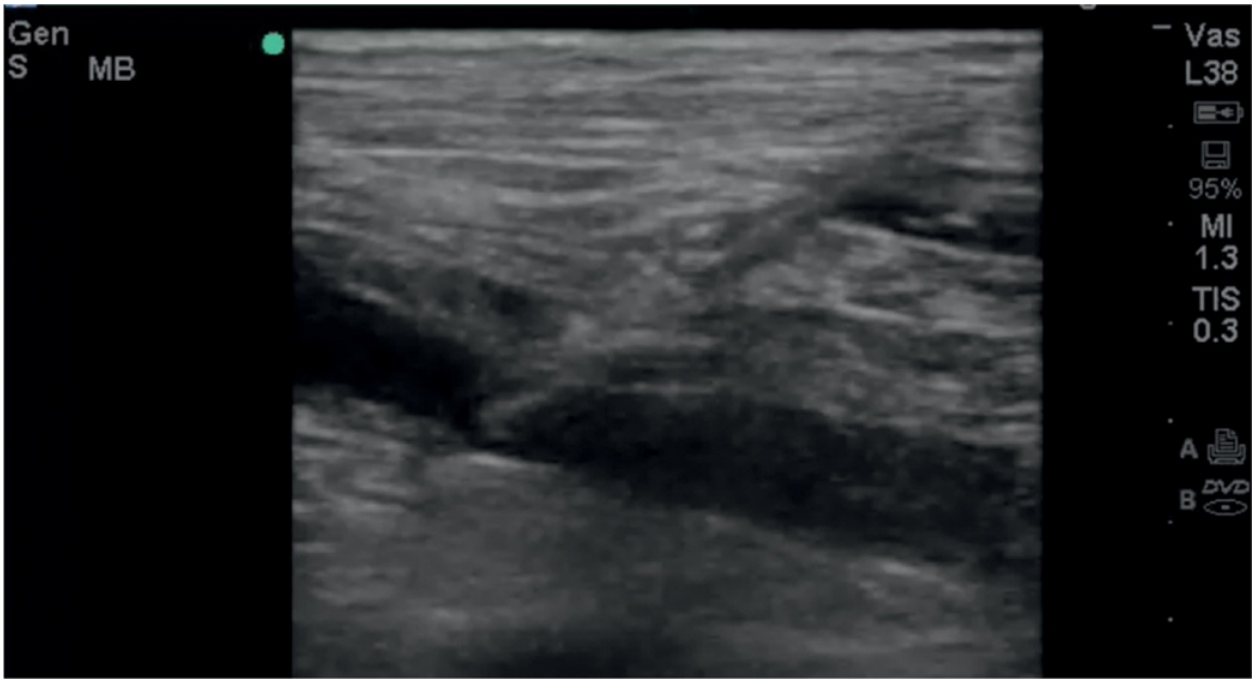

FIGURE 48.25 Ultrasound-guided cannulation using longitudinal approach.

Femoral Vein

Landmark approach: This is a useful approach during emergencies such as cardiac arrest. Externally rotate and abduct the patient's leg away from the midline. The FV lies caudal to the inguinal ligament and medial to the femoral artery in the femoral triangle (**Figure 48.15**). Palpate the femoral artery and insert the introducer needle 1 cm medial to this point at a 45 degree angle.[27] Advance the needle until there is a flash of venous blood. After stabilizing the needle, detach the syringe and advance the guide wire. Follow the remainder of the steps of the Seldinger technique. If the femoral artery is inadvertently punctured, hold compression for 5 to 10 minutes.

Ultrasound-guided approach: Using a linear array probe with the marker "operator left," identify the common FV and artery (**Figure 48.26**). As described previously, do a preprocedure scan to rule out deep vein thrombosis (**Table 48.9**). Identify the safest site for cannulation and holding the probe steady, insert the needle at a 45 to 70 degree angle into the vein. Once there is venous blood return, decrease the angle, ensuring there is still good blood flow. Holding the needle steady, detach the syringe and advance the guide wire. Use US to confirm that the guide wire is in the vein and not the artery. Follow the remaining steps for central venous cannulation.

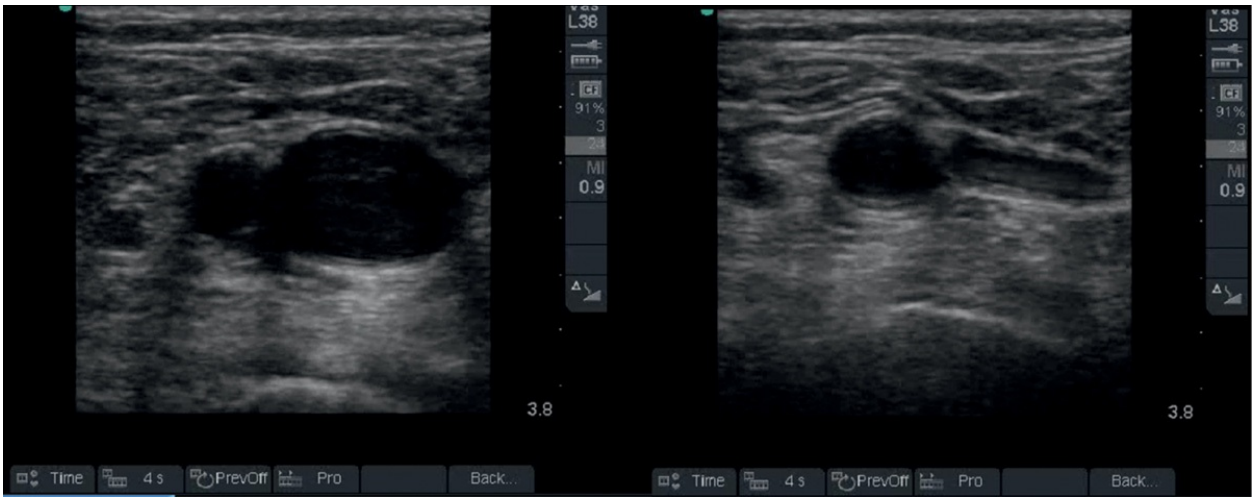

FIGURE 48.26 Common femoral vein with compression maneuver.

CENTRAL LINE VERIFICATION OF POSITION

The operator must ensure the catheter is placed in the central vein and not the artery. Arterial cannulation can lead to stroke, hemorrhage, and thrombosis. Ultrasound guidance can help with ensuring venous cannulation in IJV and FV CVC placement. The tip of the CVC must lie in the SVC or IVC and never in the RA. The catheter tip may potentially perforate the thin wall of the RA, resulting in hemorrhage and cardiac tamponade. A chest radiograph must be performed immediately after IJV and SCV CVC to confirm position and rule out complications.

For an ultrasound-guided placement of central line, confirmation of position is a multistep process. Initially, dark venous blood can be aspirated in the syringe. The operator must ensure that there is no pulsatile flow or bright red blood from the introducer needle, which may indicate cannulation of the artery. After insertion of the guide wire, the position can again be confirmed by visualizing the guide wire in the vein in the transverse and longitudinal views. This step precedes dilation of the vessel with the rigid dilator and ensures that the operator will not proceed if there is false cannulation of the carotid or femoral artery. In debatable situations, blood gas analysis is useful in differentiating arterial versus venous gas pattern. Additionally, the catheter can be connected to a pressure transducer to confirm venous waveform and pressure. With the introduction of US, this is not done routinely anymore. US is emerging as a tool to rule out malposition and pneumothorax but this is not the standard of care at this time.[29] Postprocedural chest radiography is necessary at the end of every internal jugular or subclavian venous cannulation to confirm the position of the distal tip

of the catheter and the absence of immediate complications like pneumothorax.

CORRECT POSITION

For any internal jugular or subclavian central line, the catheter tip is in correct position when it lies in the lower SVC or the cavoatrial junction. On a chest radiograph, this is at the level of the first anterior intercostal space above the carina (**Figure 48.27**). Placing an IJV or SCV catheter tip too deep can result in arrhythmias or even cardiac tamponade. A catheter can be repositioned by withdrawing it and resuturing, however it can never be advanced due to the risk of infection.

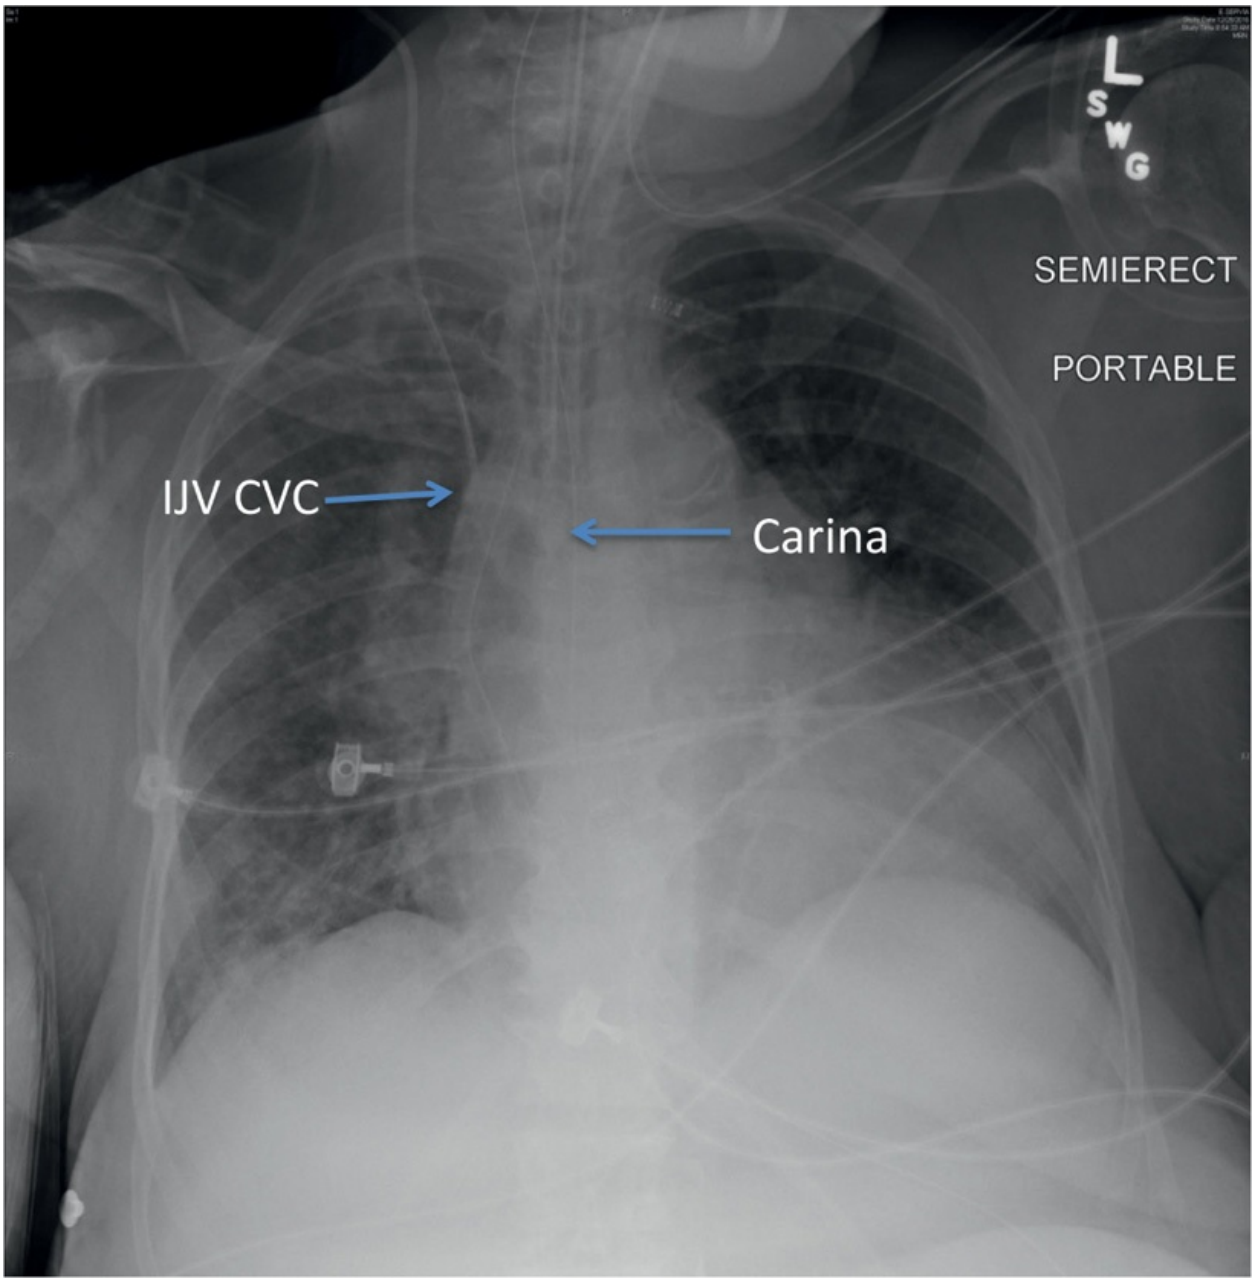

FIGURE 48.27 Central line position on chest radiograph. CVC, central venous catheter; IJV, internal jugular vein.

ROUTINE CATHETER CARE

Patency problems are common and include sluggish flow, no flashback of blood, or complete blockage. Possible causes for that would be clotted blood in the catheter or drug precipitation from infusate (eg, parenteral nutrition) or malpositioning of the catheter from initial placement. A rescue method to restore patency is by the use of a thrombolytic agent like alteplase (Cathflo or t-PA). See

Figure 48.28 for an algorithm to trouble shoot a nonfunctioning CVC.

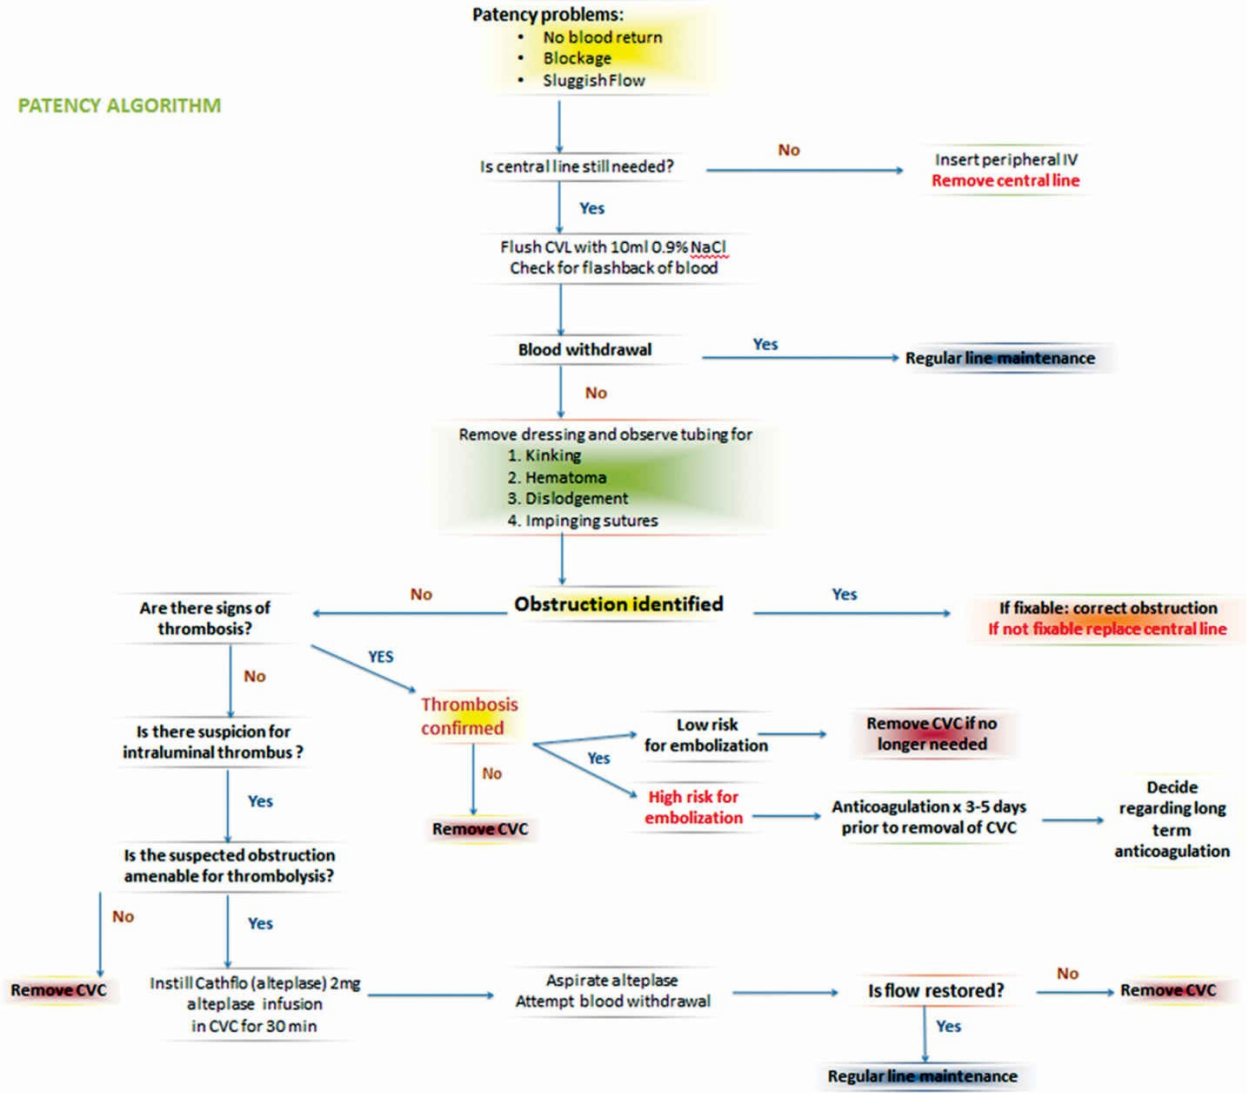

FIGURE 48.28 Central line occlusion trouble shooting algorithm.

COMPLICATIONS

Central line placement is an invasive procedure and it is not uncommon to have complications. General complications of placement of central lines are site specific and are summarized in **Table 48.12.**[30,31] The choice of site should be based on patient factors and operator's experience. In general, complication rates increase with increased number of attempts.[9,32] Simulation-based training has been shown to reduce the number of mechanical and infectious complications.[10,11,33]

TABLE 48.12 Complications of Central Venous Catheterization

MECHANICAL COMPLICATIONS	COMPLICATIONS	PREVENTATIVE MANAGEMENT
Internal Jugular CVC		
Immediate complications	Carotid puncture	Do not dilate; apply pressure.
	Pneumothorax	Insert chest tube if necessary.
	Bleeding	If severe, consider evacuation.
		Correct coagulopathy prior.
	Malposition	Correct position.
	Venous air embolism	Flush all ports with saline.
	Dysrhythmias	Retract guide wire.
	Submandibular hematoma	Watch for tracheal compression.
	Vagus nerve injury	
	Guide wire migration	Consult vascular surgery
	Thoracic duct injury (left side)	Keep NPO; requires TPN until healing; consult surgery.
Subclavian CVC		
Immediate complications	Subclavian arterial puncture	Do not dilate; apply pressure.
	Pneumothorax	Insert chest tube if necessary.
	Hematoma/hemothorax	If severe, consider surgical evacuation. Correct coagulopathy prior. Keep NPO; requires TPN until healing; consult surgery.
	Thoracic duct injury (left side)	
	Vagus nerve injury	
	Cardiac tamponade	Pericardiocentesis
	Malposition	Retract line; if needed, change.
	Venous air embolism	Flush all ports with saline.
	Dysrthymias	Retract guidewire.

	Guide wire migration	Consult vascular surgery.
Femoral CVC		
Immediate complications	Femoral artery puncture	Do not dilate; apply pressure.
	Femoral nerve puncture	Ultrasound use
	Retroperitoneal bleeding from external iliac artery puncture	Correct coagulopathy first. If severe, consider evacuation
	Venous air embolism	Flush all ports with saline.
	Guide wire migration	Might require vascular intervention.
	Punctured bladder	Urology consult
	Bowel perforation	If patient has femoral hernia
For all types of access	Bleeding	Apply pressure.
	Deep vein thrombosis (DVT)	DVT prophylaxis
	Thrombophlebitis	Prompt removal
	Infection	Early removal, antibiotics
	Extravasation	Manage as per vesicant
	Thrombosis	Consider thrombolytics.
	Nerve injury	

CVC, central venous catheter; TPN, total parenteral nutrition.

Infection

Observing standard infection control measures such as hand hygiene and using aseptic technique when placing CVC is paramount to preventing CLABSI.[1] The subclavian site carries the lowest risk of infection, however carries a higher pneumothorax risk and depends on operator experience.[13] The femoral site is associated with the highest risk of infectious complications. A central line bundle is essential for any CCU and includes hand hygiene, chlorhexidine skin antisepsis, and maximum barrier precautions during insertion, avoidance of the femoral site, a daily review of necessity of the CVC and removal when no longer necessary.[34] Interventions such as a daily goals sheet and simulation-based

training on sterile techniques have been shown to decrease CLABSI.[35] Any central line that is placed emergently or in a nonsterile fashion should be promptly removed. Routine catheter tip cultures, CVC changes, and guide wire exchanges are not recommended.

Pneumothorax

This is by far the most common complication of the subclavian site. There is no consensus as to whether all patients need chest tubes if a pneumothorax occurs. Stable patients with small pneumothoraces may be closely observed. Patients with large pneumothoraces or those who are on mechanical ventilation require chest tube placement to manage this complication and avoid tension pneumothorax, which is life threatening.

Arterial Puncture

Arterial puncture and even cannulation is not uncommon. If recognized early (ie, with introducer needle), 5 to 10 minutes of solid pressure on the site will resolve most bleeding issues without consequence. This is different, though, if the artery has been dilated or cannulated with a TLC or introducer sheath. If this occurs, leave the line in place and consult vascular surgery immediately.

Hematoma

Femoral artery puncture can lead to hematoma. Retroperitoneal hemorrhage is a feared complication and blood can flow freely into the retroperitoneum. The FV becomes the external iliac vein superior to the inguinal ligament and retroperitoneal hemorrhage can occur if the posterior wall is punctured multiple times above the inguinal ligament. This often occurs when the landmark approach is used during cardiac arrest or other emergencies. Occasionally, the FV is cannulated after the needle has traversed the femoral artery; so the bleeding will occur when the catheter is removed. Similarly, a hematoma from carotid artery puncture can compress the trachea and hence compromise the airway. US-guidance decreases the risk of all these mechanical complications.[11]

Air Embolism

This is a rarer occurrence but can be catastrophic. This can occur during CVC placement or during its removal.[36] The patient will quickly decompensate and become short of breath, altered, and hypotensive or have a cardiac arrest. If this

is suspected, place the patient in the left lateral decubitus or Trendelenburg position so as to trap the air in the right ventricle. Provide supportive care such as high-flow oxygen or mechanical ventilation, intravenous fluids, and vasopressors. The most useful technique to prevent air embolism is placing the patient in Trendelenburg when performing IJV or SCV catheterization or removal. Always cover the hub of the introducer needle or CVC once it is in the vein.

Guide Wire Embolization

Loss of a guide wire is possibly the most disturbing complication for the operator. This is a preventable complication and many institutions have policies of confirming that the guide wire was removed after the procedure. Always maintain control of the guide wire throughout the procedure and be all the more vigilant after the dilation of the vessel. If the operator does lose the guide wire, check to see if it is still in the lumen of the catheter. If so, then clamp the catheter and guide wire with a Kelly clamp or similar instrument and remove the entire apparatus, along with the guide wire. If the guide wire has embolized distally, consult vascular surgery or IR to help with retrieval. **Figure 48.29A** and **B** depict US images of guide wire embolization through the venous circulation into the RA.

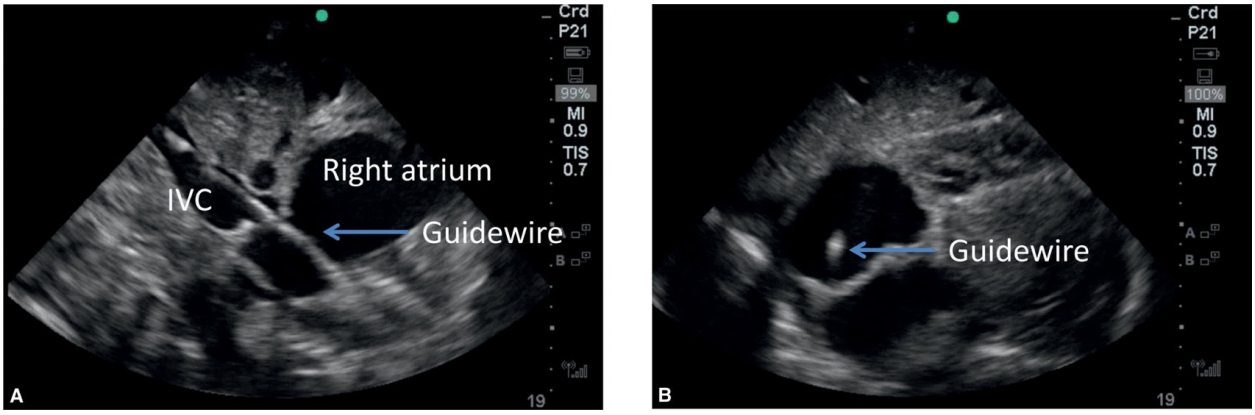

FIGURE 48.29 A, Guide wire embolization to inferior vena cava (IVC). B, Guide wire embolization to IVC/right atrium.

CENTRAL ACCESS REMOVAL

Any CVC should be removed as soon as it is no longer necessary. Central line removal is distinct from insertion, with its own set of potential complications.

Some complications of CVC removal include bleeding, air embolism, catheter fracture, and dislodgement of thrombus from the catheter tip. **Table 48.13** is a checklist of essential steps to follow during CVC removal. A working knowledge of potential complications and simulation-based training is essential for the CCU personnel removing lines. CVC removal should only be performed by professionals who have received adequate training and been assessed as competent in performing the procedure.[37]

TABLE 48.13 Checklist for Central Line Removal

CENTRAL LINE REMOVAL CHECKLIST
Place the patient in Trendelenburg position with the CVC exit site below the level of the heart.
Ensure that all CVC lumens are capped and/or clamped.
Cover the CVC exit site with gauze and apply gentle pressure while removing the catheter in a slow, constant motion.
Have the patient perform the Valsalva maneuver as the last portion of the CVC is removed.
Place pressure on the site for at least 5 min.
Apply a sterile occlusive dressing, such as gauze filled with petroleum jelly, and cover with a transparent film dressing.
Leave dressing in place for at least 24 h and change every 24 h until the exit site has healed.
Instruct the patient to remain lying flat for 30 min after removal of the catheter.

CVC, central venous catheter.

ARTERIAL LINE PLACEMENT

Arterial catheterization is indicated when continuous beat-to-beat blood pressure monitoring is needed. This applies for patients with circulatory shock, hypertensive emergencies, aortic syndromes, acute stroke, and multiorgan failure states. Arterial access is also required for diagnostic and therapeutic interventions like coronary angiography, aortic balloon pump, or left ventricular assisted devices, and ECMO. Indications for intraarterial line placement are summarized in **Table 48.14**. See Chapter 49 for a discussion on arterial blood pressure monitoring and its uses.

TABLE 48.14	Indications for Intra-arterial Lines in the CCU
INVASIVE MONITORING OR AGGRESSIVE HEMODYNAMIC RESUSCITATION INTERVENTIONS	
Hemodynamic monitoring: • Continuous blood pressure • Shock on vasoactive agents • Hypertensive emergency • Open heart surgery • Hemorrhagic stroke • Aortic syndromes • Cerebrovascular accident after thrombolysis • Blood pressure monitoring in obese patients, amputees, burn victims	
Cardiac output monitors (ie, Flotrac)	
Intra-aortic balloon pump	
Left ventricular assist device	
Arterial blood gas access	
Need for frequent arterial blood gases Acute respiratory distress syndrome or in severe metabolic derangements	

Like CVCs, intraarterial lines are interventions that require patient consent, cooperation, and sterile conditions as discussed earlier. A-lines are generally placed using the Seldinger technique (**Figure 48.16**). A-lines have a lower rate of infection, but the risk of infectious and thrombotic complications does exist; so they should be discontinued as soon as they are no longer indicated. No drugs should be injected via an A-line; the direct contact of a medication with the tissues can result in cell death, severe gangrene, and limb ischemia. **Table 48.15** contains a list of contraindications for A-line placement.[32,38]

TABLE 48.15	Contraindications for Intra-arterial Lines in the CCU
Thrombocytopenia	
Infection at insertion site	
Traumatic injury at insertion site	
Arteriovenous fistula	
Peripheral arterial insufficiency of intended limb	
Prior surgeries or radiation	

Raynaud syndrome
Thromboangiitis obliterans (Buerger disease)
Synthetic vascular graft

CCU, cardiac care unit.

Surgical and anatomic considerations are the influencing factors when choosing the site for arterial cannulation. The radial artery is the most common site for cannulation because it is thought to have a low rate of associated complications. This low rate of complications occurs as a result of extensive collateral circulation involving the ulnar artery and palmar arches with flow to the distal limb. The anatomic landmarks and advantages/disadvantages for each site are summarized in **Table 48.16.**[39] The most common complication is arterial thrombosis. Thrombotic risk factors include larger catheter size, hypotension, smaller arterial dimension, multiple arterial sticks, duration of cannulation, and administration of vasoactive agents. The cannulation site further potentiates thrombotic propensity.[40,41]

TABLE 48.16 Site-specific Characteristics of Arterial Line Placement

SITE	LANDMARKS	ADVANTAGES	DISADVANTAGES	COMPLICATIONS
Radial	Distal end of radius between tendons of brachioradialis and flexor carpi radialis	Easy to locate	Easily collapsible	Thrombosis risk
		Ease of placement	Prone to vasoconstriction if multiple attempts	Limb ischemia
		Most common site of cannulation	Difficult in profound shock	
		Presence of collateral flow (ulnar artery and palmar arch)	High thrombosis risk	
		Easily maintained		
			Frequent accidental removal	
	Below the inguinal	Easy cannulation especially with	Highest infection rate	Retroperitoneal

	ligament	ultrasound guidance		hemorrhage
Femoral artery	Palpated midway between the pubic symphysis and anterior iliac crest	Lower thrombosis risk	Compressible for bleeding control	
		Easily maintained	Avoid in peripheral arterial disease	
		Comfortable		
		Largest accessible arterial access		
Axillary artery	Palpated in the intramuscular groove between the coracobrachial and triceps muscles	Lower infection and thrombosis risk	Ultrasound guidance often needed	Brachial plexus compressive injury from hematoma
	Deep to pectoralis minor muscle	Maintains pulsation in profound shock due to proximity to aorta	High failure rate	Paresthesia
		Second largest after femoral artery	Proximity to pleural space, brachial plexus	Cannulation of left axillary is preferred compared to the right.
		Preferred in obese if radial access difficult	Right axillary line in continuity with right carotid⇒ risk for cerebral thromboembolism	
Brachial artery	Medial side of antecubital fossa	Easily accessed but lacks the anatomic benefit of collateral circulation	Highest likelihood for thrombosis and loss of radial pulsations	DO NOT USE
	Lateral border of brachial muscle			Any cannulation may lead to upper limb ischemia
				Median nerve injury

GENERAL RULES

Multiple failed attempts might lead to arterial vasoconstriction; therefore choice of radial artery requires a level of operator's comfort that he or she will be able

to place the line in with relatively low number of attempts. Prior to the procedure, the modified Allen test should be performed to assess for good collateral circulation from the ulnar artery. The modified Allen test is performed by asking the patient to make a fist. While the hand is clenched, the ulnar and radial arteries are occluded with digital pressure to obstruct blood flow to the hand. When the hand is unclenched, the pressure over the ulnar artery is released. In the presence of good circulation, the palm flushes in 5 to 10 seconds.[42] **Table 48.17** contains a list of basic items needed for arterial catheterization.

TABLE 48.17	Items Necessary for Arterial Line Placement
Arterial line kit	
Arterial catheter	
1% lidocaine 5 mL vial	
25G × 1″ needle for lidocaine administration	
22G × 1.5″ with 5 mL syringe for lidocaine administration	
20G steel introducer needle with 5 mL Luer slip syringe	
20G angiocatheter needle (in some kits)	
J-shaped guide wire	
Scalpel (#11)	
Thin dilator (not always used)	
Straight or curved needle with sutures	
Gauze: 2″ × 2″ or 4″ × 4″ pads	
Fenestrated drape	
Additional supplies	
Surgical caps	
Masks with eye shield	
Chlorhexidine swabs/scrubs	

Sterile gown
Sterile gloves
Biopatch protective disk
Transparent, occlusive dressing
A-line transducer setup with tubing connected to saline bag (supplied by registered nurse [RN])
Disposable underpad (blue Chux)
Additional items
Portable ultrasound machine with linear array (vascular) probe
Sterile probe cover

TECHNIQUE

If you are able to get arterial blood gas from radial artery, then you probably have already mastered the direct cannulation technique. Following are the basic steps of arterial catheterization. It is assumed that the operator will adhere to standard hospital policy of obtaining informed consent, performing a "time-out," and maintaining maximum barrier precautions throughout the procedure.

Catheter Over Needle Technique (Radial Artery Catheterization)

A. Palpate the radial artery and perform the modified Allen test. If you cannot feel it, aim as distally as possible, either rotate position or use US guidance to visualize the artery.
B. Once you identify the artery, position the patient with the wrist dorsiflexed using a rolled towel under the wrist and tape to maintain that position.
C. Adjust height of bed to ensure comfort during procedure.
D. Perform hand hygiene using an alcohol-based rub.
E. Don sterile gloves and prepare site using chlorhexidine swabs.
F. Don hat, mask, and sterile gown.
G. Identify the point of maximal pulsation of the radial artery and inject local lidocaine subcutaneously.
H. Hold the angiocatheter-covered needle with dominant hand while stabilizing the artery with the nondominant hand.
I. Puncture the skin at an angle of 30 to 45 degrees just distal to where the

artery is palpated. Once flashback of blood is seen, advance the needle 2 mm after flash to ensure catheter placement inside the lumen. Flatten the needle slightly and advance the catheter until flashback of blood is seen in the hub of the needle. Note that some catheters have a built-in guide wire that is advanced into the artery once there is flashback and then the catheter is advanced over the wire.

J. Withdraw the needle/wire from the catheter. There should be pulsatile flow of bright red blood coming out of the catheter. Press on the catheter proximal to the hub to control the bleeding.

K. Have an assistant hand you the transducer connecting tubing and connect it to the catheter hub. Be careful not to displace the catheter or pull it out mistakenly. Check for arterial waveform on the monitor.

L. Suture the catheter in place using a securing device and/or placing a suture around the proximal hub.

M. Clear the site and place a transparent dressing.

Catheter Over Guide Wire: Seldinger Technique (Femoral Arterial Catheterization)

A. Palpate the femoral artery in the femoral triangle, staying caudal to the inguinal ligament.

B. Perform hand hygiene; don hat, mask, and sterile drape.

C. Prepare, drape, and anesthetize the skin and soft tissue over the femoral artery.

D. Puncture the skin at an angle of 40 to 60 degrees with the introducer needle/syringe, distal to where the arterial pulse is palpated (note that a long introducer needle should be used).

E. Advance the needle until the artery is punctured and bright red blood is aspirated.

F. Decrease angle slightly ensuring good blood flow.

G. Stabilize needle and remove syringe from needle, confirming free pulsatile flow of bright red blood.

H. Pass the guide wire through the needle and withdraw the needle (**Figure 48.16**).

I. Advance the cannula over the guide wire while maintaining control of the guide wire at all times. Advance the guide wire into the lumen of the artery with rotational movements. Note a thin dilator is usually available in a vessel catheterization kit if needed.

J. Remove the guide wire and expect brisk high-pressure bright red blood flow from the catheter.

K. Attach the transducer connecting tubing to the catheter and look for a good A-line waveform on the monitor.

L. Secure the cannula with sutures and cover with a transparent dressing.

ULTRASOUND GUIDANCE

Ultrasound use is often helpful in arterial catheterization of the critically ill CCU patient. The insertion of the catheter by blind palpation can sometimes require multiple attempts and thus can cause patient discomfort and arterial vasospasm. This is particularly true in the CCU patient with profound shock. Ultrasound guidance is particularly helpful with axillary artery catheterization. The use of ultrasound guidance has been shown to increase first-pass success rate and reduce the number of attempts.[43,44]

Prior to the procedure, clean the ultrasound transducer with an antiseptic wipe. Perform a preprocedural scan with a high-frequency linear array transducer to identify the optimal site for cannulation. Ensure the transducer marker is "operator left" and the screen marker is also on the upper left hand corner. Identify the artery that will be cannulated and adjust the gain and depth to optimize the image such that the vessel of interest appears in the center of the screen. Arteries will appear round, thick walled, and are pulsatile with compression. Scan up and down in the transverse view to ensure there is no tortuosity or calcification. Locate a section with the largest diameter. The radial artery will be located adjacent to the styloid process of the radial bone (**Figure 48.30A**). The femoral artery is the pulsatile vessel located in the femoral triangle (**Figures 48.15 and 48.26**). For axillary artery cannulation, have the patient place his or her arm under his or her head and scan the axillary region until the vessels are identified. **Table 48.16** lists general anatomic landmarks and considerations for each potential site.

FIGURE 48.30 A, Radial artery in transverse view. B, Radial artery in longitudinal view.

Transverse Approach

Arterial catheterization can be performed in either the transverse view or longitudinal view (**Figure 48.30A and B**).[40] It is assumed that the operator will maintain sterility throughout the procedure and will always use a sterile sheath to cover the ultrasound transducer. Sterile gel should be applied inside the sheath without contaminating the field or the operator's sterile gloves. After locating the artery, optimize the image and center the artery in the transverse view. Anesthetize the skin and insert the angiocatheter-covered needle at the midpoint of the transducer at a 45 to 60 degree angle. Slide or angle the probe up and down until the needle tip is visualized. Make sure you are imaging the tip and not the shaft of the needle. As the needle is advanced toward the artery, follow the tip of the needle by sliding the transducer back and forth. Adjust the position of the needle until it is directly over the artery and then puncture through the vessel wall into the lumen. Follow steps for either the catheter over needle/wire technique or the Seldinger technique described previously.

Longitudinal Approach

For the longitudinal view approach, first obtain a transverse view with the vessel in the center of the screen. Hold the base of the transducer steady, turn the transducer counterclockwise with the dominant hand, and obtain a longitudinal view (**Figure 48.30B**). Notice the thick-walled vessel that is pulsatile and noncompressible. While holding the transducer steady with the nondominant hand resting on the body, insert the needle at the midpoint of the transducer at a 30 to 45 degrees angle (**Figure 48.31**) and follow the needle as it punctures the midpoint of the artery. Follow steps for catheter over needle or Seldinger techniques described earlier. The longitudinal approach can be useful for radial artery cannulation, whereas the transverse approach is preferable for femoral artery and axillary artery catheterization.

FIGURE 48.31 Transducer hold for longitudinal approach for cannulation.

CONCLUSION

Line access is essential and allows for hemodynamic monitoring and administration of lifesaving medications in the CCU patient. A working knowledge of the types of catheters, indications, contraindications, and considerations for site selection is imperative. Knowledge of vascular anatomy, familiarity with the equipment, and competency in the procedure are prerequisites for successful insertion of the catheter. A daily assessment and early removal of the line as soon as it is no longer necessary reduces the risk of complications. Limiting the number of attempts at insertion drastically reduces both infectious and mechanical complications. Ultrasound guidance and simulation-based training are helpful in achieving competence and reducing complications.

Patient and Family Information for:
LINE ACCESS IN THE CCU

During a patient's stay in the coronary care unit (CCU), various lines may be placed in the veins or arteries for close monitoring and for administering potent medications. Below are some of the lines that may be placed.

CENTRAL LINE

WHAT IS A CENTRAL LINE?

A central line, also known as a central venous catheter (CVC), is a long, thin, flexible tube that is inserted in one of the large veins in the neck, upper chest, or groin region and leads to the heart. It allows delivery of fluids and necessary medications and can stay in place much longer than a regular intravenous (IV) catheter. It can also be used to measure the pressures within the heart.

WHAT ARE THE TYPES OF CENTRAL LINES?

The most common central line is called a triple lumen catheter (TLC) because it has three ports, which all end in different openings within the catheter. It is inserted in a large vein in the neck, upper chest, or groin, with its tip residing near the heart. Dialysis catheters typically have two ports (dual lumen) and can be used on a short-term basis in order to perform dialysis while in the CCU.

A peripherally inserted central catheter (PICC line) is a really long catheter that is inserted into a vein in the upper arm and is threaded until it reaches the larger vein near the heart.

Long-term-use tunneled catheters, also known as perm-a-cath, is inserted usually in a large vein in the neck. This catheter can be used for long-term dialysis, if needed.

WHY YOU NEED A CENTRAL LINE?

Your doctor or nurse will explain the reason you need a central line.

Below are some common reasons why a patient in the CCU might require a central line.

- If the small veins in the arms are not easily found or it is difficult to place a regular IV line
- If the blood pressure is low and strong medications are needed to raise the blood pressure (These medications are too strong to be given through a regular IV.)
- If the intravenous medications that have to be given can potentially burn the smaller vessels or muscles
- If blood or other blood products need to be rapidly given
- If intravenous nutrition is needed for a number of days
- If you need to undergo dialysis or plasmapheresis, where the blood is purified

WHERE IS THE PROCEDURE PERFORMED?

The procedure is typically done at the bedside in the CCU. A PICC line or perm-a-cath may be performed in the interventional radiology (IR) department or in the operating room (OR).

WHAT IS THE CARE BEFORE AND AFTER THE PROCEDURE?

Before the procedure is done, your lab work will be checked to assess your risk of bleeding, especially if you are taking any blood-thinning medications. If your platelets are low or international normalization ratio (INR) is high, a transfusion of platelets, plasma, or vitamin K may be necessary before the procedure.

An ultrasound machine is often used to guide the procedure. The blood vessels are visualized with ultrasonography in order to decide where the central line will be placed and also to prevent placement of the catheter elsewhere.

The procedure is sterile. Your body and face will be covered with a sterile drape to minimize any risks for infection during the insertion. You will be able to talk with your doctors during the procedure. You may be placed in the Trendelenburg position, where the head is lowered and the legs are raised. This position ensures safety of the central line placement.

If the central line is placed in the neck or upper chest, a chest x-ray is performed afterward to confirm the position of the central line near the heart and also in order to make sure there is no pneumothorax, which is collapse of the

lung on the affected side.

IS THE PROCEDURE PAINFUL?

You will be awake and able to interact with the doctors performing the procedure. You will be given a numbing medication at the insertion area. After the initial injection of a local anesthetic, the procedure is pain free but you may experience pressure or discomfort. Your cooperation is of critical important during that time.

HOW LONG DOES IT TAKE?

No more than 30 to 45 minutes, accounting for the time of the procedure and preparation.

ARE THERE ANY POSSIBLE COMPLICATIONS?

All procedures carry some risk. This is a common procedure in CCUs and ICUs. A trained physician, physician assistant, or nurse practitioner usually places the line under sterile technique.

POSSIBLE COMPLICATIONS:

- Infection of the catheter
- Bleeding at the site or internally
- Puncture of the artery which is running next to the vein
- Pneumothorax or collapsed lung
- Heartbeat changes (arrhythmias)
- Blood clot in the vein where the line is placed
- Air bubbles entering the blood circulation

HOW TO CARE FOR THE CENTRAL LINE:

The catheter extends outside your body, allowing the nurses and doctors to access it to provide you medications, antibiotics, and fluids. The dressing will be getting changed at every nursing shift.

To avoid any infection, clotting, or other complications, meticulous care of the central line is important.

WHEN IS THE LINE REMOVED?

As soon as the central line is no longer needed, it should be removed. Gentle pressure should be applied on the area for 3 to 5 minutes.

The doctor will discuss with you if the line needs to be changed with a new one.

ARTERIAL LINE PLACEMENT

WHAT IS AN ARTERIAL LINE?

An arterial line is thin, flexible tube or catheter that is carefully inserted in the artery located in the wrist or groin. This catheter is connected through tubing to the monitor in the CCU, which will allow for beat-to-beat measurement of your blood pressure.

WHY YOU NEED AN ARTERIAL LINE?

Your doctor or nurse will explain the reason you need an arterial line.

Common Reasons for the Procedure:

- Low blood pressure (hypotension or shock) that requires medications in order to increase it
- High blood pressure (hypertension) requiring accurate measurements in order to control it with medications
- Lung problems or being on a ventilator, where the oxygen and carbon dioxide levels in the blood need to be checked frequently
- Severe respiratory or kidney problems that may require frequent checking of the acidity of the blood

WHERE IS THE PROCEDURE PERFORMED?

The procedure is typically performed at the bedside in the CCU.

WHAT IS THE CARE BEFORE AND AFTER THE PROCEDURE?

Before the procedure is performed, your lab work is checked to assess your risk

of bleeding. If your platelets are low or INR is high, you might need transfusion of platelets, plasma, or vitamin K in order to lower the risk of bleeding.

The radial artery is located in the wrist and femoral artery is located in the groin region. These arteries may be palpated to locate them or an ultrasound machine may be used to guide the procedure.

The procedure itself is sterile and hence your body will be covered with a sterile drape to minimize any risks for infection during the insertion.

You will be able to move and sit up with the catheter in place. Care must be taken to prevent kinking and accidental removal of the catheter, which can lead to profuse bleeding.

IS IT PAINFUL?

You will be given a local anesthetic or numbing medication at the site of insertion. After the initial injection of the local anesthetic, the procedure is pain free but you might experience pressure or discomfort. Your cooperation is of critical importance during this time.

HOW LONG DOES IT TAKE?

No more than 20 to 30 minutes.

ARE THERE ANY POSSIBLE COMPLICATIONS?

A trained physician, physician assistant, or nurse practitioner usually places the line under sterile technique and under safe and controlled settings. All procedures have a risk of potential complications.

POSSIBLE COMPLICATIONS:

- Pain at the insertion site
- Bleeding at the site or internally
- Infection of the catheter
- Clotting of the catheter and possible low blood flow to the arm or leg

WHAT IS THE CARE FOR THE ARTERIAL LINE?

To avoid any infection, clotting, or other complications, meticulous care of the

arterial line is important. Your CCU nurses and doctors will closely monitor the catheter and site.

WHEN IS THE LINE REMOVED?

As soon as the line is no longer needed, it gets removed. Gentle pressure will need to be applied on the area for 3 to 5 minutes. The site will be monitored for any further bleeding or swelling.

Invasive Hemodynamic Assessment in the CCU

INTRODUCTION

Invasive hemodynamic monitoring is very often required in the care of a critically ill patient in the cardiac care unit (CCU) and is vital to the monitoring of the CCU patient, as well as dictating therapy. Various strategies of goal-directed fluid resuscitation utilizing dynamic measures of fluid responsiveness are available, which allow for monitoring and help direct therapy. A conservative fluid management strategy with judicious use of fluids along with monitoring of indices of tissue oxygenation is optimal in the CCU patient. Proper measurement and interpretation of the data is the key in ensuring adequate tissue perfusion and oxygen delivery, which is the goal.

PATHOPHYSIOLOGY OF HEMODYNAMICS IN A CRITICALLY ILL PATIENT IN THE CCU

It is important to understand oxygen delivery before we go into the various measures available for hemodynamic monitoring. Oxygenated blood is delivered to the tissues via the aorta, and deoxygenated blood returns to the right heart

from where it enters the lungs to get reoxygenated. Tissue extraction of oxygen occurs during this transit. The normal arterial oxygen saturation (SaO_2) is 96% to 99%. The normal mixed venous saturation ($S\bar{v}O_2$) in the pulmonary artery (PA) is 65% to 75%, which denotes tissue oxygen extraction to be roughly 25% to 35%.

Determinants of cardiac output (CO) are preload, afterload, and inotropic contractility. Many monitoring systems work to incorporate these measures to determine the adequacy of CO. A hemodynamically stable patient for the most part does not require invasive hemodynamic monitoring, whereas in the hemodynamically unstable patient, invasive monitoring is frequently warranted. Such patients invariably have an arterial line and a central venous catheter (CVC), which by themselves can provide useful hemodynamic parameters. When this is not sufficient, additional invasive devices such as PA catheters (PACs) and CO monitors are utilized.

Hemodynamic data can help classify the cause of shock. The measured data can be used to calculate variables such as CO, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR). The following equations are important to understand because they determine tissue perfusion and oxygenation:

$$CO = HR \times SV \quad \text{(Eq. 1)}$$

$$DO_2 = CO \times CaO_2 \quad \text{(Eq. 2)}$$

$$CaO_2 = 1.348 \times \text{Hemoglobin} \times SaO_2 + 0.003 \times PaO_2 \quad \text{(Eq. 3)}$$

where CO is cardiac output, HR is heart rate, SV is stroke volume, DO_2 is oxygen delivery, CaO_2 is oxygen content, SaO_2 is oxygen saturation, and PaO_2 is the partial pressure of oxygen.

HEART LUNG INTERACTIONS

Both spontaneous and mechanical ventilation induce cyclical changes in intrapleural or intrathoracic pressure and lung volume. Intermittent positive pressure ventilation induces cyclic changes in the loading conditions of the left and right ventricles. This can independently affect the key determinants of cardiovascular performance, which are preload or atrial filling, afterload, heart rate, and myocardial contractility.

Spontaneous inspiration produces a negative pleural pressure, and this

reduction in intrathoracic pressure is transmitted to the right atrium (RA). In contrast, intermittent positive pressure ventilation (tidal volume > 8 mL/kg ideal body weight) produces inspiratory increases in intrathoracic pressure and RA pressure decreasing venous return and right ventricular (RV) preload, and also increases RV afterload. This leads to a decrease in RV stroke volume, which is manifested as a decrease in left ventricular (LV) stroke volume, which is at its minimum during the expiratory period due to a phase lag of 2 to 3 beats (ie, pulmonary transit time). These cyclic changes are greater when patients are volume depleted and are on the steep rather than the flat portion of the Frank–Starling curve. This can lead to changes in pulse pressure (PP) variation, stroke volume variation, and inferior vena cava (IVC) size variation, indicating a patient who may be fluid responsive.[1] The biventricular dependence is confounded if the patient on a ventilator is also making spontaneous efforts or has an atrial arrhythmia. It is important to consider this while interpreting data.

ARTERIAL BLOOD PRESSURE

DEFINITION

Arterial blood pressure (ABP) is the pressure exerted by the circulating volume of blood upon the wall of the arteries. It is measured both at its peak (systolic blood pressure, SBP) and at its trough (diastolic blood pressure, DBP). The blood pressure in the aorta during systole is a clinical indicator of afterload (ie, the forces the left ventricle must overcome to eject blood).

The normal ranges in ABP are systolic 90 to 140 mm Hg and diastolic 60 to 90 mm Hg. PP is the difference between systolic and diastolic pressure. If BP is measured in the brachial artery, the average PP is approximately 40 mm Hg. Above 60 mm Hg, the risk of coronary events and all-cause mortality increases. The main determinant of PP is large artery compliance. The less compliant arteries are, the higher the PP, which is why PP increases with age, as elastin fibers of the arterial walls are weakened by years of stress.

ABP and PP can be affected by various factors as illustrated in **Tables 49.1 and 49.2**.

TABLE 49.1 Factors Affecting Arterial Blood Pressure

SYSTOLIC BLOOD PRESSURE	DIASTOLIC BLOOD PRESSURE

Stroke volume	
Left ventricular ejection velocity	Arterial wall distensibility
End diastolic volume	Systemic arterial resistance
Arterial wall distensibility	Blood viscosity
Systemic arterial resistance	Length of the cardiac cycle
Blood viscosity	

TABLE 49.2 Factors Affecting Pulse Pressure

INCREASED PULSE PRESSURE	DECREASED PULSE PRESSURE
Fever, exercise	Cardiac tamponade
Bradycardia	Hypovolemia
Aortic regurgitation	Shock
Anemia	Massive pulmonary embolism
Hyperthyroidism	Tension pneumothorax
	Aortic stenosis

Mean Arterial Pressure

Mean arterial pressure (MAP) is often used as a surrogate indicator of blood flow and a better indicator of tissue perfusion than SBP because it accounts for the fact that two-thirds of the cardiac cycle is spent in diastole. A MAP of 65 mm Hg or greater is needed to maintain adequate tissue perfusion.

Systemic MAP is defined as the mean perfusion pressure throughout the cardiac cycle and it can be calculated as follows:

$$MAP = SVR \times CO \qquad \text{(Eq. 4)}$$

A more practical estimate can be obtained by the following equation:

$$MAP = \frac{2}{3} DBP + \frac{1}{3} SBP \qquad \text{(Eq. 5)}$$

Intra-arterial Blood Pressure Monitoring

Intra-ABP is the direct measurement of arterial pressure and it involves inserting a catheter in a suitable artery. The catheter must be connected to a sterile, fluid-filled system, which is in turn connected to an electronic patient monitor.

CLINICAL UTILITY

ABP monitoring offers several advantages over noninvasive blood pressure (NIBP) monitoring. It allows continuous beat-to-beat pressure measurement and allows accurate blood pressure readings at very low pressures. It allows close monitoring of patients on vasopressors, inotropes, or vasodilators. It enables

ABP measurement in patients in whom NIBP monitoring is difficult and allows for frequent arterial sampling. The waveforms can also provide useful information about the patient's cardiovascular status.

MEASUREMENT

Most of the ABP measuring systems consist of a column of fluid directly connecting the arterial catheter to a pressure transducer. The pressure waveform of the arterial pulse is transmitted via the column of fluid to a pressure transducer where it is converted into an electrical signal. This electrical signal is then processed, amplified, and converted into a visual display by a microprocessor.

WAVEFORM

The arterial pressure wave is a complex wave generated by a series of pressure changes that occur during valve closure, systole, diastole, and by reflection waves caused by the impedance of blood flow as it traverses distally. The waveform seen in the transducer is the summation of all these waves resulting in a single waveform. Each component can be assigned to a specific point of the cardiac cycle and has hemodynamic significance. This can be appreciated by looking at the waveform in **Figure 49.1**. The systolic upstroke represents the pressure generated at the beginning of systole. The dicrotic notch represents the closure of the aortic valve and the subsequent downstroke represents the rapid decline during diastole. Due to the differences in the characteristics of the vascular tree, ejection velocities, and the length of the fluid column, arterial waveforms differ depending on the site of catheter insertion. The further the catheter is from the aorta, the higher the SBP, the further the dicrotic notch, and the wider the PP. The MAP, however, will remain constant and hence is relied on as the main hemodynamic parameter to assess perfusion.

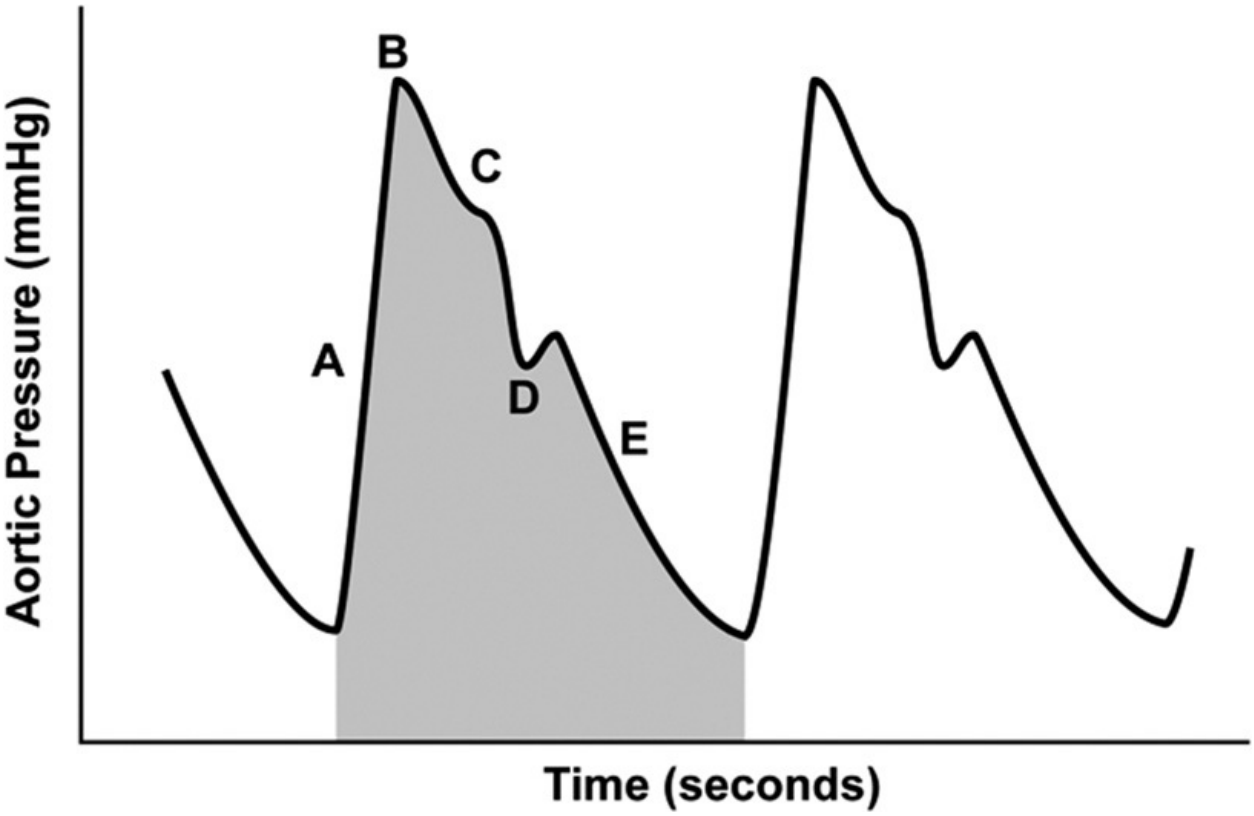

FIGURE 49.1 Arterial waveform. *A*, Systolic uptake. *B*, Peak systolic pressure. *C*, Systolic decline. *D*, Dicrotic notch. *E*, Diastolic runoff.

ACCURACY OF MEASUREMENTS

It is important that accuracy of the ABP measurements is maintained by reducing the length of tubing used and ensuring that there are no bubbles or clots in the system. The accuracy and interpretation of invasive pressure measurements depend on a number of physical principles of the systems used.

Damping

Anything that reduces energy in an oscillating system will reduce the amplitude of the oscillations. This is termed damping and measurements will be adversely affected if there is excessive (overdamping) or insufficient (underdamping) damping,

Factors that will cause overdamping include three-way stopcocks, bubbles, clots, long tubing, and kinks in the catheter or tubing. These may be a major source of error, causing an underreading of SBP and DBP, although the MAP is relatively unaffected.

Transducer position can be checked (ie, zeroed) by turning the stopcock off to

the patient and open to air, at the level of the heart. The monitor must be adjusted to display zero. Incorrect readings may be obtained if the transducer is not releveled with changes in position of the bed or patient.

Abnormal Arterial Line Waveforms

Under certain circumstances, it is possible to correlate the shape of an arterial waveform with a specific pathology. A steep systolic upstroke can be seen in hypertension or atherosclerosis due to noncompliance of the vessels. In aortic regurgitation, the PP is widened and a second peak, bisferient pulse can also be seen (**Figure 49.2**). Aortic stenosis can cause delaying of the upstroke slope and a low systolic peak due to limited outflow (**Figure 49.3**).

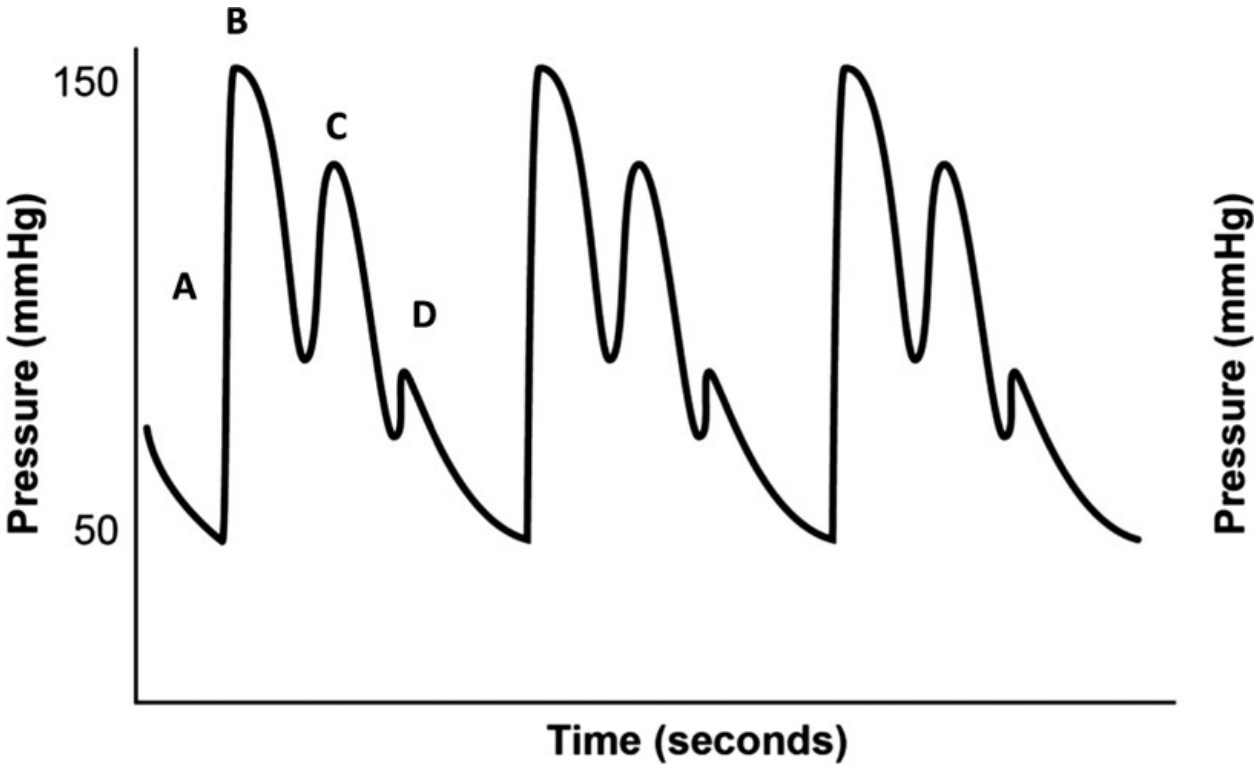

FIGURE 49.2 Arterial waveform in aortic regurgitation. *A*, Widened pulse pressure. *B* and *C*, Bisferiens pulse, peak C is a reflected wave. *D*, Dicrotic notch.

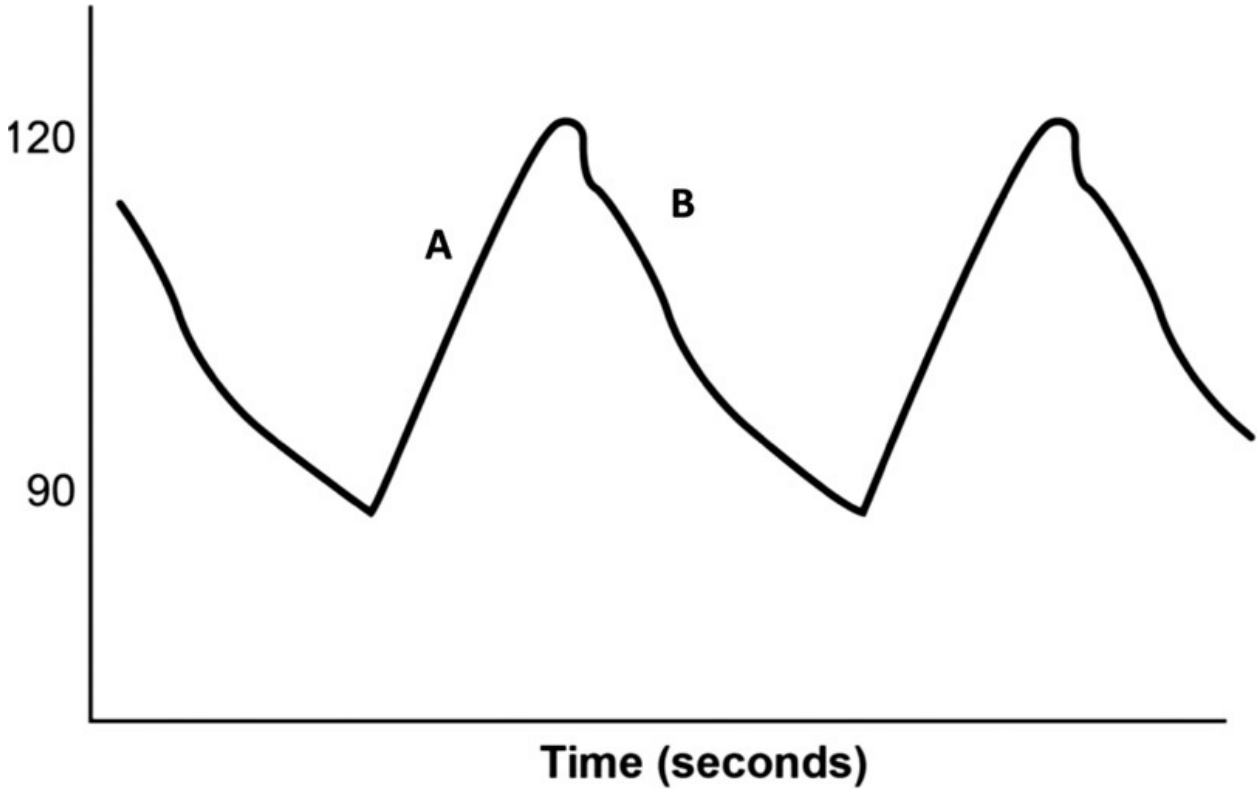

FIGURE 49.3 Arterial waveform in aortic stenosis. *A*, Slurred gradual systolic upstroke. *B*, Absent dicrotic notch.

CENTRAL VENOUS PRESSURE

DEFINITION

Central venous pressure (CVP) is the pressure measured in the lower third of the superior vena cava (SVC) and is considered a direct measurement of the pressure in the RA (ie, mean RA pressure). It is commonly used as an estimate of RV filling pressures or preload.

Some authors suggest the following equation to help health care providers:

CVP = Mean RA pressure = Right ventricular end diastolic pressure (RVEDP) = Preload.

The CVP value is determined both by the pressure of venous blood in the vena cava and the function of the right heart. The principal factors affecting CVP are shown in **Figure 49.4**. Venous return is in turn influenced by intravascular volume, compliance characteristics of the venous system (venous tone), PVR, and intrathoracic pressure. The changes in CVP are directly proportional to

volume changes and inversely proportional to venous compliance.

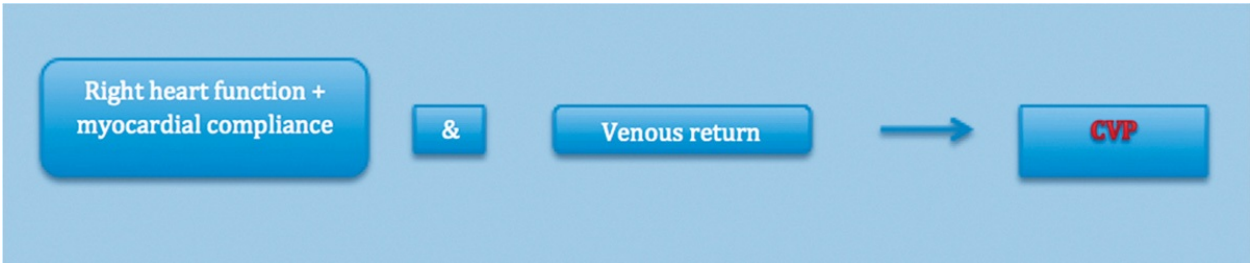

FIGURE 49.4 Factors affecting CVP. CVP, central venous pressure.

MEASUREMENT

CVP is acquired by inserting a CVC into any of several large veins. It is threaded so that the tip of the catheter rests in the lower third of the SVC. The pressure monitoring assembly is attached to the distal port of a multilumen CVC. The CVP can be measured manually (using a manometer) or electronically (using a transducer). Normal CVP is 2 to 6 mm Hg. The CVP must be set at zero at the level of the RA with the patient lying supine (the "phlebostatic axis"—usually 4th intercostal space in the midaxillary line). In the thorax, extravascular pressures should be close to zero at the end of expiration; hence, CVP is measured at end expiration and at end diastole.

CLINICAL UTILITY

Traditionally, CVP has been utilized to assess volume responsiveness, with a low CVP thought to predict fluid responsiveness whereas a patient with a high CVP is thought to be fluid replete. These concepts have been challenged based on meta analysis that have questioned the use of static measures of fluid responsiveness.[2]

CVP is elevated in conditions such as RV failure, tricuspid stenosis, or regurgitation, pericardial disorders, and mechanically ventilated patients on high positive end-expiratory pressure (PEEP) settings and does not reflect fluid status. For the last decade, the utility of CVP measurement to determine volume responsiveness has been questioned. Because of this debate, its use should be in association with information relating to other hemodynamic variables.

WAVEFORM

In sinus rhythm, the CVP waveform reflects changes in right atrial pressure during the cardiac cycle and contains five components:

- Two major positive deflections: *a* and *v* waves
- Two negative deflections: *x* and y descents
- A third positive wave: the *c* wave, which is not consistently observed

Figure 49.5 shows this anatomy of a CVP waveform in correlation with the cardiac cycle with the help of a simultaneous ECG tracing. The first peak is the *a* wave, which immediately follows the *P* wave of the ECG. This *a* wave (atrial) represents the pressure increase due to atrial systolic contraction. The *a* wave is followed by the *x* descent, which is the drop in atrial pressure during ventricular systole caused by atrial relaxation and the downward movement of the atrioventricular junction during early ventricular systole. The trough of the *x* descent is followed by the *v* wave, which represents the increase in pressure generated by the passive filling of the atria during ventricular systole. The *v* wave corresponds to the end of the *T* wave in the ECG. The *y* descent results from the drop in atrial pressure as the blood enters the ventricle during diastole. The *c* wave represents closure of the atrioventricular valves and is seen as a small positive wave early on in the interrupts the *x* descent. The waveform components and their timing in the cardiac cycle are listed in **Table 49.3**. Understanding the CVP waveform can help the clinician to interpret the various abnormalities that can be seen in certain clinical conditions. The waveform abnormalities and the conditions associated with them are listed in **Table 49.4**.

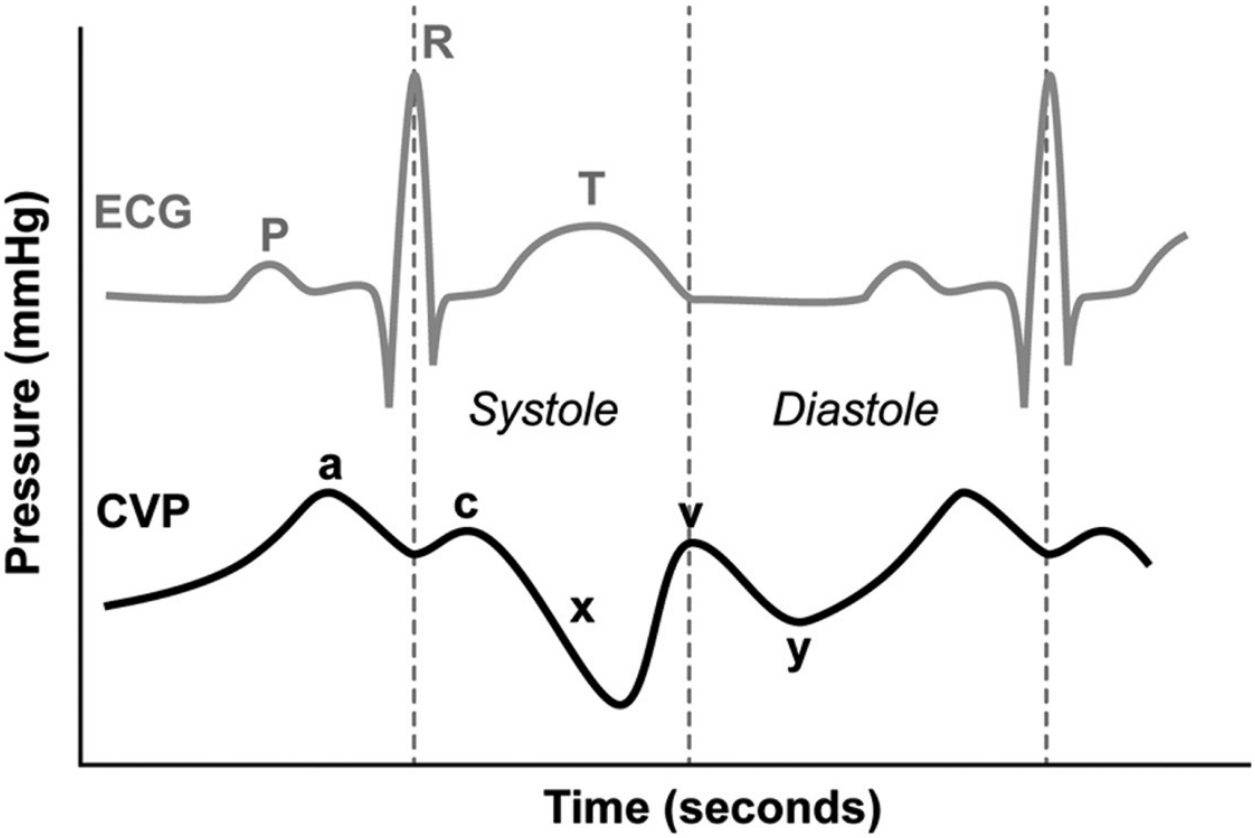

FIGURE 49.5 Anatomy of CVP waveform. CVP, central venous pressure.

TABLE 49.3	Components of the Central Venous Pressure Waveform	
WAVEFORM COMPONENT	**PHASE OF CARDIAC CYCLE**	**MECHANICAL EVENT**
a wave	End diastole	Atrial contraction
c wave	Early systole	Tricuspid bulging (inferior vena cava)
v wave	Late systole	Systolic atrial filling
x descent	Mid systole	Atrial relaxation
y descent	Early diastole	Early ventricular filling

TABLE 49.4	Abnormal Central Venous Pressure Waveforms
WAVEFORM ABNORMALITY	**CLINICAL CORRELATION**
Dominant *a* wave	Pulmonary hypertension Tricuspid stenosis Pulmonary stenosis

Canon *a* wave	Complete heart block Ventricular tachycardia with atrioventricular dissociation
Dominant *v* wave	Tricuspid regurgitation
Exaggerated *x* descent	Pericardial tamponade Constrictive pericarditis
Slow *y* descent	Tricuspid stenosis Atrial myxoma
Absent *y* descent	Tamponade
Prominent *x* and *y* descent	Constrictive pericarditis

CURRENT CONCEPTS

CVP AND ITS USEFULNESS IN GUIDING FLUID THERAPY

CVP is a static measure of right atrial pressures. Traditionally, clinicians have used the concept that a low CVP will be a measure of fluid responsiveness and a high CVP will predict someone who will not respond to a fluid challenge. This concept was promoted by the Surviving Sepsis Campaign (SSC) guidelines based on the Early Goal Directed Therapy trial by Rivers, which showed that using a target CVP goal of 8 to 12 mm Hg (12–15 mm Hg in mechanically ventilated patients) for fluid resuscitation, along with other early interventions, led to decreased mortality in patients with severe sepsis and septic shock.[3,4] However, this relationship between CVP and intravascular volume as well as its usefulness to predict fluid responsiveness has been questioned.[5] In 2008, Marik et al[2]. conducted a systematic review of the literature on this topic that included 24 studies and 805 patients. The studies analyzed demonstrated that patients with low CVPs may not be fluid responsive and patients with high CVPs may be fluid responsive. They found that there is a very poor correlation between CVP and blood volume as well as the inability of CVP or ΔCVP to predict the hemodynamic response to a fluid challenge. They concluded that CVP should not be used to make clinical decisions regarding fluid management.[2,6]

Overall, the methods for assessing fluid responsiveness have evolved over time from static parameters to dynamic measures based on either a passive leg raise (PLR) or a real fluid challenge, both of which have a higher degree of accuracy in predicting fluid responsiveness.[7] However, these dynamic measures

have not been fully incorporated into clinical practice. Although static measures of fluid responsiveness such as the CVP have fallen out of favor, extremes of CVP values still have clinical utility. Septic shock is associated with low CVP, high CO, and low SVR. In contrast, cardiogenic shock is associated with high CVP, low CO, and high SVR. A low CVP is useful because it suggests a low volume state whereas a high CVP is less useful because the patient may have fluid overload or have normal volume status with heart failure. A very high CVP in the absence of right-sided heart disease represents a patient who will likely not be fluid responsive. Although the CVP measurement has been heavily criticized in the literature, when measured correctly it is one of the few tools that is devoid of subjective interpretation by the end user. Additionally, it is a value that is easily obtained in the CCU patient and can be interpreted by various members of the health care team. A CVP should never be interpreted in isolation and should be used in context with one's physical examination, echocardiogram (ECG), and other dynamic measures of fluid responsiveness, which are described later in this chapter. For example, it should not be assumed that a patient is adequately fluid resuscitated if the CVP is normal. Similarly, a patient with right heart dysfunction with elevated CVP may be fluid responsive despite an elevated CVP. In summary, the CVP provides insight into the patient's hemodynamic status and is a useful adjunct when used in combination with other predictors of fluid responsiveness.

CENTRAL VENOUS OXYGEN SATURATION AND OXYGEN DELIVERY

The central venous oxygen saturation ($ScvO_2$) is obtained from a from a central line, preferably from an internal jugular or subclavian vein catheter, and serves as a surrogate of mixed venous oxygen saturation (SvO_2). It is estimated that the $ScvO_2$ is 3% to 5% higher than SvO_2. The femoral $ScvO_2$ is less reliable. $ScvO_2$, along with the CVP, can help guide further fluid management.

A low $ScvO_2$ serves as an indicator of poor oxygen delivery (ie, low CO, low hemoglobin or low SaO_2) or increased consumption by tissues (eg, fever, hyperthyroidism). A high $ScvO_2$ indicates poor extraction by tissues (eg, sepsis, hypothyroidism, cyanide poisoning) or arteriovenous shunting. The SSC sepsis guidelines recommend a target $ScvO_2$ of >70%[4] as a target for resuscitation for patients with severe sepsis and septic shock; however, these protocoled recommendations have since been challenged.[8–10]

THE PULMONARY ARTERY CATHETER

In 1970, Swan and his colleagues[11] described PAC with a balloon proximal to the tip, which could be directed to the branches of the PA. It permits measurement of intracardiac filling pressures. The catheter is inserted into the RA, RV, and when in position with the balloon inflated in the PA, a "wedge" pressure is obtained. This wedge pressure provides an indirect measure of LV filling pressure, which can guide the clinician in the management of fluid therapy in patients with shock and respiratory failure. CO measurements obtained by the thermodilution method and the derived SVR measurement can help distinguish mixed shock states and assist in titrating vasopressors and inotropic medications. The PAC can assist in the management of patients with acute myocardial infarctions, valvular dysfunction, intracardiac shunts, pericardial tamponade, and pulmonary hypertension. Additionally, it can help with the diagnosis and management of mechanical complications of myocardial infarction, such as ventricular septal rupture, papillary muscle rupture, and RV infarction. Contraindications to PAC include severe coagulopathy or thrombocytopenia, RV thrombus, tricuspid or pulmonic valve prosthesis, and right-sided endocarditis. In patients with left bundle branch block, passage of the catheter can induce complete heart block.

DESCRIPTION

A PAC or Swan-Ganz catheter is a flexible, balloon-tipped, flow-directed catheter that is guided through the right side of the heart and into a branch of the PA. Under sterile conditions, the catheter is generally inserted through the subclavian, internal jugular, or femoral, vein. The right internal jugular vein and left subclavian vein are ideal because the curvature of the PAC facilitates passage through the heart. The procedure, also known as right heart catheterization, may be performed with or without the use of fluoroscopy.[12]

The typical PAC is 110 cm long and has four lumens: the distal, proximal, thermistor, and inflation lumen. The distal lumen port is located at the tip of the catheter. This port allows monitoring of systolic, diastolic, and mean pressures in the PA and allows visualization of the waveform to guide proper placement. It can also be used for drawing mixed $S\bar{v}O_2$ samples. The proximal port, located approximately 30 cm from the tip of the catheter, is used to monitor RA pressure, CVP, and to inject the solution used to assess intermittent CO by thermodilution.

Additionally, there may be an accessory RA proximal port with its lumen at 30 cm from the catheter tip, which may be used for infusion of medications. **Figure 49.6** shows a standard PAC with the balloon inflated.

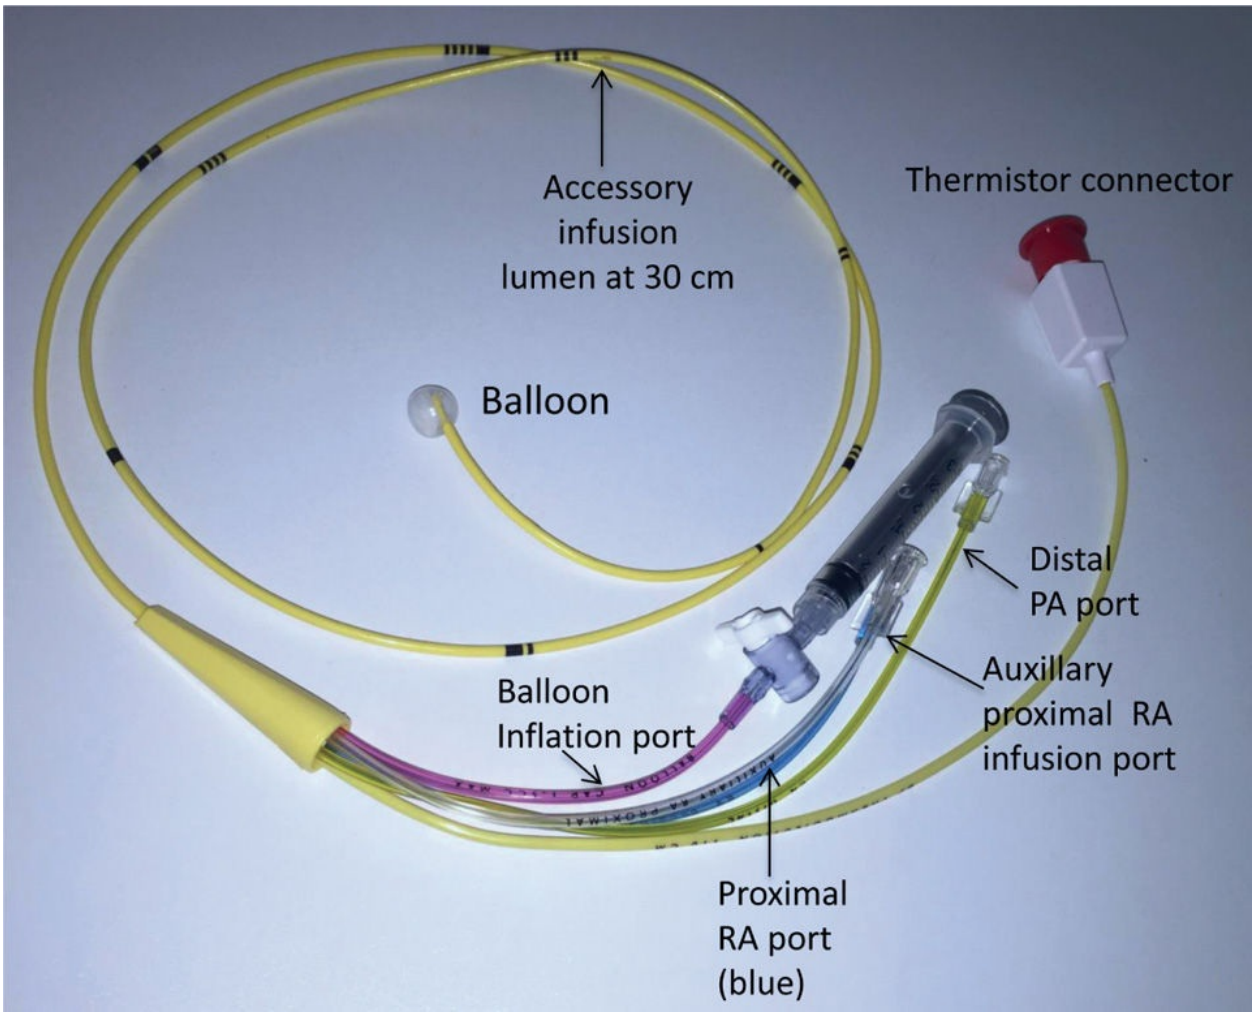

FIGURE 49.6 Standard pulmonary artery catheter.

Thermodilution involves injection of a known amount of solution with a known temperature rapidly into the RA lumen of the catheter. Usually cold fluid is injected into the proximal lumen and the temperature of the blood is measured downstream in the PA by a thermistor. This information is plotted on a time–temperature curve that represents the time it takes for the blood to change from a warmer baseline temperature to a cooler temperature after the injection and then back to the baseline temperature as the blood circulates. The rate of blood flow is inversely proportional to the change in temperature over time. When CO is

low, it takes longer for the blood temperature to return to baseline; when CO is high, the cooling fluid is carried faster through the heart, and the temperature returns to baseline faster.

The inflation lumen connects to a balloon that is located less than 1 cm from the catheter tip, which is inflated with 1.5 mL air to advance into the PA. The waveform is constantly observed on the monitor during advancement until a wedged position is obtained. It is important that on deflation of the balloon, a PA waveform is obtained so as to avoid over wedging. It is used to obtain PAWP, which is also called pulmonary artery occlusion pressure (PAOP) or pulmonary capillary wedge pressure (PCWP).

Once lodged in the PA, the inflated balloon serves as a continuous conduit from the catheter tip through the pulmonary vein, left atrium (LA), and open mitral valve into the left ventricle. This allows the distal lumen to indirectly measure LV pressure. The balloon should be deflated once PAOP measures are obtained. The pulmonary artery diastolic pressures (PADP) can also serve as a surrogate to PAOP. Newer catheters come with continuous cardiac output (CCO) and continuous S_{VO}^{2} monitoring. In order to measure CO continuously, thermal energy emitted by the filament located on the catheter is used to calculate CO using thermodilution principles.

INSERTION

Prior to PAC insertion, the system must be zeroed to ambient air pressure. The reference point for this is the midpoint of the LA, estimated at the fourth intercostal space in the midaxillary line with the patient lying in supine position. With the transducer at this height, the membrane is exposed to atmospheric pressure and the monitor is then adjusted to zero. The PAC should be checked for cracks and kinks. The balloon should be checked and all lumens flushed to remove air bubbles.

The catheter is inserted through an introducer catheter sheath and advanced using continuous pressure monitoring from the distal lumen (**Figure 49.7**). It is recommended to insert the catheter 15 cm so that the tip is outside of the sheath. The balloon is then inflated before advancing into the PA. **Figure 49.7** shows the various waveforms obtained during right heart catheterization. If an RV waveform is still present approximately 20 cm after the initial RV pattern appears, the catheter may be coiling in the RV. The catheter is withdrawn slowly and advanced again until the PA tracing is obtained and even further until a wedge tracing is obtained. Sometimes fluoroscopy is necessary in difficult cases.

Measure CO by connecting the thermistor to a computer and perform thermodilution. The assistant should note down the systolic, diastolic, and mean pressures in the right heart, including the PAOP at end expiration.

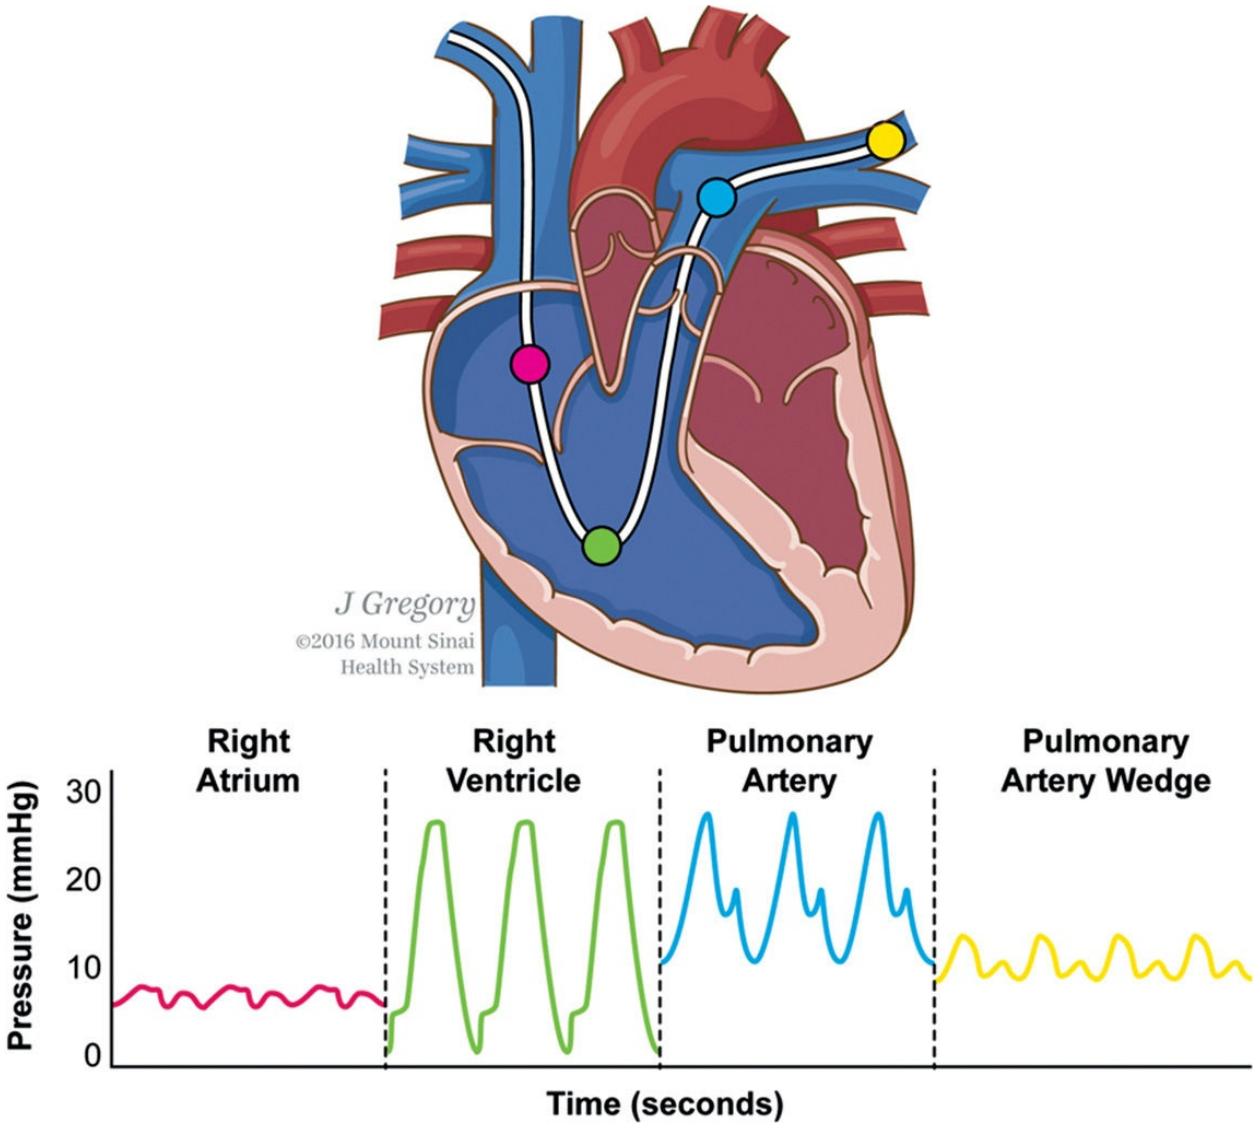

FIGURE 49.7 Waveforms during right heart catheterization.

An ideal positioning of the PAC is one which shows the PA tracing with the balloon deflated and a pulmonary occlusion tracing with the balloon inflated. It is important to deflate the balloon after acquiring readings and values. A chest X-ray is obtained to ensure proper placement preferably in West Zone 3, where the pulmonary capillary pressure exceeds the mean alveolar pressure.[13] This zone is located in the most dependent portion of the lung, where vascular pressures are the highest. If the PAOP is greater than the PA diastolic pressure or if there is marked respiratory variation, this may be a clue that the catheter has not migrated into Zone 3. The tip of the catheter should therefore be ideally positioned below the level of the LA. In a patient on a ventilator, high PEEP can

alter the baseline intrathoracic pressure. However if it is located in the right zone as mentioned earlier, the effects of PEEP on PAOP are usually small, and often do not affect clinical management.

The PAOP waveform is similar to the CVP waveform obtained from the proximal port, which reflects RA pressures. However, it is important to recognize that the PAOP waveform is shifted to the right by 80 to 120 ms in relation to the ECG because of the time delay in the waveform travelling through the pulmonary circuit.

As a review, let us contrast PAOP versus CVP. PAOP measures left atrial pressure, and approximates left ventricular end diastolic pressure (LVEDP) when the mitral valve functions properly.

Some authors simplify this concept by the following formula:

$$\text{PAOP} = \text{Mean LA pressure} = \text{LVEDP},$$

while

$$\text{CVP} = \text{Mean RA pressure} = \text{RVEDP} = \text{Preload}.$$

MEASUREMENTS

Direct measurements that can be obtained from an accurately placed PAC are the following:

- Central venous pressure
- Right atrial pressure (RAP)
- Right ventricular pressure (RVP)
- Pulmonary arterial pressure (PAP)
- Pulmonary artery occlusion pressure
- Cardiac output
- Mixed venous oxyhemoglobin saturation (SvO_2)

The PAC can also indirectly measure the following:

- Systemic vascular resistance
- Pulmonary vascular resistance
- Cardiac index (CI)
- Stroke volume index (SVI)
- Left ventricular stroke work index (LVSDI)

Right ventricular stroke work index (RVSI)
Oxygen delivery (DO_2)
Oxygen consumption (VO_2)

INTERPRETATION

Right ventricle: During catheter insertion using the distal tip, the peak RV systolic pressure and the RVEDP are measured from the RV pressure waveform. Normal RV systolic pressure varies from 15 to 30 mm Hg and normal RVEDP varies from 1 to 7 mm Hg. Elevations in RV pressure are associated with diseases that elevate the PAP, pulmonic valve disorders, and diseases that primarily affect the RV.

Pulmonary artery: Normal PA systolic pressures range from 15 to 25 mm Hg, whereas PA diastolic pressures range from 8 to 12 mm Hg. The mean PAP (mPAP) is typically 16 mm Hg (10 to 22 mm Hg). Pulmonary hypertension is defined as mPAP ≥ 25 mm Hg. The PA tracing is similar in appearance to the systemic arterial pressure tracing, except that the PAPs are normally much lower.

Pulmonary artery occlusion pressure: The PAOP or PCWP estimates the left atrial pressure. This is measured when the catheter tip is in the PA with the balloon inflated. Normal wedge pressures vary from 8 to 12 mm Hg, with a mean of 10 mm Hg. The PAOP usually estimates the LVEDP, which gives an idea of LV preload, assuming that there is no obstruction to flow between the LA and left ventricle and that the compliance of the left ventricle is normal. The PAOP may not reliably indicate LV preload when compliance of the left ventricle is abnormal (eg, LV hypertrophy, ischemia, or restrictive cardiomyopathy). Valvular pathology such as mitral stenosis, myxoma, or mitral regurgitation will overestimate PAOP, whereas PAOP will underestimate LVEDP in aortic regurgitation. **Table 49.5** outlines the conditions that cause abnormal PAOP values.

TABLE 49.5 Abnormal PAOP Values

Conditions that cause a high PAOP
Left ventricular systolic heart failure
Left ventricular diastolic heart failure
Mitral and aortic valve disease

Hypertrophic cardiomyopathy
Hypervolemia
Large right-to-left shunts
Cardiac tamponade
Constrictive and restrictive cardiomyopathies
Conditions that cause a low PAOP
Hypovolemia
Pulmonary venoocclusive disease
Obstructive shock due to pulmonary embolism

PAOP, pulmonary artery occlusion pressure.

ABNORMAL PAOP WAVEFORMS

Physiologically, the PAOP tracing has similar components to the RA with three positive and two negative deflections. The abnormal waveform seen in the PAOP tracing reflects changes on the left side of the heart. Electrocardiographic correlation is required for correct identification of these events. The PAOP waveform is delayed by >120 ms when compared with the ECG.

Large *a* waves: Increased amplitude of the *a* wave in the PAOP tracing can be seen with increased resistance to LV filling of any cause such as mitral stenosis or decreased LV compliance. Cannon *a* waves can also be seen with complete atrioventricular block due to atrial contraction against higher ventricular pressures.

Large *v* waves: The common cause of large *v* waves on a PAOP tracing is mitral regurgitation (MR). Other conditions such as ventricular septal defects can also cause large *v* waves due to increased atrial pressures. Giant *v* waves can be seen in cases of severe MR and often this may be mistaken for a PA tracing. This can be avoided by using the ECG tracing and understanding that the peak of the systolic PAP occurs within the *T* wave whereas the giant *v* wave occurs after it.

Conditions such as cardiac tamponade and constrictive pericarditis may present hemodynamic alterations prior to clinical manifestations. Whereas both conditions may produce equalization of diastolic pressures (RAP = RV diastolic pressure = PADP), waveform identification can assist in differentiating the two.

In cardiac tamponade, all right-sided pressures will be elevated and there is a prominent *x* descent and a loss of the *y* descent in a PAOP or RA tracing as a result of higher diastolic values. In constrictive pericarditis, there are exaggerated *y* descents from rapid diastolic filling as a result of the rigid pericardium.

Acute ventricular septal defect (VSD) can also produce low CO when the blood volume from the left ventricle shunts over to the right ventricle. This shunting causes a "step-up" of oxygen saturation from the right ventricle to the PA. By determining saturation values in the PA, a VSD can be detected. In severe cases, a resultant elevation in the *v* wave during a wedge recording may also be seen. This is due to the increase in blood volume from the left ventricle, which during atrial filling, records as an elevation in the *v* wave.

MEASURING THE PAOP

The correct reading of a PAOP waveform in relation to an ECG strip is shown in **Figure 49.8**. As opposed to a CVP tracing, there is a delay of two to three squares of the waveform in the PAOP tracing. The "*Z* point" (occlusion pressure at end diastole) is measured by any one of the following methods (see **Figure 49.8**):

1. The pre *c* wave location
2. Mean of the highest and lowest pressure of the *a* wave: $\text{PAOP} = \frac{a + x}{2}$
3. The *Z* point, a perpendicular line drawn two to three squares after the QRS complex

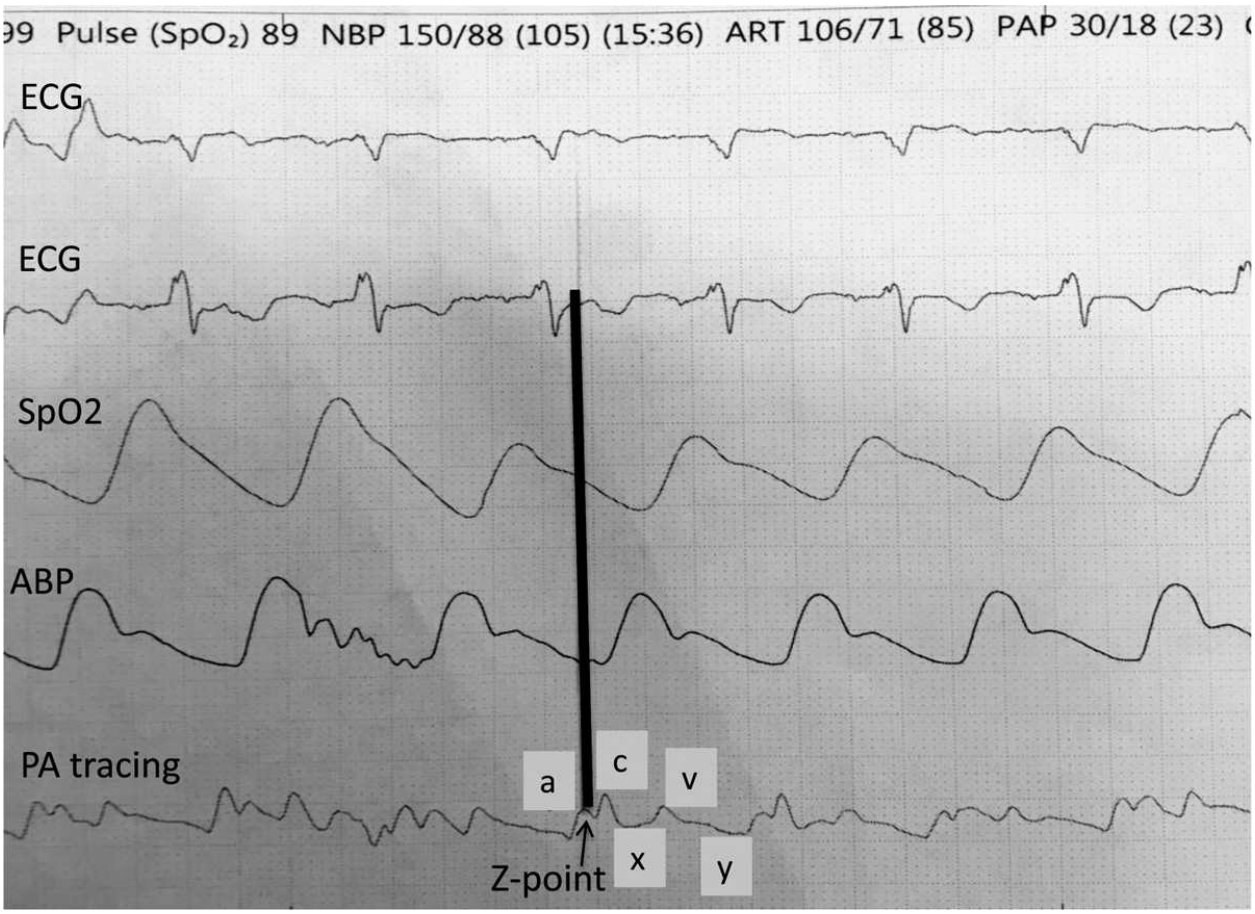

FIGURE 49.8 Pulmonary artery occlusion pressure waveform in relation to ECG. ECG, Electrocardiogram.

The abnormal waveform seen in the PAOP tracing reflects changes on the left side of the heart. The objective of placing a Swan-Ganz catheter is to obtain LVEDP, which is used to estimate LV end diastolic volume (LVEDV). The location of the end diastole period correlates to the point just before the *c* wave. If the *c* wave is not located, then the next approach would be to measure the mean of the highest and lowest pressures of the *a* wave. A third method is to find the *Z* point that correlates with the wedge pressure. This is located on the PAOP tracing by drawing a line, two to three boxes (0.08 to 0.12 seconds) after the QRS segment of the ECG tracing.

It must be remembered that respiratory efforts strongly affect the waveforms. Spontaneous ventilation tends to drop vascular pressures, whereas positive pressure ventilation raises the pressures in the inspiratory cycle. Pleural pressures become negative during inspiration in a spontaneously breathing patient and positive during the inspiratory cycle of a mechanically ventilated

patient. Since expiration is the longer and more stable phase, pressures are measured at the end of expiration, when pleural pressures are close to zero.

In summary, an ideal measurement of wedge pressure involves obtaining simultaneous tracings of ECG, respiration, and the PAOP tracing, then identifying the *Z* point using the ECG at the end of expiration, or measuring the average of the highest and lowest pressures of that *a* wave. Other interpretations of the waveforms are similar to what was mentioned in the CVP tracings except that they reflect left-sided function.

CALCULATION OF CARDIAC OUTPUT

Thermodilution Method

The thermodilution method has been well validated and is performed as specified earlier. Approximately 10 mL of cold or room temperature saline is injected into the proximal lumen and the temperature difference is sensed by the distal lumen. The bedside computer monitor integrates the time–temperature curve and calculates CO using the Stewart–Hamilton equation. The area under the temperature–time curve is inversely proportional to CO. Usually three CO measurements are performed in rapid succession and averaged.[14]

Clinicians should be aware of several important sources of error such as tricuspid regurgitation and intracardiac shunts. Tricuspid regurgitation leads to an underestimation of CO. Right-to-left and left-to-right intracardiac shunts can produce falsely elevated cardiac output measurements by the thermodilution technique. Variations in temperature (eg, after cardiopulmonary bypass) can also falsely affect the measurements. Accurate measurements also depend on calibration of transducers and a fluid-filled system that is devoid of air bubbles and blood clots. The CO can also be elevated physiologically. A high CO with or without heart failure can also be seen in a number of conditions such as sepsis, hyperthyroidism, anemia, Beriberi, renal disease, hepatic disease, and systemic arteriovenous malformation.

Fick Method

Fick's concept proposes that the uptake or release of a substance by an organ is the product of blood flow through that organ and the difference between arterial and venous values of that substance. Although the Fick method is considered the gold standard for CO measurement, it is not widely applied outside the cardiac

catheterization laboratory, because it has many limitations including a patient who is in steady state and the requirement of simultaneous expired air and blood samples.[14]

$$CO = \frac{\dot{V}o_2}{Cao_2 - Cvo_2} \qquad \text{(Eq. 6)}$$

where $V.O_2$ is oxygen consumption, CaO_2 is normal arterial oxygen content, and CvO_2 is normal venous oxygen content.

Oxygen consumption is either measured by exhaled breath analysis or estimated from a nomogram that is based on age, sex, height, and weight. The arteriovenous oxygen difference requires additional calculations:

$$Cao_2 - Cvo_2 = 1.34 \times Hgb \times (Sao_2 - S\bar{v}o_2) \times 10 \qquad \text{(Eq. 7)}$$

$$S\bar{v}o_2 = Sao_2 - \frac{\dot{V}O_2}{1.34 \times Hgb \times CO} \qquad \text{(Eq. 8)}$$

where Hgb is the hemoglobin, $S\bar{v}O_2$ is the mixed venous oxygen content and the SaO_2 is the arterial oxygen content.

DETECTION OF LEFT-TO-RIGHT SHUNTS

Arterial blood sampling from the RA, right ventricle, and PA provides helpful information when evaluating a suspected intracardiac (left to right) shunt. Detection of an oxygen saturation “step-up” in the right-sided chambers allows confirmation of the left-to-right shunt and determination of its location.

SYSTEMIC AND PULMONARY VASCULAR RESISTANCE

Once the CO has been determined, SVR and PVR can be estimated. Since the calculations of vascular resistance are based on direct measurements (ie, pressures) and indirect measurements (i.e., CO), each one can has its own intrinsic sources of error, giving rise to incorrect calculated values. Nonetheless, SVR can provide valuable information when distinguishing the classes of shock from each other and PVR is often useful when determining the prognosis of patients with pulmonary hypertension. **Table 49.6** lists the common formulas used for interpretation of Swan-Ganz values and **Table 49.7** lists the normal values. The derived values are illustrated in **Table 49.8**. Obtaining these values is very useful in creating a hemodynamic profile of the critically ill patient in the CCU. The commonly observed hemodynamic profile in the critically ill patient in various conditions is listed in **Table 49.9**.

TABLE 49.6 Formulas for Swan-Ganz Interpretation

FORMULAS
DO_2 (mL/min) = CO × CaO_2
CO (mL/min) = HR × SV
Ca_{O_2} (mL O_2/dL) = 1.34 × Hb × Sa_{O_2} + 0.003 × P_{O_2}
V_{O_2} (mL O_2/min) = CO × (CaO_2 − CvO_2)
SVR (dyne · s/cm^5) = $\frac{MAP - CVP}{CO} \times 80$
PVR (dyne · s/cm^5) = $\frac{MPAP - PAOP}{CO} \times 80$
CI (L/min/m^2) = $\frac{CO}{BSA}$
SVI (mL/m^2/beat)= $\frac{CI}{HR}$
LVSWI (g/m^2/beat)= (MAP − PAOP) × SVI × 0.136
RVSWI (g/m^2/beat)= (MPAP − CVP) × SVI × 0.136

BSA, body surface area; Ca_{O_2}, oxygen content; CI, cardiac index; CO, cardiac output; Cv_{O_2}, venous oxygen content; CVP, central venous pressure; DO_2, oxygen delivery; HR, heart rate; LVSWI, left ventricular stroke work index; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure; PVR, pulmonary vascular resistance; RVSWI, right ventricular stroke work index; SV, stroke volume; SVI, stroke volume index; SVR, systemic vascular resistance; V_{O_2}, oxygen consumption.

TABLE 49.7 Normal Values

CO: 4–8 L/min
CI: 2.5–4 L/min
CVP: 2–6 mm Hg
PAWP: 8–12 mm Hg
PAP: 25/10 mm Hg
$S_{\bar{v}O_2}$: 0.65–0.70

CI, cardiac index; CO, cardiac output; CVP, central venous pressure; PAP, pulmonary arterial pressure; PAWP, pulmonary artery wedge pressure.

TABLE 49.8	Derived Values
USE OF FORMULA: CO = (MAP − CVP)/SVR	
SV:50–100 mL/beat	
SVI: 25–45 mL/beat/m^2	
SVR: 900–1300 dyne · s/cm^5	
SVRI: 1900–2400 dyne · s/cm^5	
PVR: 40–150 dyne · s/cm^5	
PVRI: 120–200 dyne · s/cm^5	

PVR, pulmonary vascular resistance; PVRI, pulmonary vascular resistance index; SV, stroke volume; SVI, stroke volume index; SVR, systemic vascular resistance; SVRI, systemic vascular resistance index.

TABLE 49.9	Hemodynamic Profile in Common Critical Conditions				
CONDITION	**CVP**	**PAOP**	**CO**	**PVR**	**SVR**
Right heart failure	↑		↓	↑	
Left heart failure		↑	↓		↑
Pericardial tamponade	↑	↑	↓		↑
Hypovolemia	↓	↓	↓		↑
Cardiogenic shock	↑	↑	↓		↑
Distributive shock	↓	↓	↑		↓

CO, cardiac output; CVP, central venous pressure; PAOP, pulmonary artery occlusion pressure; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

CONTROVERSIES ON THE MODERN USE OF THE PAC

PA catheterization is no longer routinely performed, perhaps due to a combination of overuse by inexperienced operators and lack of validity in various studies. Although it is an invasive and expensive technique, it remains a useful bedside tool in the management of select patients such as those with acute respiratory distress syndrome (ARDS) and sepsis, pulmonary hypertension, cardiogenic shock, or patients who have more than one condition.

Early studies showed that the PAC predicted hemodynamic profiles correctly in only 53% of critically ill patients; however in a subgroup analysis, PAC reduced mortality in patients with shock compared to those managed without a PAC.[15] Later studies showed that the PAC does not change clinical outcomes and that physicians had a poor understanding of how to interpret the hemodynamic data.[16] Gore et al[17] showed in a retrospective review of 3263 patients that patients managed with a PAC had a higher case fatality rate. An accompanying editorial called for a moratorium on the PAC.[18]

Additional studies in the 1990s, including the SUPPORT trial, showed that in critically ill patients, the PAC was associated with increased cost, length of stay, and mortality.[19] In patients with congestive heart failure, it was shown that management with a PAC increased anticipated adverse events and, in fact, did not affect overall mortality or hospitalization.[20] A large metaanalysis of 14 trials by Shah et al. further validated that the PAC neither decreased mortality nor hospital stay.[21] The PAC-Man study evaluated the effects of PAC-driven therapy in 65 British intensive care units (ICUs) and concluded that the PAC conferred neither benefit nor harm when used to manage critically ill patients.[22] The “nail in the coffin” was evidence from the U.S. National Institutes of Health sponsored FACTT trial, which showed that in patients with acute lung injury (ALI), PAC-guided therapy did not improve survival or organ function but was associated with more complications than CVC-guided therapy. These results, when considered with those of previous studies, suggested that the PAC should not be routinely used for the management of ALI.[23]

Overall, there has been a downward nationwide trend in the use of the PACs up to 65% between 1993 and 2004, most notably after acute myocardial infarction.[24] Nevertheless, PACs continue to be used in CCUs and cardiothoracic ICUs internationally, so one must still maintain a good understanding of its functionality. Although they are no longer used on a routine basis, they certainly provide valuable hemodynamic information in postoperative cardiac patients and in certain CCU patients who need close hemodynamic monitoring. One of the arguments in favor of ongoing management with PAC is that prior trials included broad populations of cardiac patients in shock states and acute respiratory failure and may not have identified the exact population who may benefit from PAC monitoring. Along with its overuse in the 1990s and a lack of proper understanding of the hemodynamic data, these factors likely contributed to the fallout of the PAC.

ESOPHAGEAL DOPPLER

Esophageal Doppler monitoring involves placement of a probe in the esophagus of the patient and measuring blood flow velocity in the descending aorta. By measuring aortic blood flow (ABF), esophageal Doppler monitoring allow a reliable estimation of CO.[25] This can be done with transesophageal echocardiography or with a commercially available device that can track changes in SV and CO after a volume challenge or vasoactive agents. Probes are inserted orally to a depth of 35 to 40 cm from the incisors or nasally to 40 to 45 cm. The probe is manipulated till the distinct descending aorta waveform shape is visualized. From the aortic Doppler waveform that is obtained, valuable information such as preload and SV can be obtained.

Application of esophageal Doppler may be used intraoperatively in the recovery room or the CCU. Generally speaking, a change in ABF of 10% or higher is considered to indicate that the patient is fluid responsive. An actual fluid challenge or a PLR can be performed to see if the SV increases and this can guide further fluid management.[26] In a study of mechanically ventilated patients in normal sinus rhythm, Monnet et al[27] showed that a respiratory variation in ABF before volume expansion of at least 18% predicted fluid responsiveness with a sensitivity of 90% and a specificity of 94%. Intraoperative esophageal Doppler-guided fluid management has been shown to improve postoperative outcomes, including length of stay, after abdominal surgery and orthopedic procedures.[28,29] Precise, goal-directed fluid management in the operating room has now become standard of care and a prerequisite by many insurance companies in the United States.

PULSE PRESSURE VARIATION AND STROKE VOLUME VARIATION

The principles underlying pulse pressure variation (PPV) and stroke volume variation (SVV) are based on simple physiology that intermittent positive pressure ventilation induces cyclic changes in the loading conditions of the left and right ventricles. Mechanical insufflation increases intrathoracic pressure, decreases preload, and increases afterload of the right ventricle. The inspiratory reduction in RV ejection fraction leads to a decrease in LV filling after a phase

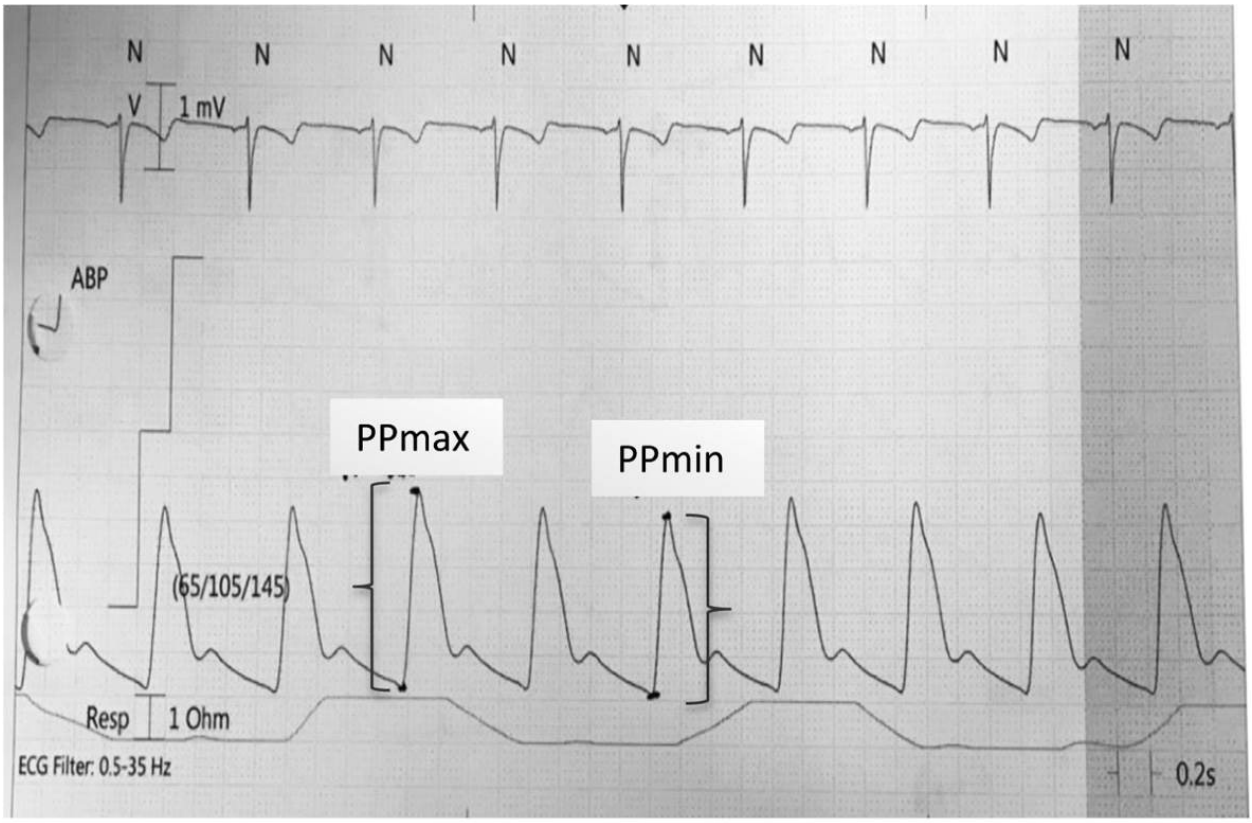
lag of two or three heart beats because of the long pulmonary transit time. Thus, the LV preload reduction may induce a decrease in LV stroke volume, which is at its minimum during the expiratory period. Therefore, the magnitude of the respiratory changes in LV stroke volume is an indicator of biventricular preload dependence

It should be appreciated that both arrhythmias, low tidal volumes (<8 mL/kg ideal body weight [IBW]), and spontaneous breathing activity, even on mechanical ventilation, will lead to misinterpretations of the respiratory variations in PPV and SVV.[26] Hence, when measuring PPV or SVV, the patient should be passive on the ventilator, on ≥ 8 mL/kg IBW tidal volume, and in normal sinus rhythm.

$$PPV\% = \frac{PPmax - PPmin}{PPavg} \times 100$$

Figure 49.9 shows PPV measurement.

Seminal studies by Michard and others have found that a PPV of > 12%, in the appropriate patient, predicts fluid responsiveness with a sensitivity of 94% and specificity of 96%.[30,31] Based on this data, the patient in **Figure 49.9** would be fluid responsive. Goal-directed fluid management in the operating room (OR), with minimizing of PPV, has been shown to improve postoperative outcomes and decrease length of stay in high-risk surgical patients.[32]



$$\text{PPV \%} = \frac{\text{PPmax} - \text{PPmin}}{\text{Mean of the 2 PP}} \times 100$$

FIGURE 49.9 Pulse pressure variation. PPV, pulse pressure variation.

NEWER HEMODYNAMIC MONITORING DEVICES

Various commercially available devices utilize the concepts described above in providing hemodynamic data.

FLOTRAC/VIGELEO

The FloTrac device (Edwards Lifesciences, Irvine, CA) is a CO monitor that uses pulse contour analysis to provide hemodynamic data. It requires a specialized sensor with a proprietary transducer attached to a radial or femoral arterial catheter. It analyzes the shape of the arterial pressure readings and calculates CO and other derived parameters such as SV, SVV, SVR, and CI. It updates key flow-based parameters such as CO, SV, and SVV every 20 seconds.

Although the variables themselves are not always exact, when compared to the PAC, variability and trends are helpful in the management of critically ill patients. Additionally, the autocalibration feature is advantageous and make it user-friendly for all CCU staff.

PICCO TECHNOLOGY

PiCCO (Maquet, Rastatt, Germany) is a CO monitor that combines pulse contour analysis and transpulmonary thermodilution technique. The pulse contour analysis provides continuous information while transpulmonary thermodilution provides static measurements. It requires a central venous line as well as the PiCCO arterial catheter, which has a thermistor on the end. For the transpulmonary thermodilution measurement, a defined bolus (eg, 10 mL cold 0.9% normal saline) is injected via a CVC. The cold bolus passes through the right heart, the lungs, and the left heart and is detected by the PiCCO catheter, commonly placed in the femoral artery. Using intermittent thermodilution and arterial pulse contour analysis, along with proprietary algorithms, various parameters such as CO, PPV, SVV, extravascular lung water, and global end diastolic volume can be obtained.

LITHIUM DILUTION CARDIAC OUTPUT (LIDCO)

LiDCO (LiDCO, London, UK) is another noninvasive method of CO measurement that utilizes thermodilution. A small dose of intravenous lithium is injected through a peripheral or central venous line, and subsequently the lithium concentration is measured by a lithium ion-sensitive electrode placed in a peripheral arterial line. A concentration–time curve is thus created, and from that curve, CO is calculated. This measurement is then used to calibrate the pulse contour analysis software. This initial calibration enables continuous subsequent CO measurement by analyzing the arterial pressure waveform. The LiDCOplus system also calculates the PPV and SVV during the respiratory cycle but uses different processing software from that used in PiCCO. This system has the advantage of not requiring a CVC but does require intermittent thermodilution.

These less-invasive hemodynamic devices have become more popular over the past decade. Data from a pooled analysis show that SVVs from these devices have a sensitivity of 82% and specificity of 86%.[31] These devices may also be useful in determining the hemodynamic response to a PLR. In this regard, an increase in CO by more than 10% in response to a PLR has been shown to

accurately predict volume responsiveness in mechanically ventilated patients with spontaneous breathing activity.[33]

CONCLUSION

Invasive hemodynamic monitoring is essential to the care of the critically ill patient. Clinicians should be aware of the various modalities available and their respective advantages and pitfalls. CVP has become controversial in fluid management. Although the PAC provides extremely useful information about the hemodynamic status of the patient, its role has diminished because studies show it does not change clinical outcomes. Heart–lung interactions can be utilized to look for dynamic changes in pulse pressure and stroke volume. No measurement should be used in isolation to make clinical decisions with regard to fluid management. Proper measurement and interpretation of the data is the key to ensuring adequate oxygen delivery and tissue perfusion, which is the goal of successful hemodynamic monitoring.

Patient and Family Information for: Invasive Hemodynamic Assessment in the CCU

WHAT IS HEMODYNAMIC MONITORING?

Invasive hemodynamic monitoring allows doctors and nurses to closely monitor the patient's clinical status. Using catheters that are placed into veins and arteries, measurements can be made of the patient's blood pressure and the pressures within the chambers of the heart. These measurements can be used to guide the clinical team to determine fluid and medical therapy.

WHAT IS THE PREPARATION?

The clinical team will explain the type of invasive hemodynamic monitoring that is being planned, including its purpose, risks, and benefits. Most procedures in the cardiac care unit (CCU) that are performed for hemodynamic monitoring are done at the bedside. Occasionally, invasive procedures will be performed in the cardiac catheterization lab. Be sure to wear your hospital gown, as parts of your body may be uncovered to facilitate the exam. You may be asked to position yourself a certain way and lay still for the procedure. Local anesthesia or numbing medication will be administered to prevent pain. Sometimes, an intravenous antianxiety medication may be given to help facilitate the procedure.

HOW LONG DOES IT TAKE?

It can take anywhere from 15 to 30 minutes to insert catheters for invasive hemodynamic monitoring. Once the catheter is in place, it may be left in place for anywhere from 1-2 days to the entire stay in the CCU. The catheter will be removed as soon as it is no longer necessary.

WHAT IS THE PROCESS?

Measurements from invasive hemodynamic monitors will be displayed on the patient monitor in the room and also at the nursing station. These measurements will help your clinical team to guide your medical management.

WHAT ARE THE RISKS AND COMPLICATIONS?

Your clinical team will weigh the risks and benefits before proceeding with catheters for invasive hemodynamic monitoring. The main risks of any catheter placement are bleeding, infection, clotting of the catheter or vessel, and damage to the blood vessel or nearby structures. There may be risks of abnormal heart rhythms when the catheter is being placed and also risk of air entering the circulation. Your clinical team will take appropriate precautions to ensure that it is a safe procedure.

WHAT ARE SOME TYPES OF INVASIVE HEMODYNAMIC MONITORING?

1. CENTRAL VENOUS PRESSURE (CVP) MONITORING

A central venous catheter (CVC) or a central line is a sterile, flexible, small hollow tube inserted into the internal jugular vein in the neck or the subclavian vein in the upper chest. The tip of catheter rests within a vein connected to the heart called the superior vena cava. When this catheter is connected to additional tubing from the patient monitor, the CVP can be measured.

Normal CVP is between 8 to 12 cmH2O. A very low CVP can indicate that you may need additional intravenous (IV) fluids, and a very high CVP can mean that you do not need any additional IV fluids. Keep in mind that CVP monitoring has come under controversy recently, and hence your clinical team will interpret

the numbers in conjunction to their clinical exam and other available data to help guide your treatment.

2. ARTERIAL BLOOD PRESSURE (ABP) MONITORING

An arterial line (or A-line) is a small, sterile tube that is inserted into an artery, commonly either in the wrist (radial artery) or groin (femoral artery). When this catheter is connected to additional tubing from the patient monitor, it can obtain beat-to-beat measurements of the arterial blood pressure. These measurements are much more accurate that the regular blood pressure (BP) that is obtained from a standard BP cuff. These accurate measurements will help guide your doctors and nurses in adjusting your medications. In addition, A-lines can be used for obtaining frequent blood samples to assess the degree of acidity and levels of oxygen and carbon dioxide in the blood.

3. PULMONARY ARTERY CATHETERIZATION OR SWAN-GANZ CATHETERIZATION

A pulmonary artery catheter (PAC) is a thin tube or catheter that is placed into the right side of the heart and the artery leading to the lungs (pulmonary artery). An experienced physician, physician assistant, or nurse practitioner typically performs the procedure with local anesthesia and under sterile conditions. The catheter is generally inserted into one of three veins: the right internal jugular (RIJ) vein, located in the neck, which is the shortest, most direct path to the heart; the left subclavian vein, located under the clavicle or collar bone; or the femoral veins in the groin. During the procedure, your heartbeat and electrocardiogram will be closely monitored. A PAC measures how well the heart is functioning and monitors pressures within the heart and lungs. It is routinely used during heart surgery or when large amounts of certain heart support medications are needed. Occasionally, the catheter may damage the pulmonary artery or lung. It can also cause irregularity of the heart rhythm usually during insertion. Chest X-rays are routinely done to check for any complications.

The PAC travels through the right side of the heart and the tip rests in the pulmonary artery. Using the PAC, pressures can be obtained from the right-sided chambers of the heart and the pulmonary arteries. There is a balloon at the tip of the PAC, which can be inflated to obtain the pulmonary artery occlusion pressure (PAOP). This provides an estimate of the pressures in the left side of the heart.

These measurements can help guide your clinical team to make crucial decisions about your treatment. That said, the usefulness of the PAC has also come under controversy recently, and in light of the invasive nature of the procedure, this is no longer a routine procedure done in the CCU.

Noninvasive Hemodynamic Assessment in the CCU

Hemodynamic assessment using Doppler echocardiography in the evaluation of transvalvular gradients, valvular regurgitation, and certain clinically important variables such as pulmonary artery (PA) pressures is common among echocardiographers. In comparison, the use of echocardiography in measuring intracardiac pressures as it is done during cardiac catheterization is an underutilized tool. These measurements done by echocardiography can aid in the assessment and management of patients in the intensive care unit. This chapter focuses on the practical aspects of such an examination with the demonstration of a comprehensive hemodynamic evaluation in a patient. The information in this chapter is based on known and accepted hemodynamic and Doppler echocardiographic techniques. More data and references can be found in larger, more detailed textbooks.[1]

The simplified Bernoulli equation is the basis for the calculation of most intracardiac pressures.[2]

$$\Delta \boldsymbol{P} = 4\boldsymbol{V}^2$$

where $\Delta \boldsymbol{P}$ = pressure gradient in mm Hg and $\boldsymbol{V}$ = velocity in m/s.

EVALUATION OF RIGHT ATRIAL PRESSURE

The evaluation of the inferior vena cava provides information regarding right atrial pressures (RAPs). With the transducer in the subxiphoid position, the inferior vena cava can be evaluated as it travels through the liver into the right atrium. During its course, the inferior vena cava becomes perpendicular to the ultrasound interrogation beam, allowing for its size and changes in its diameter during the respiratory cycle to be recorded by M-mode echocardiography. The normal diameter of the inferior vena cava in adults is 1.5 to 2.5 cm measured just proximal to its entrance into the right atrium. Normally, with inspiration, there is a decrease of 50% or more in its diameter. Failure to collapse with respiration and a dilated inferior vena cava suggests elevated RAPs.[3,4] **Table 50.1** correlates inferior vena cava characteristics (diameter and respiratory changes) and RAP. **Figure 50.1** shows a two-dimensional image and M-mode echocardiogram of a patient with a markedly elevated RAP.

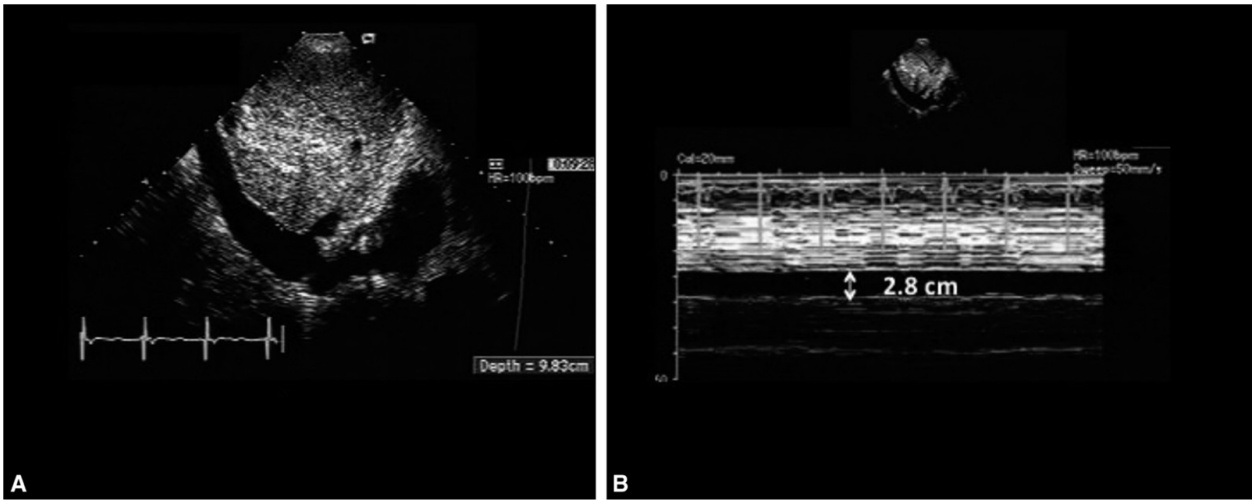

FIGURE 50.1 Assessment of right atrial pressure (RAP). A, The inferior vena cava (IVC) is markedly dilated at its entrance to the right atrium (2.8 cm). B, The M-mode recorded demonstrates lack of respiratory variations in diameter. RAP is estimated to be 15 to 20 mm Hg

TABLE 50.1 IVC Size and Respiratory Variation in the Evaluation of RA Pressure[3]

IVC (cm)	Δ WITH RESPIRATION (%)	RA PRESSURE (MM HG)
≤2.1	>50	0–5

≤2.1	<50	5–10
≥2.1	>50	10–15
≥2.1	<50	15–20

IVC, inferior vena cava; RA, right atrial.

EVALUATION OF RIGHT VENTRICULAR SYSTOLIC PRESSURE

Echocardiographic measurement of right ventricular systolic pressure (RVSP) is related to the velocity of flow across the tricuspid valve during systole. **Figure 50.2** shows the superimposed pressure curves of the right atrium and right ventricular and PA pressure. Under normal circumstances, there is a negligible gradient across the tricuspid valve during diastole and a negligible gradient across the pulmonic valve during systole. These gradients are so small that their measurement is beyond the sensitivity of cardiac catheterization. During systole, with the tricuspid valve closed, there is a pressure gradient between the right ventricle and the right atrium. Approximately 90% of normal adults have some degree (usually trace or mild) of tricuspid regurgitation. The velocity of the tricuspid regurgitant (TR) jet, as measured by continuous wave Doppler, is related to the pressure gradient between the right ventricle and right atrium. Using the simplified Bernoulli equation, the tricuspid regurgitation gradient can be calculated. The RVSP equals the TR gradient plus the RAP.

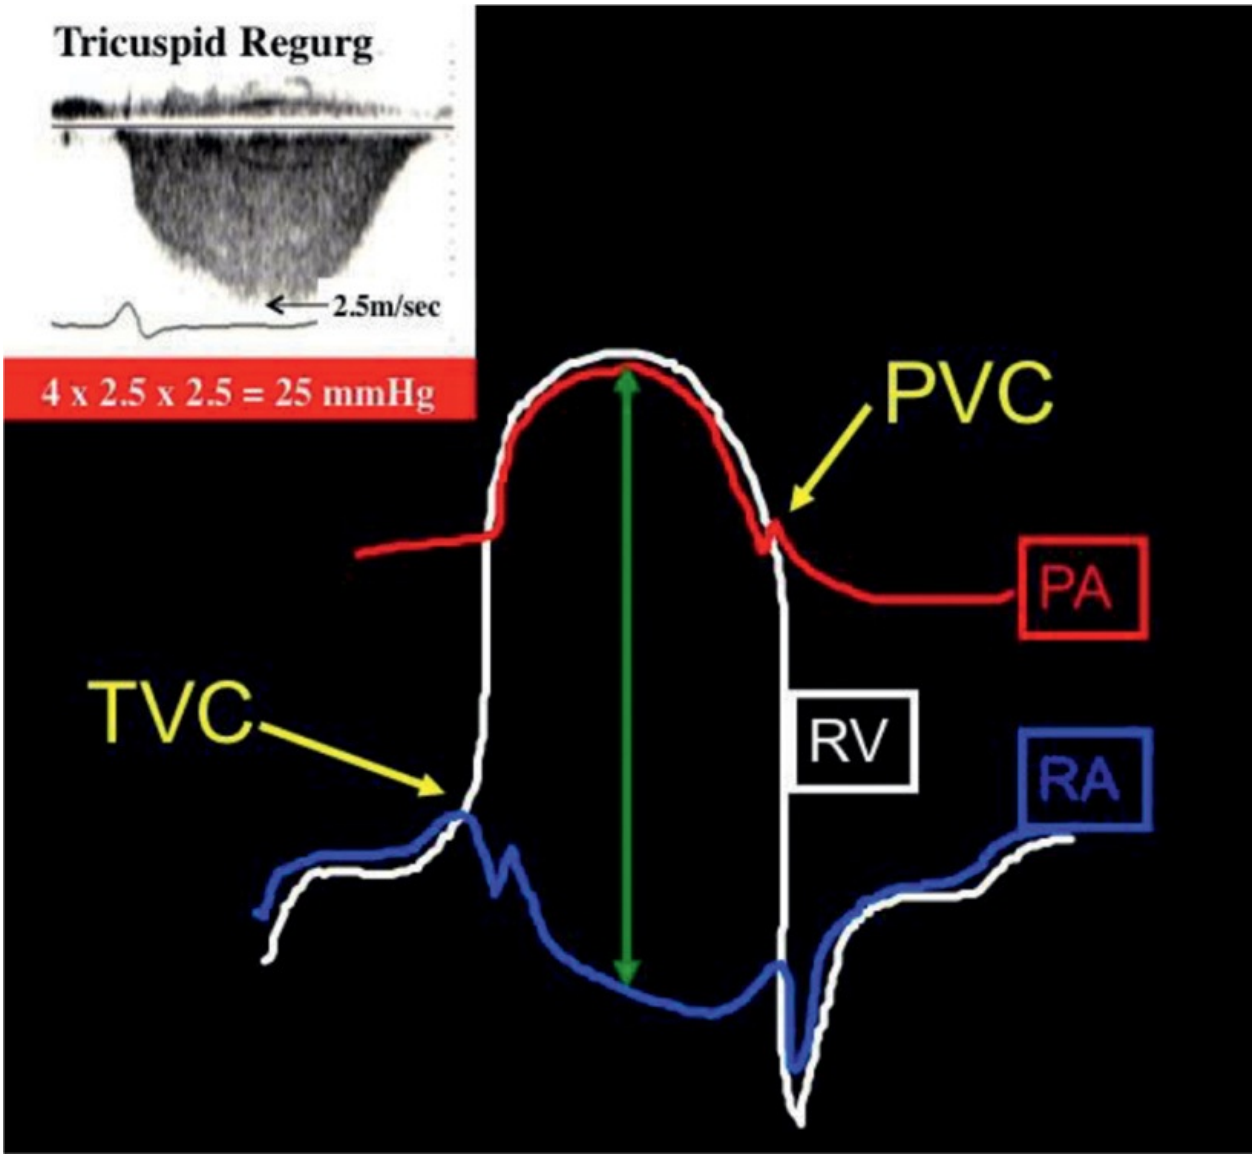

FIGURE 50.2 Assessment of RV systolic pressure (see text). The diagram shows normal right-sided pressures with no significant systolic gradient across the pulmonic valve and no significant diastolic gradient across the tricuspid valve. The gradient across the tricuspid valve in systole (green arrow) is responsible for the tricuspid regurgitation velocity seen in the upper left corner. With a peak regurgitant velocity of 2.5 m/s, the gradient between the right ventricle and right atrium is 25 mm Hg. PA, pulmonary artery pressure; PVC, pulmonic valve closure; RA, right atrial pressure; RV, right ventricular; TVC, tricuspid valve closure.

$$\text{RVSP} = \text{TR gradient} + \text{RAP}$$

Calculating RVSPs in patients who have a ventricular septal defect (VSD) with a left-to-right shunt requires measuring the gradient across the right and left ventricles. This gradient is related to the defect jet velocity between the ventricles. In the absence of aortic stenosis, the systolic pressure in the left

ventricle equals the systolic blood pressure (SBP) measured by a blood pressure cuff. Thus, the RVSP equals SBP minus the systolic ventricular septal defect (SVSD) gradient.

$$\text{RVSP} = \text{SBP} - \text{SVSD gradient}$$

The lower the SBP and the higher the RVSP, the smaller the interventricular gradient. VSDs that are associated with lower blood pressure and with high RVSP (as may be the case in VSD during acute myocardial infarction) will have a lower VSD systolic flow velocity and lower systolic VSD gradient. **Figure 50.3** shows an example of calculating RVSP in a patient after a myocardial infarction that developed a VSD with a left-to-right shunt.

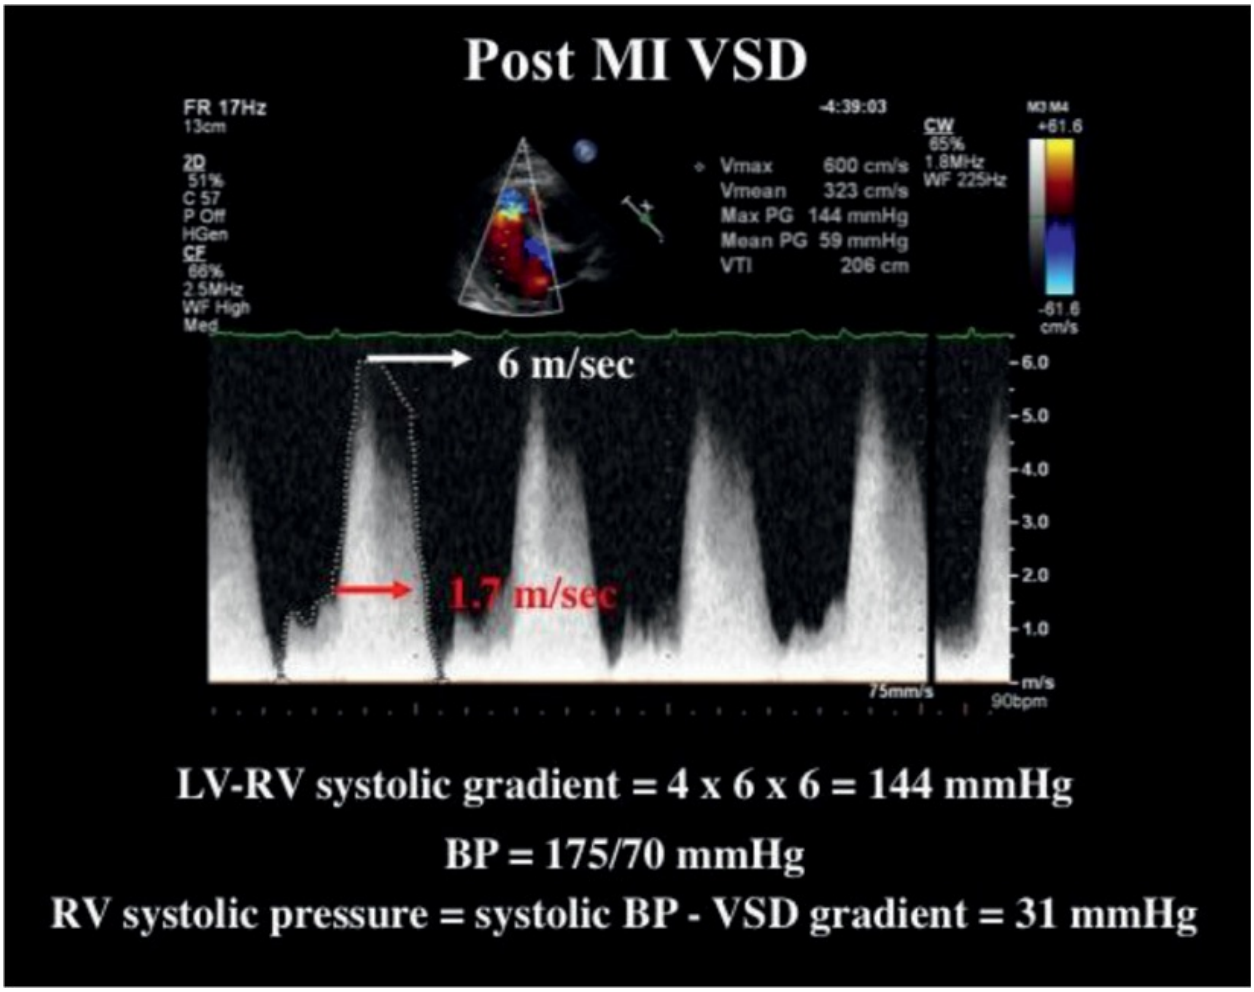

FIGURE 50.3 Assessment of right ventricular systolic pressure in a patient with a ventricular septal defect after myocardial infarction. Note that there is flow in both systole (white arrow) and diastole (red arrow). BP, blood pressure; LV, left ventricle; MI, myocardial infarction; RV, right ventricle; VSD, ventricular septal defect.

EVALUATION OF RIGHT VENTRICULAR DIASTOLIC PRESSURE

In the absence of tricuspid stenosis, there is a negligible gradient between the right atrial diastolic pressure and the right ventricular diastolic pressure (RVDP), and this gradient can therefore be ignored. As a result, it can be said that RVDP equals RAP.

$$RVDP = RAP$$

In the presence of VSDs with left-to-right shunt, the left ventricular diastolic pressure (LVDP) is usually higher than the RVDP. Therefore, there is flow between the left ventricle and right ventricle that continues throughout diastole. However, this velocity is significantly smaller when compared to the velocity of the jet across the VSD during systole (**Figure 50.3**). If the LVDP is known, then the RVDP can be calculated as the LVDP minus the diastolic ventricular septal defect (DVSD) gradient.

$$RVDP = LVDP - DVSD\ gradient$$

EVALUATION OF PULMONARY ARTERY SYSTOLIC PRESSURE

In the absence of pulmonic stenosis (PS), the pressure gradient between the right ventricle and the PA is negligible and can be ignored. It can be assumed that the pulmonary artery systolic pressure (PASP) equals the RVSP. Therefore, the PASP equals the tricuspid regurgitation (TR) gradient plus the RAP.

$$PASP = TR\ gradient + RAP$$

However, in the presence of PS, the gradient across the pulmonic valve must be accounted for. The flow velocity across the stenotic pulmonic valve can be evaluated and the PS gradient can be calculated. In these patients, the PASP equals the RVSP minus the PS gradient.

$$PASP = RVSP - PS\ gradient$$

EVALUATION OF PULMONARY ARTERY DIASTOLIC PRESSURE

The majority of patients normally have some degree (trace to mild) of pulmonic regurgitation (PR). The velocity of the PR is defined by the diastolic pressure gradient between the PA and the right ventricle. Thus, the pulmonary artery diastolic pressure (PADP) equals the pulmonary regurgitation gradient plus the RVDP.

$$\text{PADP} = \text{PR gradient} + \text{RVDP}$$

Because the RAP (in the absence of tricuspid stenosis) is approximately equal to the RVDP, this equation can be simplified to the PADP equaling the PR gradient plus RAP.

$$\text{PADP} = \text{PR gradient} + \text{RAP}$$

The ability to measure the PR velocity may be helpful in the evaluation of the PA pressure in patients who do not have tricuspid regurgitation. **Figure 50.4** shows a continuous wave Doppler tracing of pulmonic valve flow in a patient evaluated for significant pulmonary hypertension (HTN) who did not have tricuspid regurgitation. The end-diastolic velocity of the pulmonic regurgitant flow is 2.5 m/s, which indicates an end-diastolic gradient of 25 mm Hg across the pulmonic valve. Therefore, the diastolic pulmonary artery pressure is at least 25 mm Hg, a markedly elevated value.

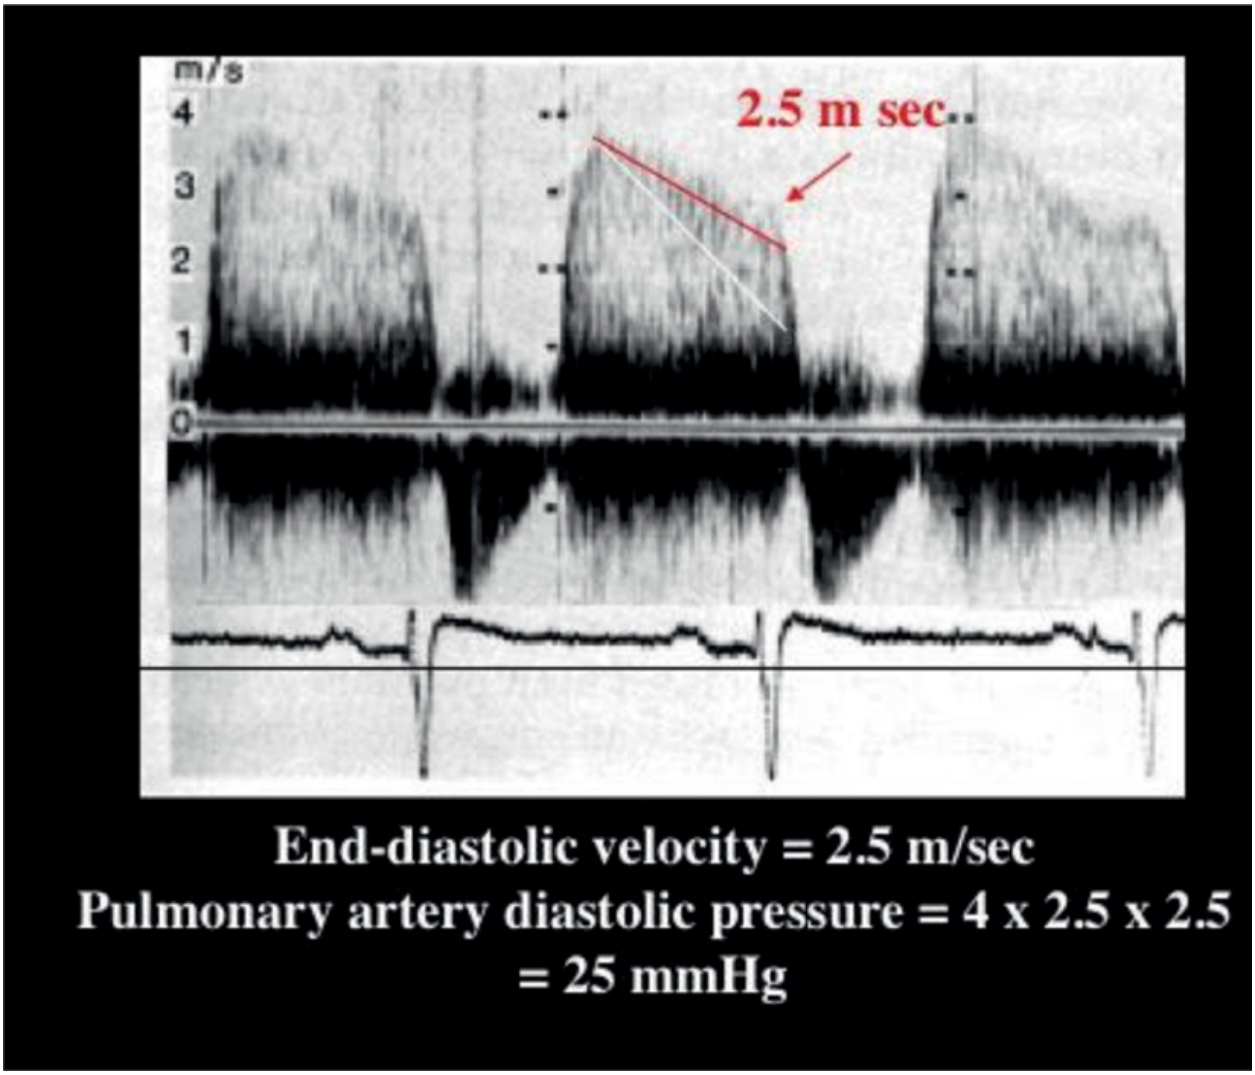

FIGURE 50.4 Assessment of pulmonary artery diastolic pressure in a patient with pulmonary hypertension. The continuous wave Doppler of the pulmonic valve shows an end-diastolic velocity of 2.5 m/s. This indicates an end-diastolic gradient of 25 mm Hg between the pulmonary artery and the right ventricle.

An estimation of PA pressures in the absence of tricuspid regurgitation or PR can be obtained with M-mode echocardiography and pulse wave Doppler. The characteristic M-mode pattern of the pulmonic valve in patients with severe pulmonary HTN (>70 mm Hg) includes absence of “a” deflection during atrial contraction (in spite of normal sinus rhythm), “flying W” appearance of the systolic opening, and lack of backward motion of the diastolic closure line (**Figure 50.5**). A more accurate estimation of mean PA pressures can be obtained by measuring the systolic acceleration time of the antegrade flow velocity measured by pulse wave Doppler just proximal to the pulmonic valve. The acceleration time is inversely proportional to the mean PA pressure.[5] The

equation used for this estimation is

$$PAMP = 79 - (0.45 \times AcT)$$

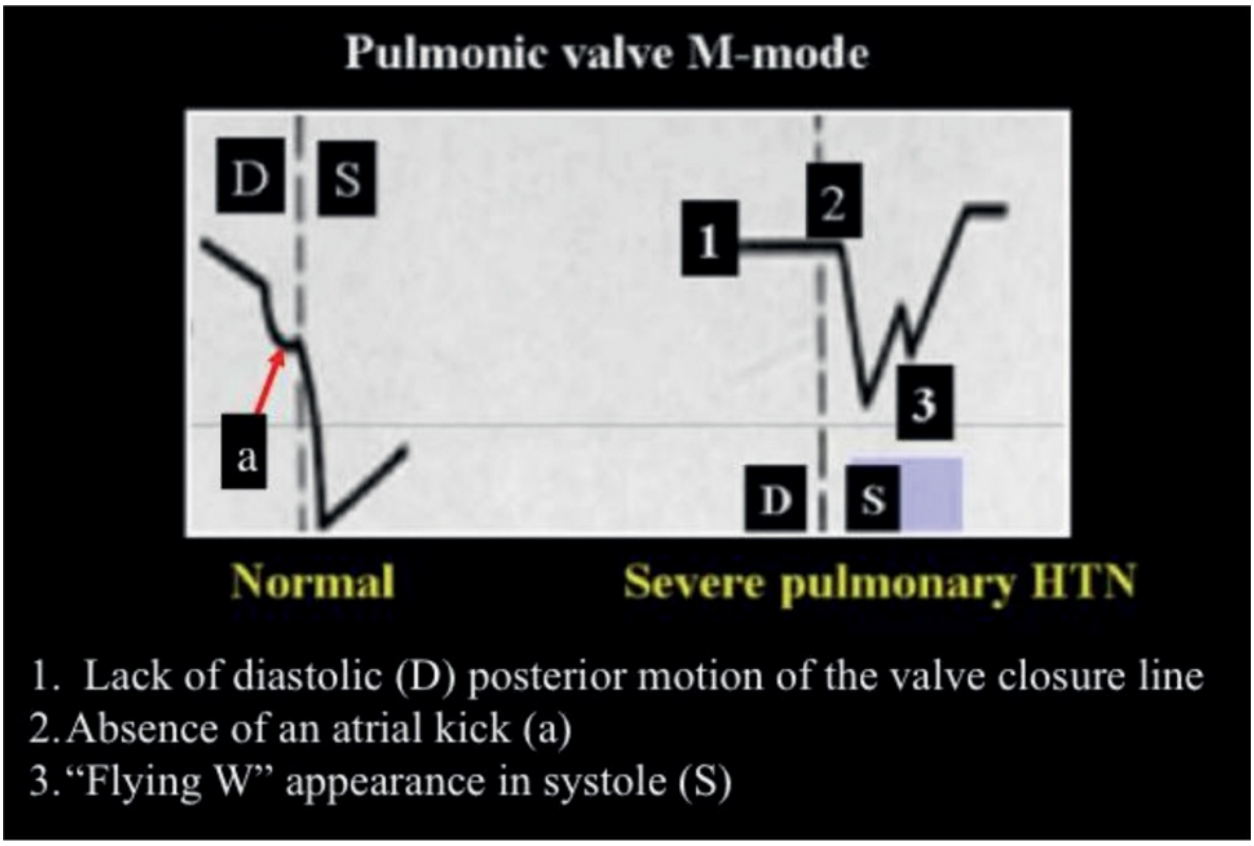

FIGURE 50.5 Comparison M-mode echocardiography of the pulmonic valve in individuals with and without severe pulmonary hypertension (HTN).

where PAMP is mean PA pressure in mm Hg and AcT is acceleration time in milliseconds.

A normal acceleration time is greater than 120 ms. Values less than 90 ms are associated with a PA mean pressure of 40 mm Hg or more.

EVALUATION OF LEFT VENTRICULAR SYSTOLIC PRESSURE

In patients without aortic valve or left ventricular outflow disease, the gradient between the left ventricle and the aorta during systole is negligible. Therefore, left ventricular systolic pressure (LVSP) is equal to the SBP.

$$LVSP = SBP$$

However, patients with aortic valve, subvalvular, or supravalvular stenosis have a gradient between the left ventricle and the ascending aorta. Because the systolic ascending aortic pressure equals the SBP, the LVSP equals the SBP plus the systolic pressure gradient across the aortic valve (or other subvalvular or supravalvular sites).

$$LVSP = SBP + \text{aortic stenosis gradient}$$

Gradients across the aortic valve can be measured using the Doppler examination. The maximal gradient that is recorded is the maximum instantaneous gradient (MIG), which differs from the peak-to-peak (P2P) gradient which is the gradient between peak aortic systolic pressure and peak LVSP. The P2P gradient is frequently measured and reported during cardiac catheterization. The value of the MIG is typically higher than that of the P2P gradient. In most cases of severe aortic stenosis, the P2P gradient is approximately 70% of the MIG. Both Doppler echocardiography and pressure measurement during invasive procedures are able to calculate a mean pressure gradient across the aortic valve (**Figure 50.6**). When using Doppler for the calculation of left ventricular pressure, the P2P gradient is estimated by taking 70% of the MIG and adding it to the SBP. Therefore,

$$LVSP = SBP + 70\% \text{ MIG}$$

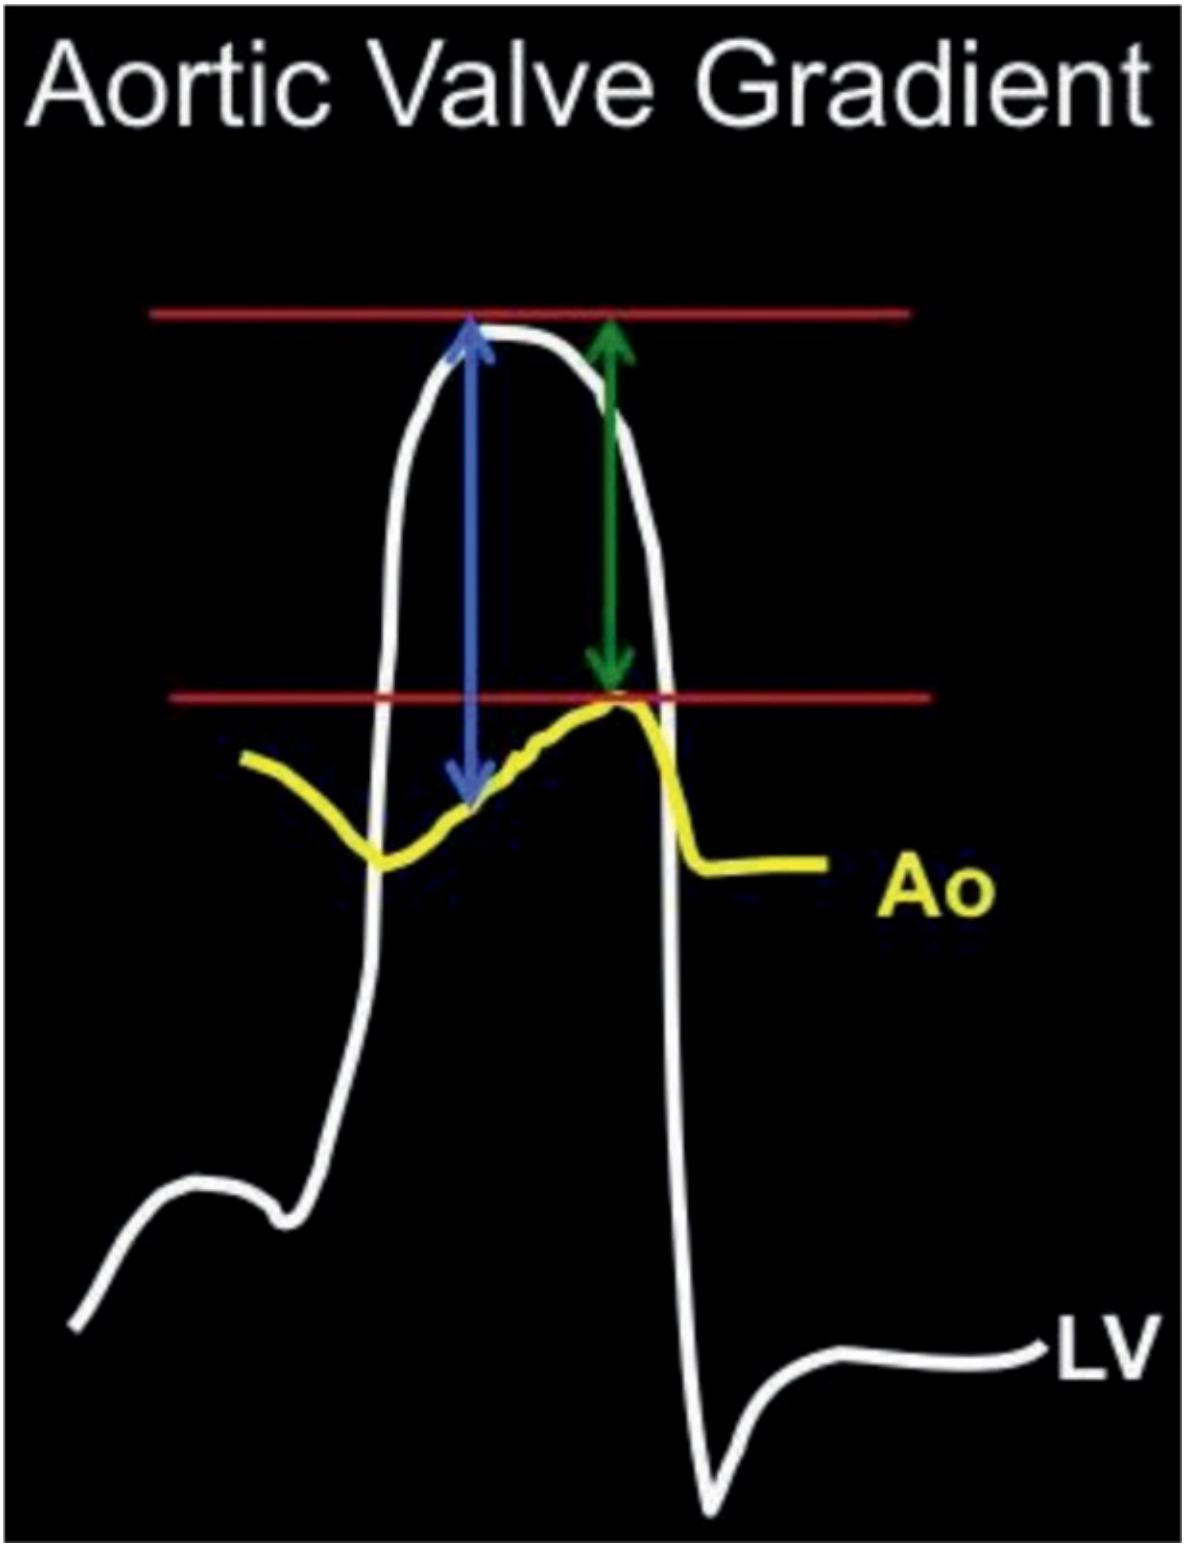

FIGURE 50.6 Left-sided pressure curves in aortic stenosis demonstrating maximum instantaneous gradient (blue arrow) and the peak-to-peak gradient (green arrow). Ao, aorta; LV, left ventricle.

EVALUATION OF LEFT VENTRICULAR DIASTOLIC PRESSURE

In the absence of mitral stenosis, the gradient between the left atrium and the left ventricle during diastole is small and can be ignored. Therefore, the left atrial pressure (LAP) is similar to the LVDP. The LAP can be estimated and will approximate left ventricular end-diastolic pressure (LVEDP).

$$\text{LVEDP} = \text{LAP}$$

In patients who have aortic regurgitation (AR), the regurgitant jet velocity is a function of the diastolic gradient between the aorta and the left ventricle. If the aortic diastolic pressure is known, then the LVEDP equals the diastolic blood pressure (DBP) minus the AR gradient at end diastole. In most patients, the aortic pressure equals the cuff pressure in the arm.

$$\text{LVEDP} = \text{DBP} - \text{end-diastolic AR gradient}$$

In patients with VSD with a left-to-right shunt, the LVEDP can be calculated if the RAP, which estimates RVDP (in the absence of tricuspid stenosis), is known. In these patients, the addition of the RAP and the VSD end-diastolic gradient equals the LVEDP.

$$\text{LVEDP} = \text{RAP} + \text{VSD end-diastolic gradient}$$

Figure 50.7 demonstrates a continuous wave Doppler tracing taken from a patient with both aortic stenosis and AR. The aortic stenosis peak velocity jet is 4 m/s and AR end-diastolic velocity is also 4 m/s. The blood pressure during the examination was 150/80 mm Hg. Therefore, the LVSP equals the SBP (150 mm Hg) plus 70% of the aortic systolic gradient. Because the maximum instantaneous aortic gradient is 64 mm Hg, the P2P gradient is 70% of 64 mm Hg, which is 45 mm Hg. The LVSP is therefore 150 + 45 = 195 mm Hg. The LVDP equals the DBP (80 mm Hg) minus the aortic diastolic gradient (64 mm Hg), which equals 16 mm Hg. Therefore, this patient’s left ventricular pressure is 195/16 mm Hg.

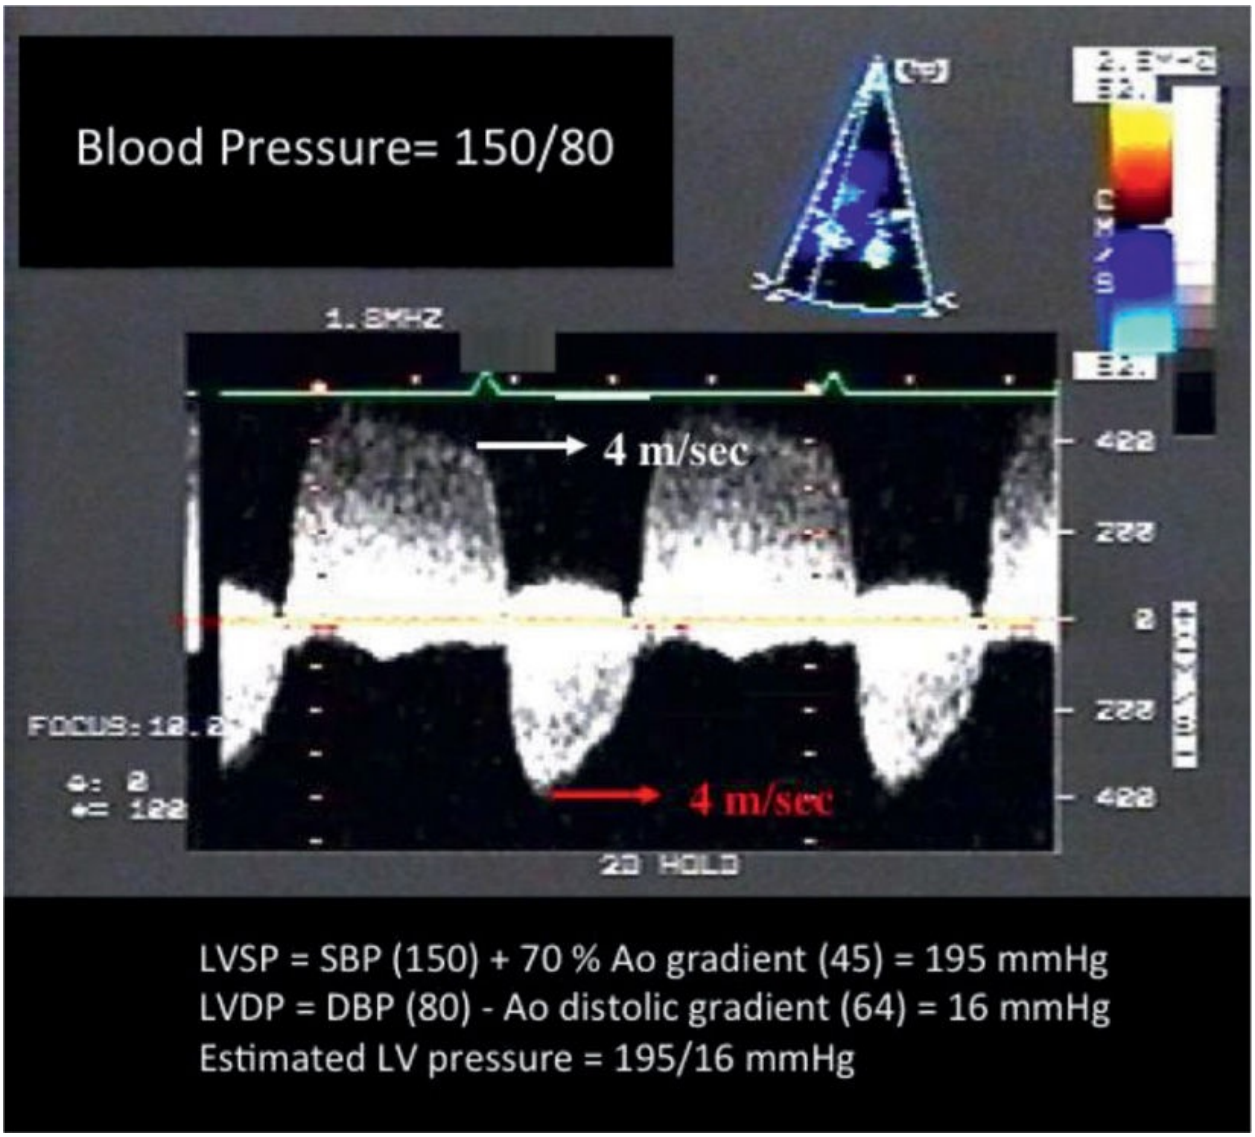

FIGURE 50.7 Continuous wave (CV) Doppler in the calculation of LV pressures in a patient with aortic stenosis and insufficiency (see text). Aortic stenosis peak velocity (red arrow) and aortic regurgitation end-diastolic velocity (white arrow) both measure to be 4 m/s. Ao, aorta; DBP, diastolic blood pressure; LV, left ventricular; LVDP, left ventricular diastolic pressure; LVSP, left ventricular systolic pressure; SBP, systolic blood pressure.

EVALUATION OF LEFT ATRIAL PRESSURE

Estimation of LAP by Doppler echocardiography can be performed in the absence of atrial fibrillation, ventricular pacing, left bundle branch block, left ventricular assist device, or mitral valve disease (mitral stenosis, moderate mitral annular calcification, more than moderate mitral regurgitation [MR], and mitral

valve repair or replacement). Pulsed Doppler of the transmitral and pulmonary venous flow, along with tissue Doppler of the lateral and septal mitral annulus allows for the estimation of LAP. Under normal flow patterns, the pressure in the left atrium is 6 to 12 mm Hg. Impaired relaxation results in a flow pattern with a low E-wave and high A-wave on pulse Doppler. This corresponds with a normal or minimally elevated LAP of 13 to 19 mm Hg. In pseudonormalization of transmitral flow, the LAP is elevated ranging from 20 to 24 mm Hg. Lastly, a restrictive pattern with a high E-wave, low A-wave, and rapid transmitral deceleration time (150 ms or less), the LAP is usually at least 25 mm Hg. A simpler alternative to calculating LAP uses the ratio of the transmitral flow ***E***-wave velocity and the tissue Doppler (***E′***). In general, as the LAP increases, ***E***-wave becomes higher and the ***E′*** becomes lower. An ***E/E′*** ratio of less than 9 is associated with normal LAPs, whereas a ratio of greater than 14 is highly specific for elevated LAPs (>14 mm Hg). An equation reported by Nagueh et al[6] describes the relation between LAP and ***E/E′***.

$$\text{LAP} = 1.24[(E/E') + 1.9]$$

A more simplified equation that may be used is

$$\text{LAP} = E/E' + 4 \text{ mm Hg}$$

PASPs can also be used to increase the accuracy of estimated LAP. **Table 50.2** provides estimations of LAP based on Doppler findings.[7] A more comprehensive analysis of diastolic dysfunction and estimation of LAP can be found by Nagueh et al.[8]

TABLE 50.2 Estimation of LAP Based on Doppler Findings

DOPPLER FINDING	MILD LAP ELEVATION (13–19 MM HG)	MODERATE LAP ELEVATION (20–24 MM HG)	SEVERE LAP ELEVATION (>25 MM HG)
E/A	0.8–1	1.2–1.5	>2
Deceleration time (ms)	N/A	N/A	<150
Average (*E*/*E*′)	9–12	13–18	>20
Estimated PASP (mm Hg)	35–40	45–55	>60

The predictive accuracy is enhanced with the presence of three to four of the above findings.[7]
LAP, left atrial pressure; PASP, pulmonary artery systolic pressure.

In patients with MR and without aortic stenosis, the LAP during ventricular systole (LAS) equals the SBP minus the MR gradient. In the absence of aortic stenosis, the LVSP equals the SBP.

$$\text{LAS} = \text{SBP} - \text{MR gradient}$$

In patients with mitral stenosis, the LAP during ventricular diastole (left anterior descending [LAD]) equals the LVEDP plus the mean transmitral gradient.

$$\text{LAD} = \text{LVEDP} + \text{transmitral gradient}$$

CALCULATION OF CARDIAC OUTPUT

Cardiac output (CO) can be calculated by measuring blood flow in either the left heart (systemic blood flow [SBF]) or right heart (pulmonary blood flow [PBF]). In the absence of shunts, the PBF is equal to the SBF. SBF is best calculated by evaluating the left ventricular outflow tract (LVOT). The cross-sectional area (CSA) of the LVOT can be calculated by measuring its diameter. The product of LVOT CSA and the velocity time integral (VTI) of the LVOT is the stroke volume (SV). Multiplying the SV with the heart rate (HR) provides the CO (**Figure 50.8**).

$$\text{SV} = \text{CSA}_{\text{LVOT}} \times \text{VTI}_{\text{LVOT}}$$

$$\text{CO} = \text{SV} \times \text{HR}$$

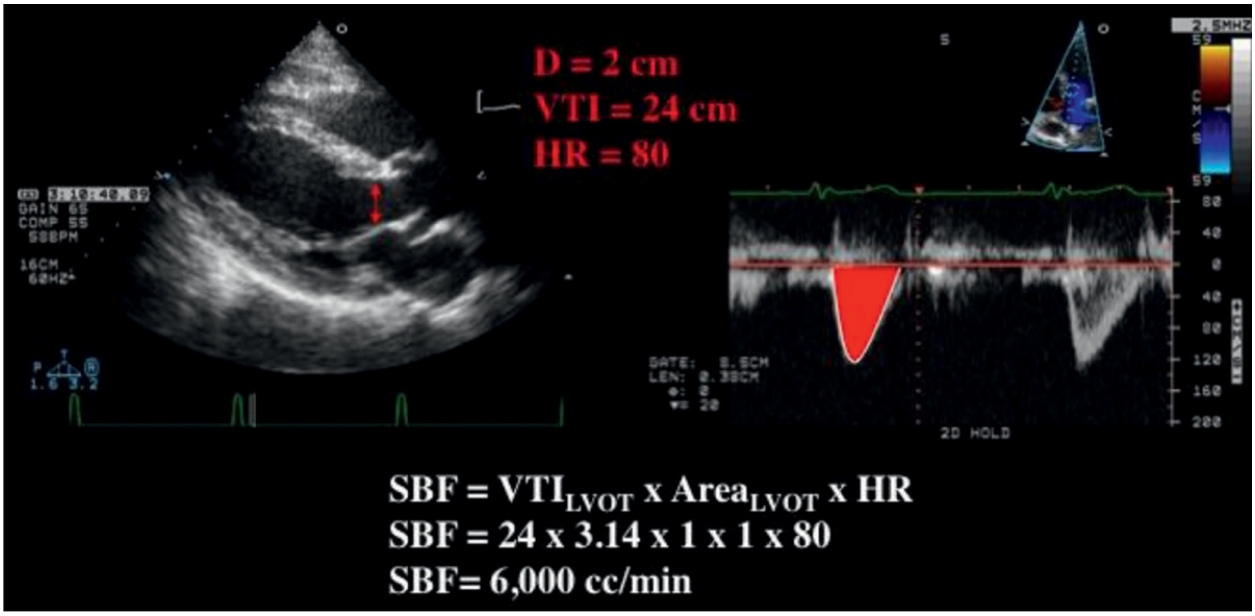

FIGURE 50.8 Calculation of systemic blood flow. The diameter (D) is measured at the LVOT in parasternal long axis view (left) and the VTI (right) is determined by pulse wave Doppler at the LVOT. HR, heart rate; LVOT, left ventricular outflow tract; SBF, systemic blood flow; VTI, velocity time integral.

Similarly, calculation of PBF can be done at the right ventricular outflow tract just proximal to the pulmonic valve.

CALCULATION OF SHUNT FLOW

The evaluation of shunt flow in patients with an atrial septal defect (ASD) or VSD with a left-to-right shunt can be performed by subtracting the SBF from the PBF.

$$\text{Shunt flow} = \text{PBF} - \text{SBF}$$

Alternatively, the product of the defect orifice area (DOA), the shunt VTI and HR equals the shunt flow across an ASD or VSD. **Figure 50.9** is an example of the calculation of ASD flow with a left-to-right shunt with an orifice area of 1.2 (radius of 0.6 cm), a VTI of 80 cm, and HR of 80 beats/minute. Using the equation given, the shunt flow is calculated.

$$\text{Shunt flow} = \text{DOA} \times \text{VTI}_{\text{shunt}} \times \text{HR}$$

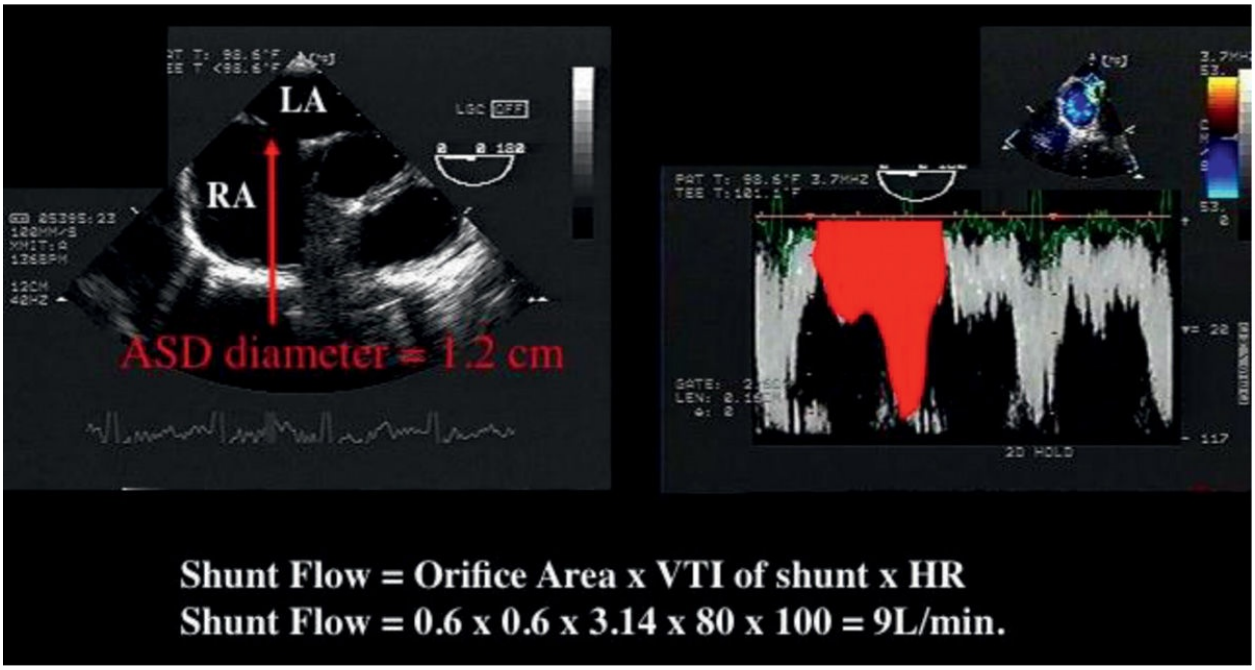

FIGURE 50.9 Calculation of ASD with left-to-right shunt flow. The red arrow marks the ASD orifice diameter (left). The VTI of the shunt flow is shown in the shaded red area (right). ASD, atrial septal defect; HR, heart rate; LA, left atrium; RA, right atrium; VTI, velocity time integral.

ESTIMATION OF PULMONARY VASCULAR RESISTANCE

Pulmonary vascular resistance (PVR) is defined as the ratio between the pressure gradient and the blood flow across the pulmonary vascular tree, measured in Wood's units. Invasively, PVR can be calculated using the following equation:

$$PVR = (PAMP - LAMP)/PBF$$

where PAMP is pulmonary artery mean pressure in mm Hg, LAMP is left atrial mean pressure in mm Hg, and PBF is the pulmonary blood flow in liters/minute. In patients with a normal PAMP (15 mm Hg), normal LAMP (5 mm Hg), and normal PBF (5 L/min), the calculated PVR is approximately 2 units.

The PVR is directly related to the PA pressure (and therefore to the maximal TR jet velocity) and inversely related to the SV in the RVOT (which can be measured noninvasively by pulsed Doppler, using the VTI at the RVOT, just proximal to the pulmonic valve). PVR can therefore be calculated by Doppler using the following equation[9]:

$$PVR = 10\ [(\text{peak TR velocity}/VTI_{RVOT}) + 0.16]$$

where PVR is expressed in Wood's units, TR = tricuspid regurgitation in m/s, and VTI_{RVOT} = velocity time integral at the right ventricular outflow tract in centimeters (**Figure 50.10**).

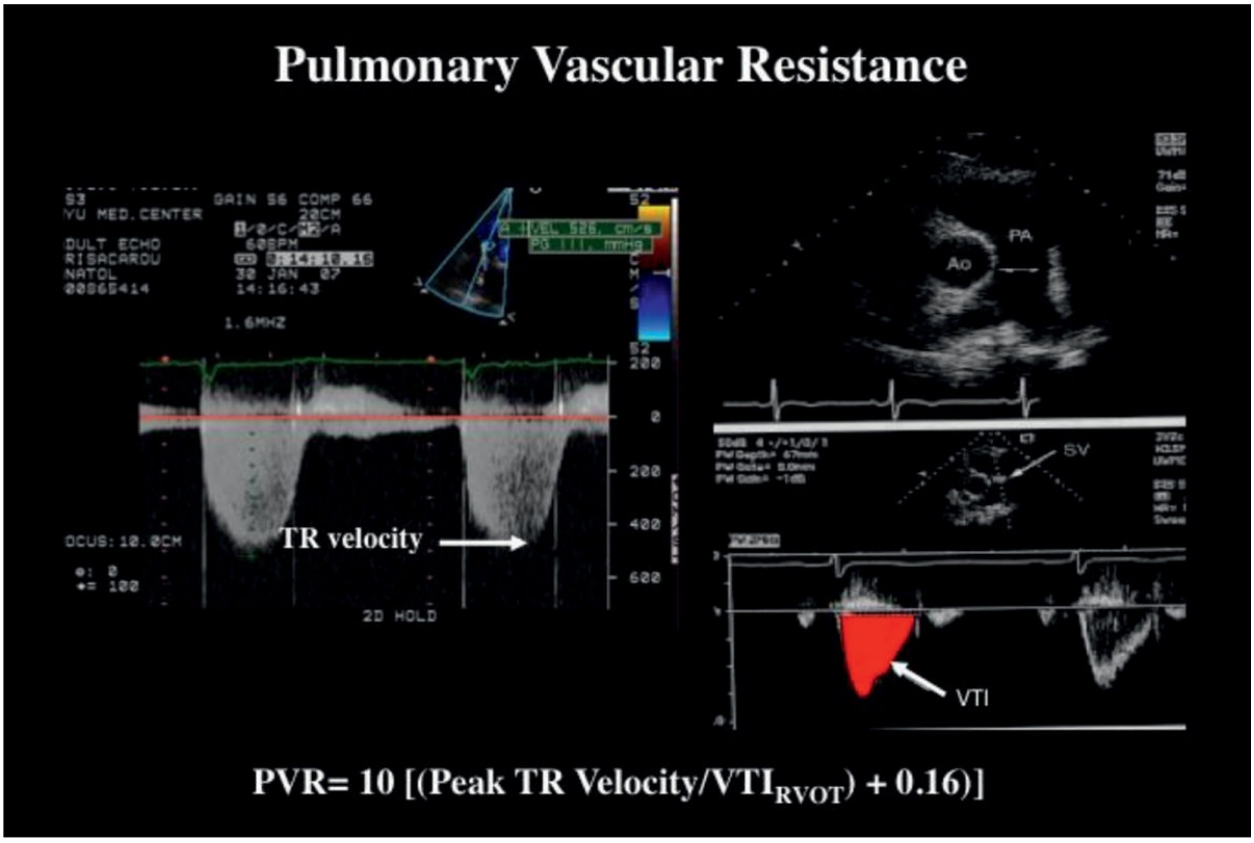

FIGURE 50.10 Noninvasive calculation of PVR in Wood's units using the peak TR velocity and VTI at the RVOT. PVR, pulmonary vascular resistance; RVOT, left ventricular outflow tract; TR, tricuspid regurgitant; VTI, velocity time integral.

CLINICAL CASE

COMPREHENSIVE HEMODYNAMIC EVALUATION

A complete echocardiographic examination can provide important information on a patient's hemodynamic profile. The information obtained may be comparable to invasive methods of hemodynamic evaluation and can guide therapy. The next few paragraphs evaluate the hemodynamic profile by means of echocardiography of a 63-year-old male with acute shortness of breath.

His vital signs during the evaluation showed a blood pressure of 100/55 mm

Hg and HR 70 beats/minute. His physical examination was notable for a regular HR, an apical diastolic rumble (mitral stenosis), apical holosystolic murmur (MR), a basal systolic ejection murmur radiating to the carotids (aortic stenosis), basal diastolic murmur (AR), and presence of jugular venous distension. **Figure 50.11** shows the hemodynamic information that was available at this stage. It is assumed that the aortic pressure was the same as the blood pressure measured by a blood pressure cuff.

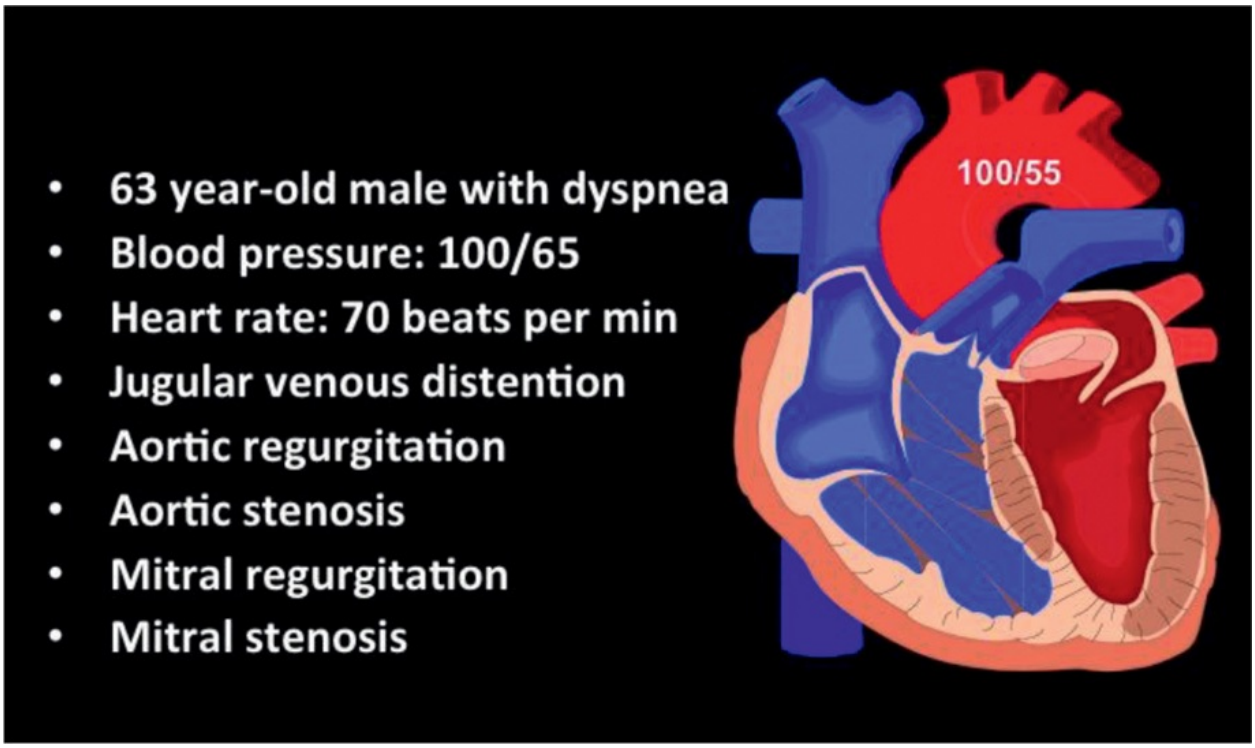

FIGURE 50.11 Initial hemodynamic profile and synopsis of history on presentation.

The evaluation begins with the inferior vena cava with subxiphoid echocardiography. As can be seen in **Figure 50.12A**, the inferior vena cava measured to be 2 cm and there was less than 50% respiratory collapse. Therefore, the inferior vena cava and the RAP (and also the superior vena cava) are slightly elevated (5 to 10 mm Hg); and for the sake of simplicity, a value of 10 mm Hg will be used. At this point, the known hemodynamic profile can be seen in **Figure 50.12B**.

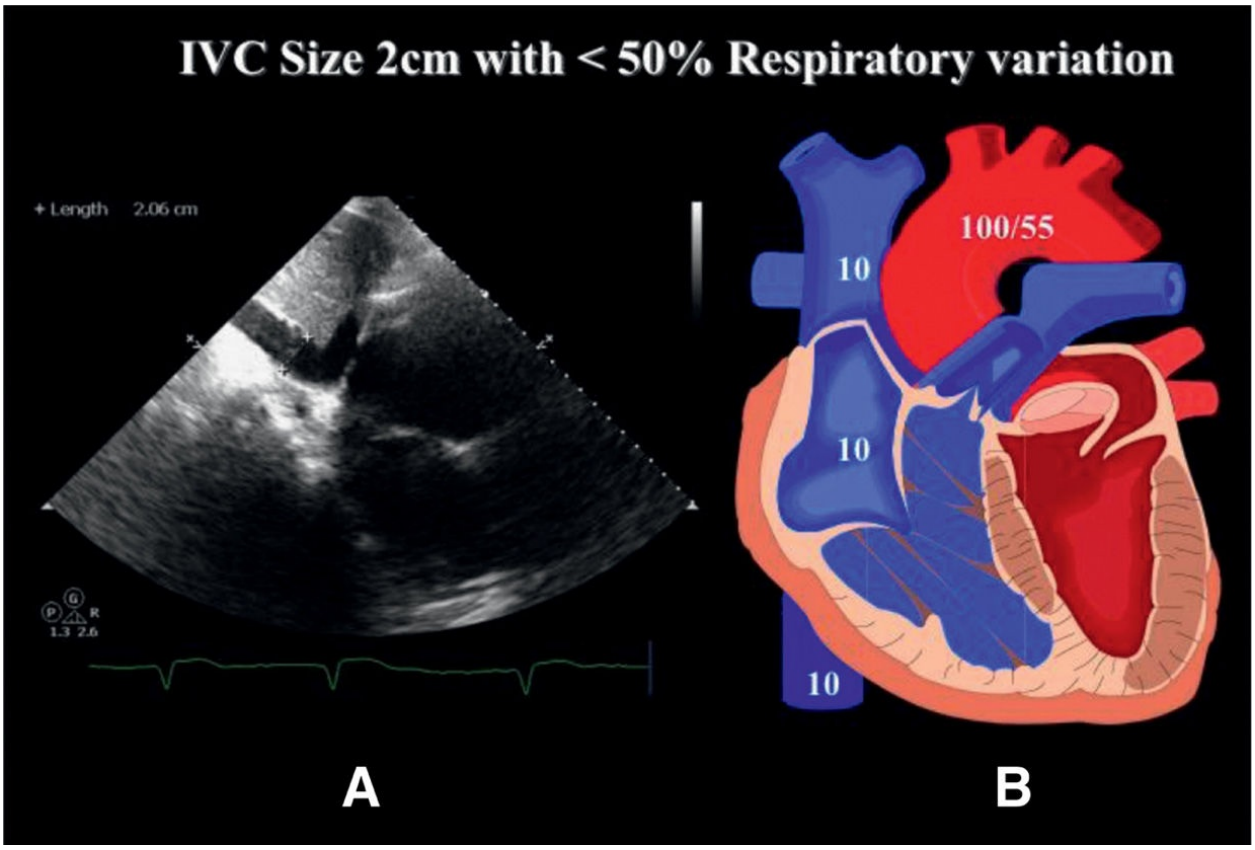

FIGURE 50.12 Calculation of right atrial pressure. A, IVC measuring 2 cm with less than 50% respiratory variation suggestive of slightly elevated right atrial pressure (5 to 10 mm Hg). B, The hemodynamic diagram shows a right atrial pressure of 10 mm Hg. IVC, inferior vena cava.

The right ventricular pressures can be estimated by evaluating flow across the tricuspid valve. The peak jet velocity of the tricuspid regurgitation (**Figure 50.13A**) is 3.7 m/s and, therefore, the gradient between the right ventricle and the right atrium is 56 mm Hg. The RVSP equals the RAP (10 mm Hg) plus the tricuspid regurgitation gradient (56 mm Hg), which equals 66 mm Hg. In the absence of tricuspid stenosis, the RVDP equals the RAP. Therefore, the pressure in the right ventricle is 66/10 mm Hg (**Figure 50.13B**).

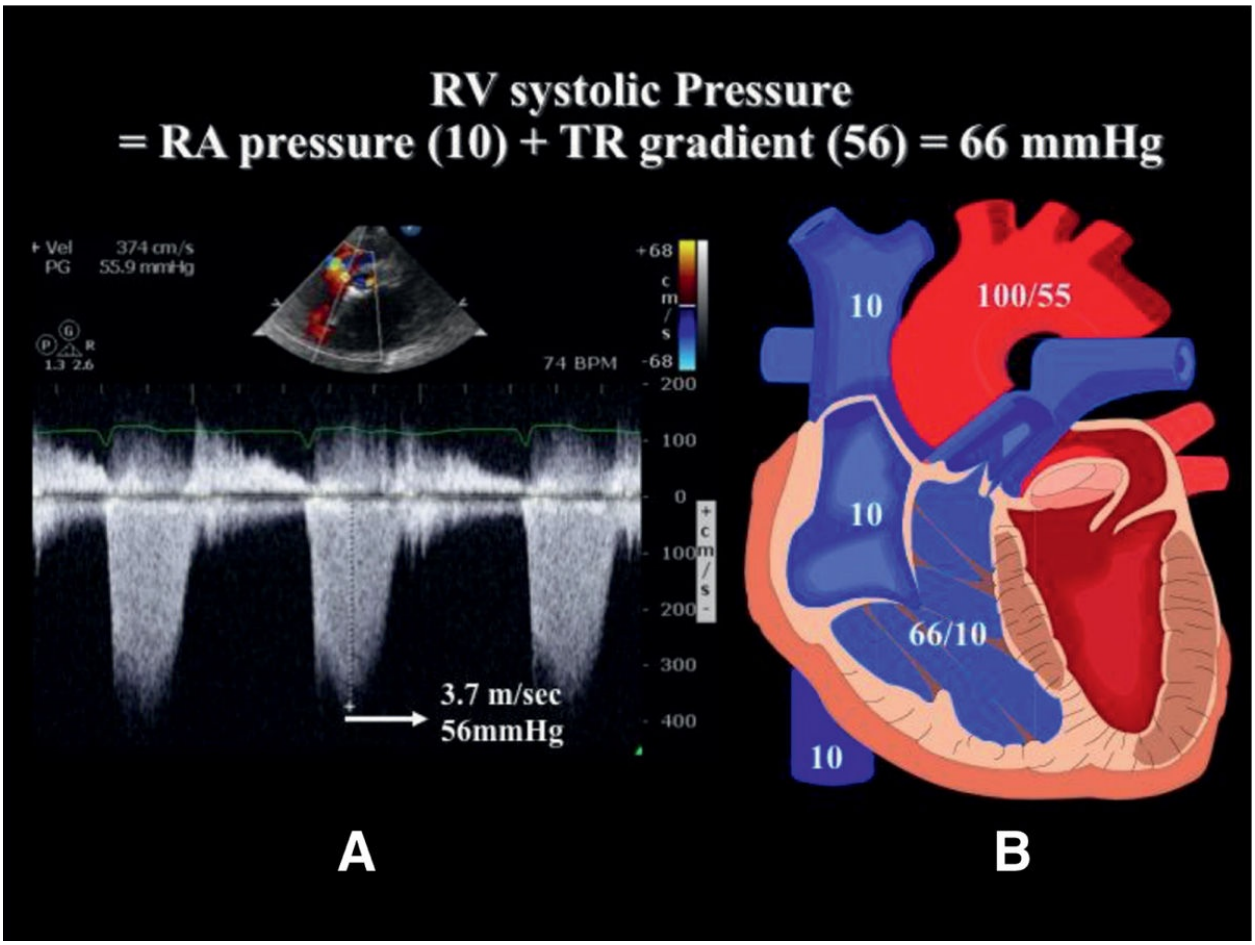

FIGURE 50.13 Calculation of right ventricular pressures. A, Tricuspid regurgitation velocity showing the gradient between the right ventricle and RA of 56 mm Hg. B, The hemodynamic diagram shows a right ventricular pressure of 66/10 mm Hg. RA, right atrium; RV, right ventricle; TR, tricuspid regurgitant.

The PA pressure can now be calculated. In the absence of PS, the RVSP (66 mm Hg) practically equals pulmonary arterial systolic pressure. As demonstrated in **Figure 50.14**, this patient has PR. The pulmonary diastolic pressure can be calculated by measuring the PR velocity at end diastole. The velocity of the PR jet is 2.2 m/s, which indicates a pulmonic regurgitant gradient of 20 mm Hg. The PADP is therefore the pulmonary regurgitation gradient (20 mm Hg) plus RAP (10 mm Hg), which equals 30 mm Hg.

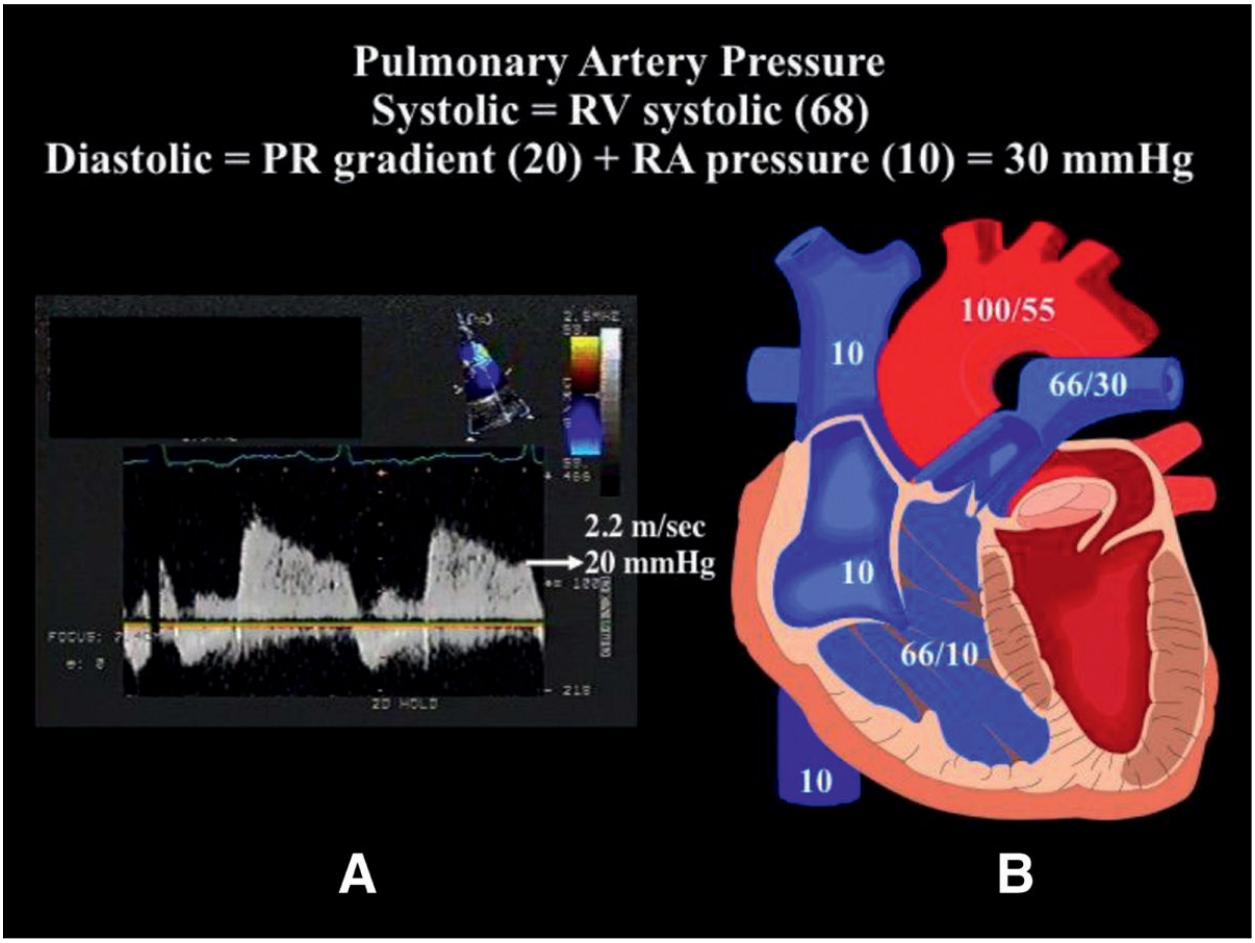

FIGURE 50.14 Calculation of pulmonary artery pressures. A, PR end-diastolic velocity of 2.2 m/s showing the gradient between the pulmonary artery and right ventricle of 20 mm Hg. B, The hemodynamic diagram shows a right pulmonary pressure of 66/30 mm Hg. RA, right atrium; RV, right ventricle; PR, pulmonic regurgitation.

Left ventricular pressures are calculated by evaluating flow across the aortic valve. The patient has AR (**Figure 50.15**). The end-diastolic velocity of the AR jet is 3 m/s and therefore the aortic end-diastolic gradient is 36 mm Hg. Therefore, the LVEDP equals the aortic diastolic pressure (55 mm Hg) minus the AR gradient (55 mm Hg), which equals 19 mm Hg. In addition, this patient has aortic stenosis (**Figure 50.16**) with a peak instantaneous aortic flow velocity of 4 m/s, which is equivalent to a MIG of 64 mm Hg. Because the P2P gradient is 70% of the MIG, the P2P equals 45 mm Hg. The LVSP is therefore the aortic systolic pressure (100 mm Hg) plus 70% of the MIG (45 mm Hg), which equals 145 mm Hg.

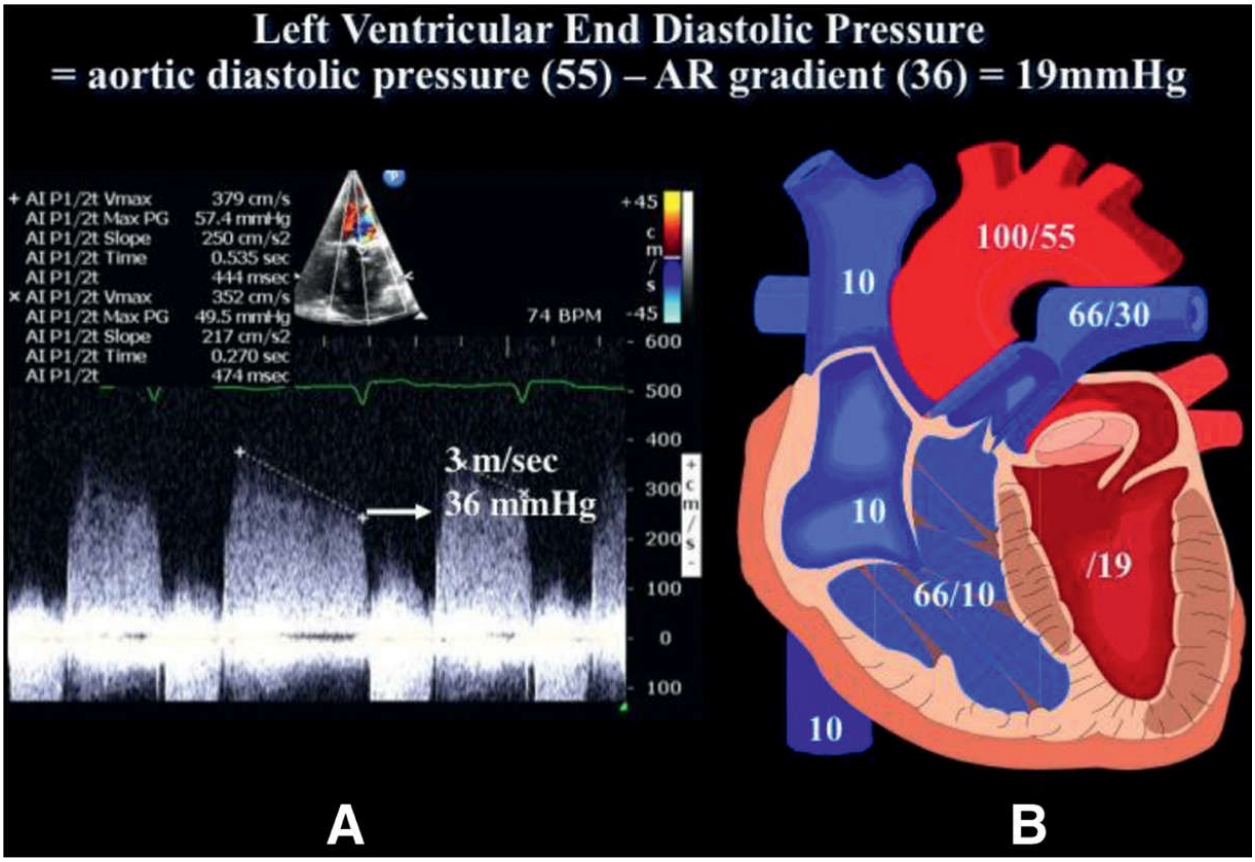

FIGURE 50.15 Calculation of left ventricular diastolic pressure. A, AR end-diastolic velocity of 3 m/s showing the gradient between the aorta and left ventricle of 36 mm Hg. B, The hemodynamic diagram shows a left ventricular diastolic pressure of 19 mm Hg. AR, aortic regurgitation.

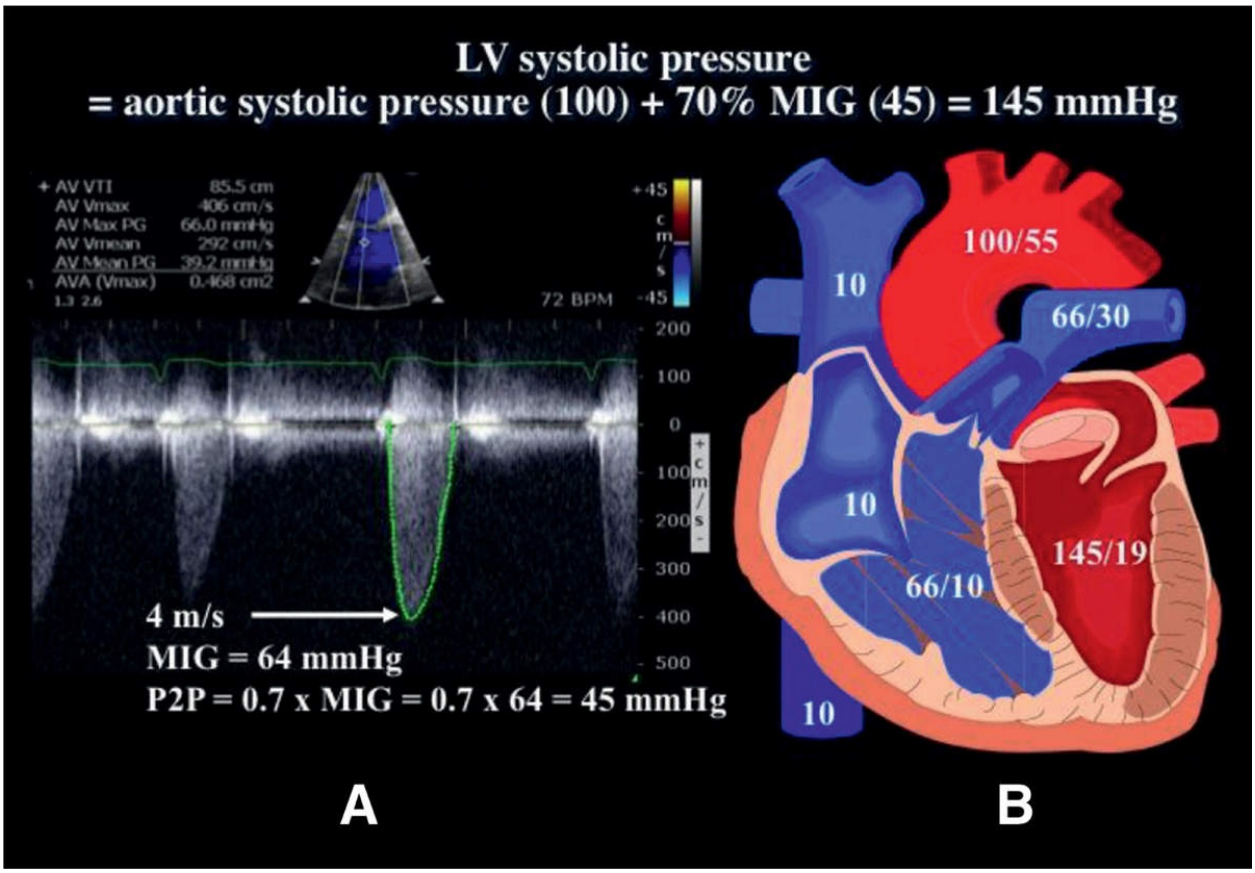

FIGURE 50.16 Calculation of LV systolic pressure. A, The peak instantaneous velocity of 4 m/s is used to calculate the MIG between the left ventricle and the aorta, which equals 64 mm Hg. Peak-to-peak (P2P) gradient, which is 70% of the MIG, equals 45 mm Hg. B, The hemodynamic diagram shows a left ventricular systolic pressure of 145 mm Hg. LV, left ventricular; MIG, maximum instantaneous gradient.

Finally, this patient has mitral stenosis (**Figure 50.17**). The mean mitral gradient was calculated to be 7 mm Hg. The LAP, therefore, equals the LVDP (19 mm Hg) plus the mitral valve mean gradient (7 mm Hg), which equals 26 mm Hg. Thus, with the use of echocardiography and without the use of invasive measures, the pressures in the cardiac chambers, the great arteries, and the veins can be calculated.

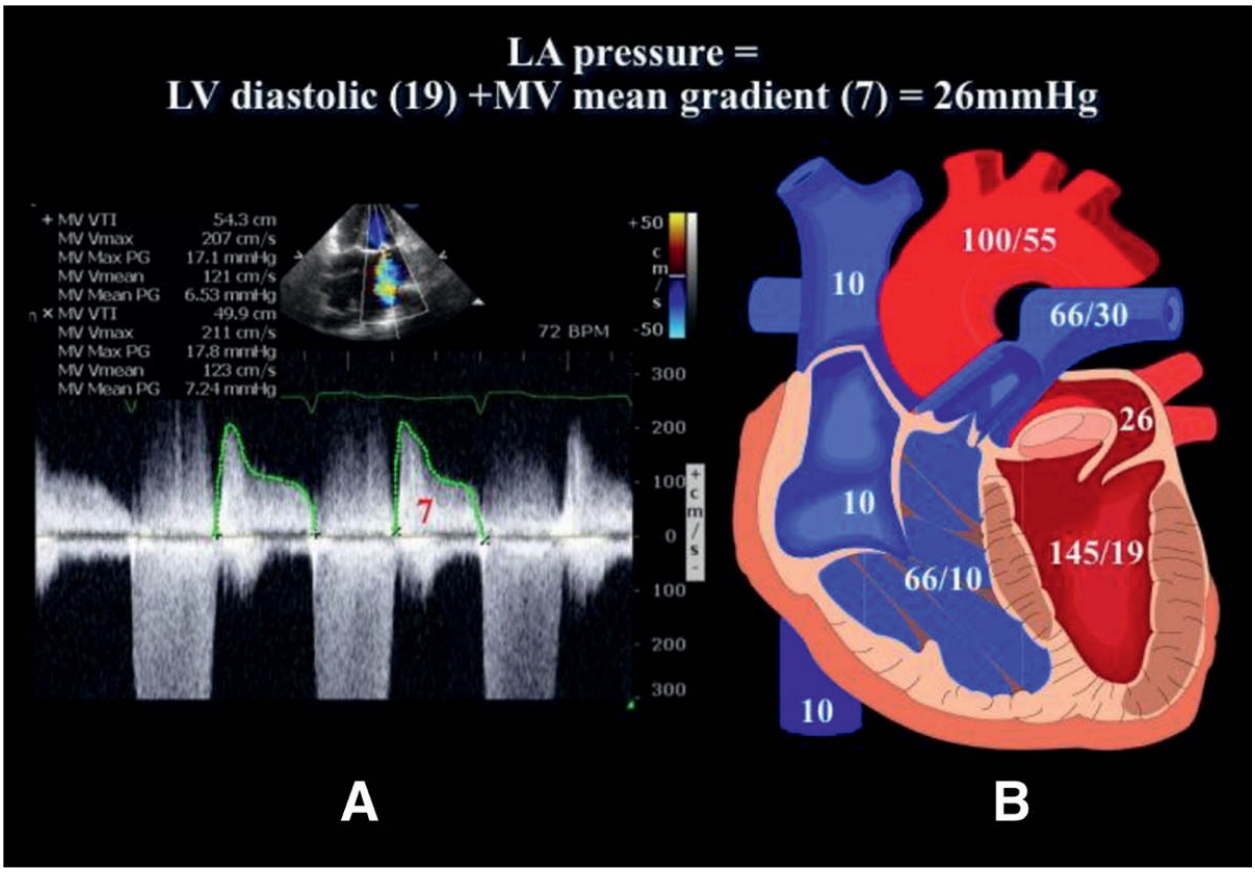

FIGURE 50.17 Calculation of LA pressure. A, Flow across the MV showing a mean mitral gradient of 7 mm Hg. B, The hemodynamic diagram shows an LA pressure of 26 mm Hg. LA, left atrial; LV, left ventricular; MV, mitral valve.

This hemodynamic evaluation provides an example of noninvasive pressure measurements in a patient with heart failure and valvular disease. Although these data are not available in all patients, some information is available in most. Invasive studies may be required when the clinical picture is not consistent with the echocardiography findings.

Noncardiac Point-of-Care Ultrasound in the CCU

INTRODUCTION

Goal-directed point-of-care ultrasound (POCUS) is real-time, organ-focused ultrasonography (USG) performed by a nonradiologist to answer a clinical question or guide a procedure. POCUS, also referred to as critical care ultrasonography (CCUS) or goal-directed USG, is performed and interpreted by clinicians at the point of clinical care.[1–3] Over the past decade, POCUS has become essential in the early diagnosis and treatment of critically ill patients. It allows for rapid, safe, and accurate assessment of a patient's condition and has great utility in guiding invasive bedside procedures. Safe application and interpretation of ultrasound (US) findings requires knowledge of the basic principles of USG and familiarity with the equipment and the modalities.

POCUS requires that all image acquisition, interpretation, and clinical application is performed by the clinician at the point of care, allowing for rapid integration of the results with the history and physical, laboratory, and imaging data to guide diagnosis and treatment.[4] When POCUS is performed with a focused clinical question and goal in mind, it serves as a valuable adjunct to the physical examination. We believe that POCUS is the most important contemporary innovation in critical care—an extension of the physical

examination or “visual stethoscope,” so to speak—and its adoption and incorporation into clinical care will certainly prove of value in the diagnosis and treatment of the patient in the cardiac care unit (CCU). We highlight the role of POCUS in making a rapid and acceptably accurate differential diagnosis of the patient in the CCU who is hypotensive, in respiratory distress, or in multiorgan failure.[5]

HISTORY

Although clinicians in these specialties such as radiology, cardiology, and obstetrics have been doing point-of-care bedside USG for the past several decades, bedside POCUS did not really advance until the 1990s, when more compact and affordable machines led to adoption by specialties such as emergency medicine (EM), anesthesiology, and pulmonary-critical care medicine. Early use of US in CCUs and intensive care units (ICUs) were driven by its success with improving the success and safety of central line placement.[6] Trauma surgeons and EM physicians started assessing patients with trauma using US, and the FAST (Focused Assessment with Sonography in Trauma) examination became fully integrated into Advanced Trauma Life Support (ATLS) guidelines.[7] US guidance is now standard of care for procedures such as thoracentesis and internal jugular vein central line placement.[8,9] Focused USG has now become part of nearly every specialty’s practice in some form.[5]

THE CASE FOR POINT-OF-CARE ULTRASONOGRAPHY

Traditionally, USG and echocardiography are performed by a technician and interpreted by a radiologist or cardiologist. Patients have to be transported for these examinations and the services are often only available during daytime hours on weekdays, thus leading to delays in performance, interpretation, and communication of the results. This is very limiting to units such as the CCU where questions need to be answered at all times of day or night and on weekends. POCUS is performed at the bedside by the treating clinician, interpreted right away, and the results applied right away in conjunction with the clinical presentation and laboratory data. POCUS by no means is a replacement for a comprehensive examination and consultation by radiology or cardiology

services.[4] Although POCUS is often limited to one organ system, multiple systems may have to be assessed for diagnostic purposes; but this can be done in a quick and efficient manner by the trained sonographer.[10] In addition, just like the physical examination, the sonographic examination can be repeated to reassess the patient.

The current evidence supporting the use of POCUS is overwhelming. Early studies by Lichtenstein and Axler[11] showed that focused sonography changed management in one out of every four patients in the ICU. In patients with trauma, the FAST examination has a sensitivity of 94% and specificity of 98% with a high negative predictive value for clinically significant intra-abdominal injury.[12] Multiorgan POCUS was shown to correlate accurately with the final diagnosis in patients in the emergency department (ED) with undifferentiated hypotension.[13] Lichtenstein's pioneering research showed that bedside USG could identify the correct diagnosis of acute respiratory failure, shock states, and even function as a noninvasive Swan Ganz catheter to guide fluid resuscitation.[10,14,15] Focused goal-directed echocardiography (GDE) can be helpful in the evaluation of shock states, and assessment of inferior vena cava (IVC) variability in mechanically ventilated patients has been used to accurately predict fluid responsiveness.[16,17] Work by Kory and Blaivas showed that non-radiologists could accurately detect deep vein thrombosis (DVT) at the point of care, saving time and expediting treatment.[18,19]

BASIC PRINCIPLES OF ULTRASONOGRAPHY

USs are sound waves with frequencies that exceed those perceived by the human ear (>20 kHz). Medical USG uses sound waves (2 to 10 MHz) created by a vibrating crystal within a ceramic probe (also called a transducer) that can both send and receive sound waves. Images are created on the basis of the piezoelectric principle, by which electric current causes crystals to vibrate and returning sound waves create electric current that the machine translates into real-time images. The strength or amplitude of the returning echo waves determines the brightness (ie, whiteness) of the echo pixel. Modern-day US machines generate B-mode or two-dimensional USG from an array of crystals (>128) across the footprint of the transducer.[5,20]

US waves travel through different tissue and are partly reflected at each tissue

interface. They penetrate well through solid organs and fluid; however, they do not penetrate air or bone, limiting the usefulness. Hence, the ribs are often an impediment when doing echocardiography and thoracic USG. Air is completely reflected back to the transducer. If air is in the way of sound waves, it generates "A-lines" or "air lines," which are a reverberation artifact. Bone typically has a white leading edge and then a black shadow due to near-total reflection of US waves.

Bright structures are referred to as *hyperechoic*. These "white" areas represent echogenic structures that transmit and reflect US waves. "Black" areas represent areas that are *anechoic*. This occurs when US waves encounter a structure that does not reflect any waves and no waves return to the transducer (eg, fluid). Sound waves propagate through fluid and thus fluid is a great window to see other nearby structures. US waves often lose energy after their interaction with a structure and return with a low amplitude. These low-amplitude waves are translated into shades of gray or *hypoechoic* regions. Lastly, lines occur at boundaries between two markedly different tissue reflectors, delineating the two structures. Soft tissue often has white, gray, and black planes and borders, representing different speeds of propagation and reflection of US waves.[20] **Table 51.1** lists examples of structures of different echogenicity. **Figure 51.1** shows the parasternal long-axis (PLAX) view of a patient with a posterior mediastinal mass presenting with rapid atrial fibrillation demonstrating the echogenicity of different structures in the thorax.

TABLE 51.1 Differences in Tissue Echogenicity

GRAY SCALE	TERMINOLOGY	STRUCTURE	EXAMPLE
	Anechoic	Pure fluid	Pleural or pericardial effusion Ascites Bladder Veins and arteries

Hypoechoic	Thick fluid Thrombosis Consolidation Tissue/organs	Hemothorax or hemoperitoneum DVT Pneumonia Liver, spleen, kidney, bowel Fat, lymph nodes, nerve
Hyperechoic	Bone/calculus Strong interface	Ribs; kidney or gallstones Pleura, pericardium Diaphragm, nerve, tendon

DVT, deep vein thrombosis.

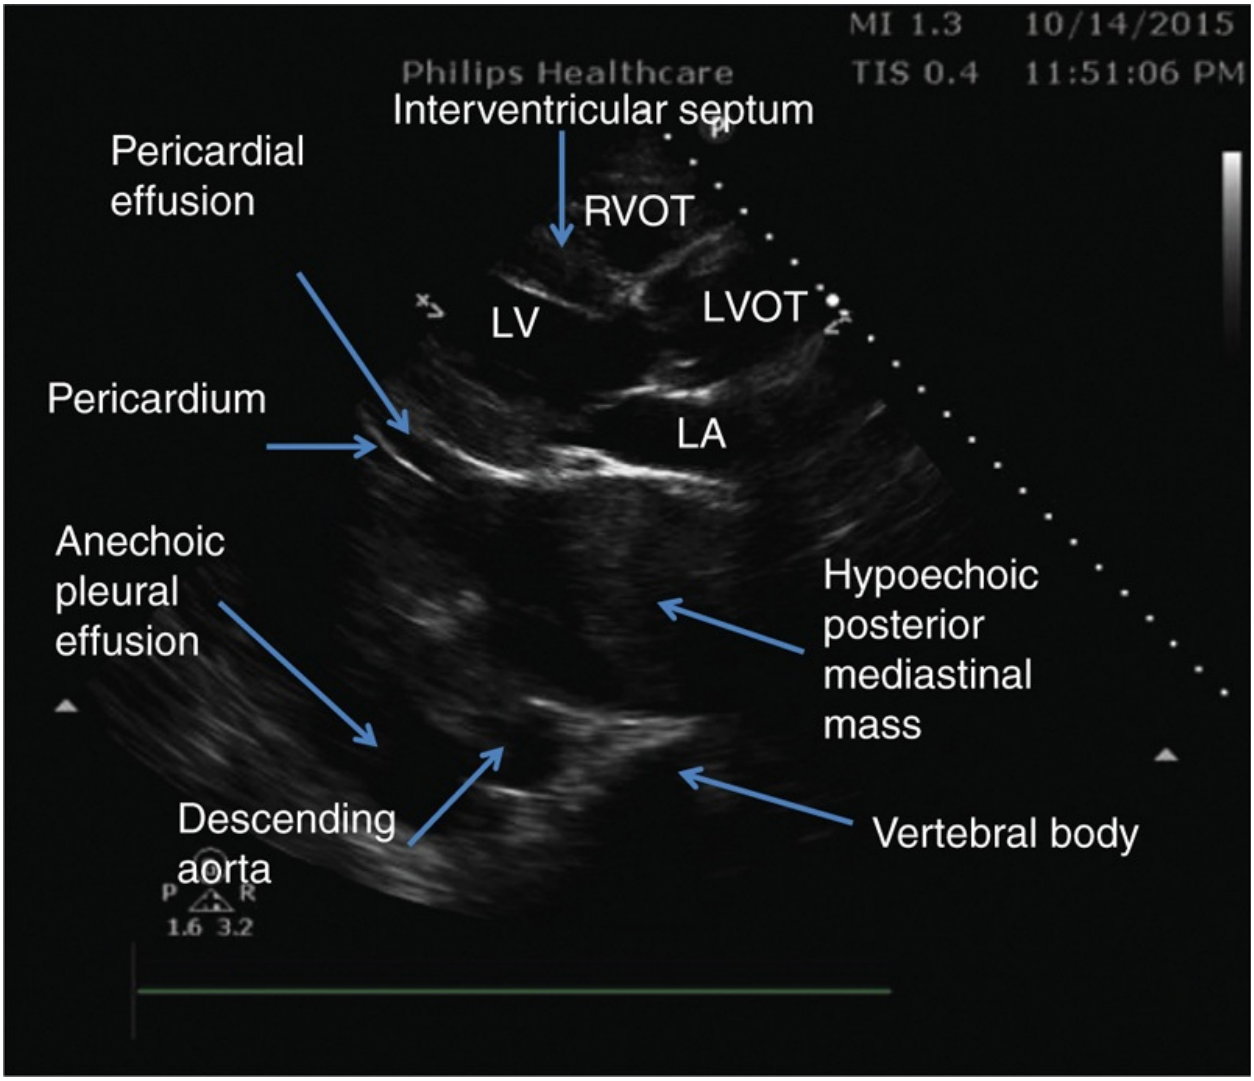

FIGURE 51.1 Differences in tissue echogenicity. LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; RVOT, right ventricular outflow tract.

EQUIPMENT AND IMAGE ACQUISITION

Modern US machines are portable and consist of multiple transducers or probes (**Figure 51.2**). Linear array transducers emit high-frequency US waves at a frequency of 5 to 15 MHz and provide excellent resolution of superficial structures such as vascular structures. For POCUS, this transducer is mainly used for US guidance for vascular access and to assess for DVT. Because of its high resolution, it can be used to assess the pleura for pneumothorax. It has poor penetration and so is not used to image deeper structures. Phased array transducers are low-frequency transducers (1 to 5 MHz) and have good penetration; hence, they are used to image deeper structures. The small footprint of the transducer allows for image acquisition between the ribs, and is hence used for lung, pleural, and cardiac USG. This transducer can also be used for abdominal and pelvic imaging. The curvilinear transducer is a hybrid, multipurpose probe that images at lower frequencies ranging between 1 and 8 MHz. It has a larger footprint, which generates a beam that fans outward, resulting in a wide field of view. These probes are most often used for abdominal and pelvic applications and the FAST examination where the subcostal (SC) cardiac view can also be obtained. The microconvex probe has a small footprint that fits in between the rib interspace and can be used for thoracic imaging. **Table 51.2** summarizes the basic characteristics and uses of the different types of transducers.

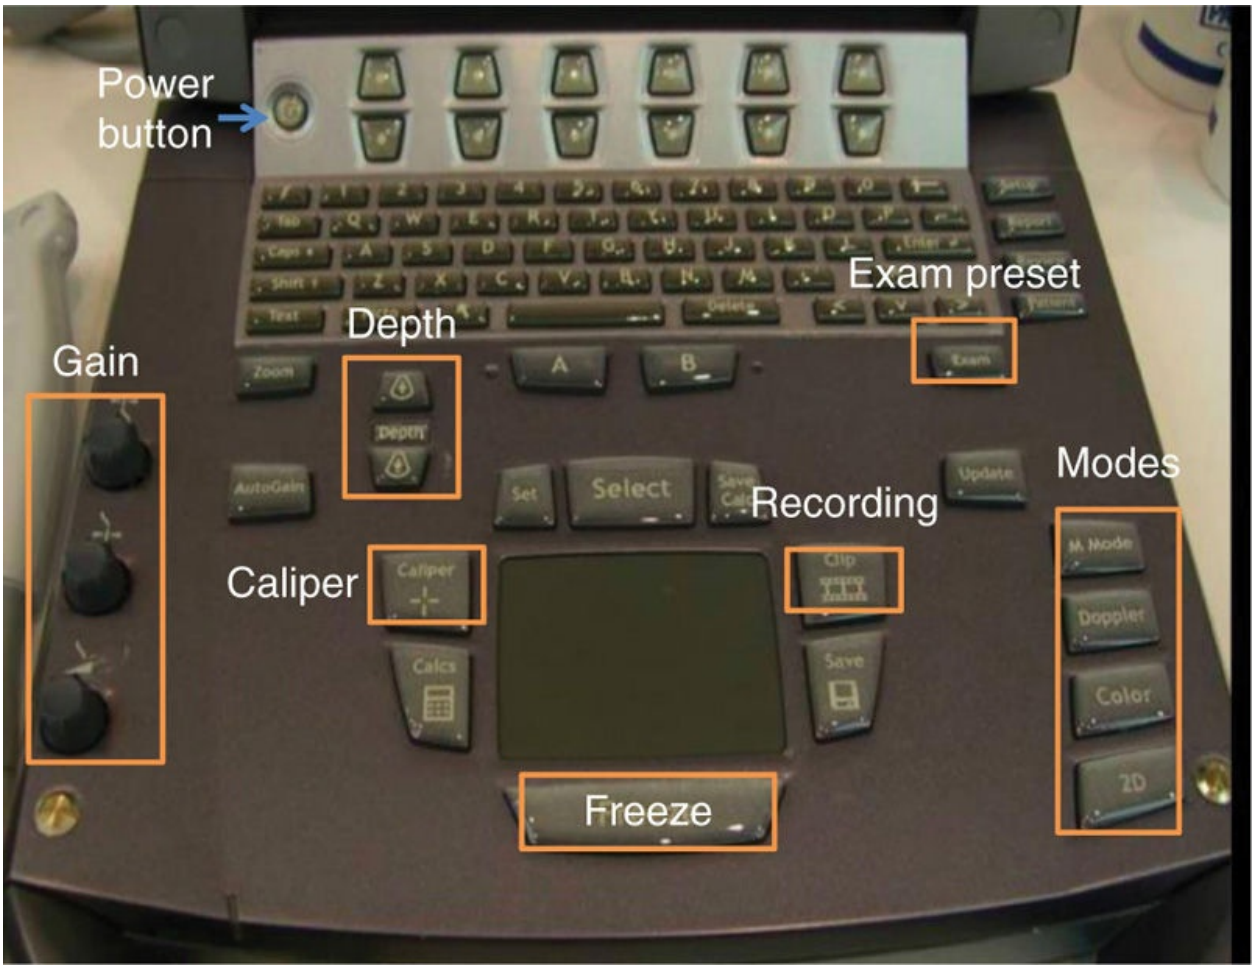

FIGURE 51.2 Portable ultrasound machine.

TABLE 51.2 Transducer Characteristics

TRANSDUCER	FREQUENCY	CHARACTERISTICS	USES
Linear array	5–15 MHz	High frequency Excellent resolution of superficial structures Loss of depth	Vascular access DVT study Pleural lines Soft tissue and musculoskeletal imaging

Phased array	1–5 MHz	Low frequency Small footprint Deep penetration	Cardiac Lung/pleural Abdomen
Microconvex	5–8 MHz	Small footprint Good resolution	Lung Abdomen Vascular Nerve
Curvilinear	1–8 MHz	Low frequency, low resolution Multipurpose Full depth of penetration	Abdominal/pelvic imaging FAST exam Lung/cardiac

DVT, deep vein thrombosis; FAST, focused assessment with sonography in trauma.

Transducer orientation and manipulation is of utmost importance in obtaining good images for diagnostic purposes or procedural guidance. The transducer should be held steady, as if holding a pencil (**Figure 51.3**). All US probes have a marker that correlates with the side of the marked screen. Structures adjacent to the probe marker will appear on the same side of the image as the screen marker, helping to orient the viewer and guide probe manipulations. The operator should always be aware of the orientation of the probe marker in relation to the marker on the monitor screen. Structures closest to the footprint of the transducer will appear on the top of the screen (near field) and those furthest away will appear on the bottom (far field). Portable US machines have preset examination settings (eg, abdomen versus cardiac) for each type of examination, which sets the resolution, frame rates, and the location of the screen marker.

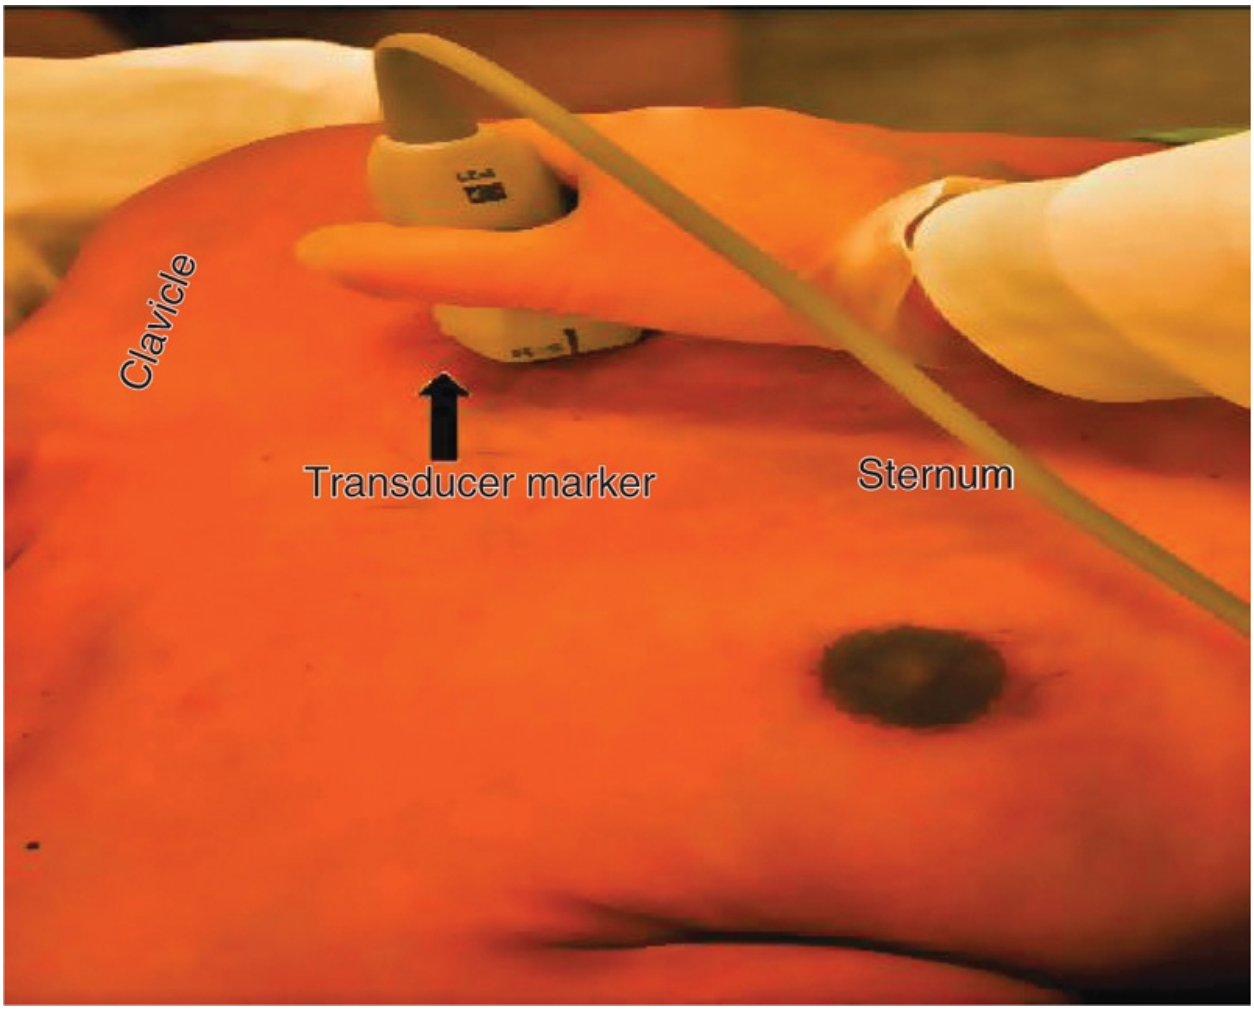

FIGURE 51.3 Transducer position for thoracic ultrasonography.

ULTRASOUND MANIPULATION

To obtain quality images, the gain and depth of imaging have to be optimized. *Depth* is manipulated on the console such that the structure of interest should always be in the center of the screen. The depth of interrogation is usually shown on a scale on the monitor. *Gain* adjusts the brightness of the entire image and should be adjusted such that there is maximal resolution between the different tissues that are imaged. Failure to adjust gain can lead to misinterpretation of image. Ensure that gain is uniform in both near (top half of screen) and far field (bottom half). The operator should be familiar with other features of the machine such as how to *freeze* and measure structures using the *caliper* button, how to *save* images and clips, and utilize features such as *M-mode* (motion mode) and

Doppler. The operator must always ensure that the portable US machine is in the appropriate exam preset. For example, the frame rates acquired in abdominal preset are not optimal for cardiac imaging and the screen marker on the opposite side will reverse all the cardiac images.

IMAGE MANIPULATION

In general, the probe marker should be pointed to the operator's left side when imaging in the transverse (short-axis) plane or cephalad when imaging in the coronal or sagittal (long-axis) planes. Additional maneuvers that are used to optimize the views include *moving* the probe such that the entire transducer is moved on the body (eg, from one rib interspace to another). This maneuver helps find the optimal location and view to locate the structure of interest. *Sliding* the probe is a maneuver that slides the transducer along the course of the structure of interest (eg, blood vessel). *Compression* allows visualization of deeper structures and allows one to differentiate structures (eg, vein from artery and nerve) based on their compressibility. *Rocking* involves angling the transducer side to side and extends the plane of imaging. This is useful to center the image on the screen (eg, centering a central vein and separating it from the artery). *Rotation* is used to switch between short-axis and long-axis imaging. This is useful for vascular access procedures and for obtaining short-axis cardiac views. *Tilting* (also called *fanning* or *sweeping*) allows the operator to scan along the course of a structure along a narrow acoustic window that is used. The transducer is held in place on the skin and angled on the long axis of the transducer face to aim the US beam in different planes (eg, obtaining multiple short-axis views of the heart).

MODES

The standard mode used for POCUS is *B-mode* or 2D USG. *M-mode* is used to display and measure the movement of structures over time. This feature is used to assess variation in the IVC diameter, diaphragmatic excursion, and to assess the pleura in the evaluation of pneumothorax. *D-mode* or *Doppler* mode evaluates the characteristics of direction and speed of blood flow (and tissue motion) through a structure. This is presented in audible, color, or spectral display.[20] Color Doppler converts measurements into an array of colors to

visualize speed and direction. This is particularly useful in vascular imaging to distinguish arteries from veins. The conventional color code is such that flow toward the transducer is depicted as red and flow away from the transducer is blue ("BART": blue away, red toward). Spectral Doppler is used mainly in echocardiography and displays the movement of blood in a graph depicting flow velocities with respect to time. **Table 51.3** lists examples of the imaging modes used in POCUS.

Table 51.3 Modes of Ultrasonography

MODES		
B-mode	Brightness mode	M-mode	Motion mode	D-mode	Examines the characteristics of direction and speed of blood flow (and tissue motion) • Color Doppler • Spectral Doppler • Power Doppler • • • •	
PRACTICAL APPLICATION OF POINT-OF-CARE ULTRASONOGRAPHY IN THE CCU

The standard critical care US examination involves scanning the major regions that would answer the question about the presenting condition. The standard multiorgan POCUS examination generally includes four organ systems: thoracic (lung and pleural), cardiac, and limited abdominal and vascular imaging. The organ of interest is often scanned first (eg, heart in shock or lungs in respiratory failure), although a standardized multiorgan approach can be used for the critically ill patient in the CCU. Although a focused examination is often all that is needed, studies have shown that a multiorgan or whole-body approach leads to a more accurate diagnosis.[13,21] The US examination should always be performed in conjunction with the patient's clinical data. It should be repeated to reassess the patient and to see if certain therapeutic interventions were effective.

The most common indication for a point-of-care examination in the CCU is for cardiopulmonary failure. POCUS is indicated in the evaluation of the patient with undifferentiated shock and can help distinguish between obstructive, cardiogenic, hypovolemic, and distributive shock states.[4,13,21,22] Another major indication would be in the setting of acute respiratory failure. A focused US examination of the heart, lungs, and deep veins can be useful in diagnosing various causes of respiratory failure.[10] Overadministration of fluids in the patient in the CCU with limited cardiopulmonary reserve can be harmful and leads to increased days of ventilator support. Assessing IVC size and variation, as well as the heart and lungs, can help guide fluid resuscitation.[17] US is very helpful in the patient whose condition suddenly deteriorates. It can be used to quickly rule out pneumothorax, massive pulmonary embolism (PE), pericardial tamponade, valvular rupture, and intra-abdominal bleeding.

FUNDAMENTALS OF THORACIC ULTRASONOGRAPHY IN THE CCU

BASIC PRINCIPLES

The utility of bedside lung ultrasound (LUS) is gaining increasing popularity as an attractive alternative to chest radiography. Easily performed by the trained intensivist, it is safe, accurate, and cost-effective. Conventionally, thoracic US is limited to the evaluation of pleural effusions; however, more recently LUS has become an attractive new tool for assessing lung status in hypoxemic critically ill patients. A frontline intensivist, Dr Daniel Lichtenstein, has been largely

responsible for developing the field of critical care LUS, publishing a series of definitive reports in the 1990s that established the basis for the field.[23–26]

Traditionally, the lungs were not considered an organ amenable to USG, because US waves are not transmitted through air-filled structures. When air is displaced from the lung by a disease process, US findings change in a predictable manner. Because the lung parenchyma is normally filled with air, which is a near-total reflector, the healthy or "unhealthy" pleural line serves as the generator of reflecting signs, which can be interpreted. Lung disorders can be separated into dependent disorders and nondependent disorders, whereby fluid descends and air rises. The findings of LUS relate to the ratio of air to fluid within the lung. Most lung processes that are pertinent to the patient in the CCU (eg, pulmonary edema, pneumonia, pneumothorax, pleural effusion, and atelectasis) all extend to the lung periphery allowing the US machine's ability to distinguish air and water to produce artifacts. These artifacts are used to diagnose various disorders such as alveolar-interstitial syndrome and accurately assess lung aeration in patients with acute lung injury. LUS is therefore based on the clinical interpretation of a number of mostly dynamic artifacts.

THE LUNG EXAMINATION

To examine the thorax, a micro-convex (5 to 8 MHz) transducer is preferable or, alternatively, a low-frequency (1 to 5 MHz) phased array transducer can be used because it fits in the rib interspace (**Table 51.2**).[27] A high-frequency linear array transducer (5 to 15 MHz) can be used to visualize the superficial pleural line; however, it is limited by the depth of penetration and the linear trajectory of the US beam.

The scanning of the lung occurs in the intercostal spaces. The transducer is held in a longitudinal orientation and perpendicular to the skin surface, with the marker facing cephalad (**Figure 51.3**). Initial scanning should be performed at a maximum depth (around 16 cm) and then the gain and depth must be adjusted to optimize and center the image. By moving the transducer along a series of longitudinal scan lines while imaging through adjacent intercostal spaces, the examiner can perform a complete lung examination and construct a 3D image of the thorax. The thorax can be divided into three zones: anterior, lateral, and posterior zones and then further into upper and lower zones (**Figure 51.4**).[27] Thus, a complete examination consists of 12 imaging regions, 6 in each hemithorax.

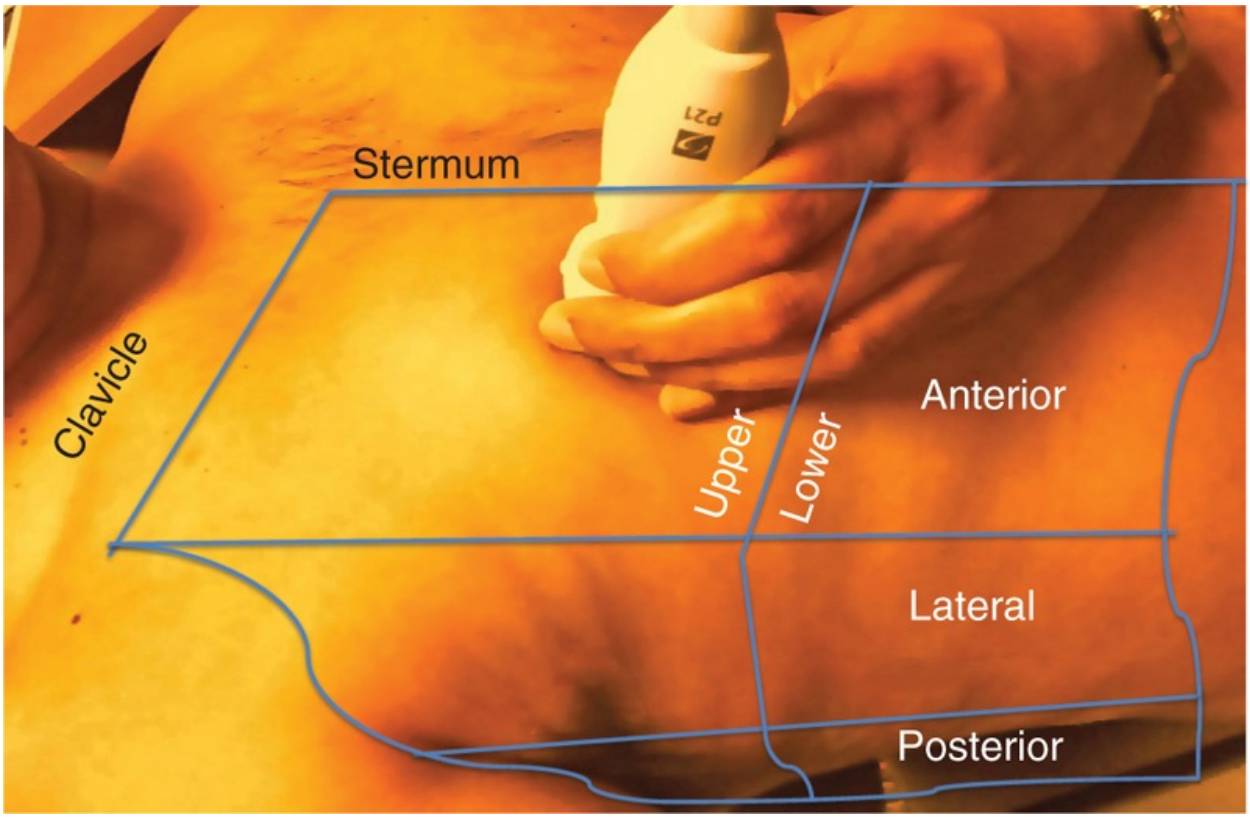

FIGURE 51.4 Lung zones for thoracic ultrasonography.

The sternum and the anterior axillary line border the *anterior lung zone*, whereas the *lateral zone* lies between the anterior and posterior axillary lines. The *posterior lung zone* lies behind the posterior axillary line. The anterior lung zone is assessed for alveolar-interstitial syndromes, lung consolidation, and pneumothorax. When examining the lateral zone, it is important to identify the hemi-diaphragm, which appears as a hyperechoic structure that separates the lungs from abdominal contents. Pleural effusions, atelectasis, and consolidation can often be seen above the hemi-diaphragm in this region. The posterior lung zone is a forgotten region where dependent pleural effusions and lung consolidation may be seen, so it is important to turn the critically ill patient to assess this area. Alternatively, Lichtenstein describes four points that can be quickly assessed as part of the BLUE (bedside lung ultrasound in emergency) protocol (**Figure 51.5**), a goal-directed LUS examination that can be performed in <3 minutes.[10]

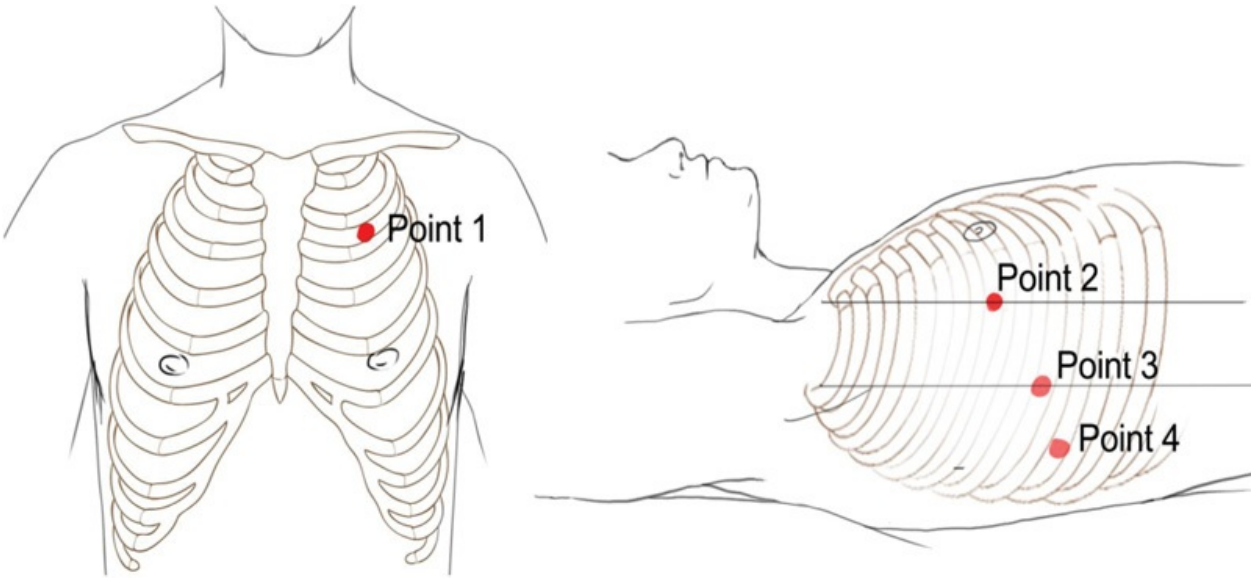

FIGURE 51.5 Bedside lung ultrasound in emergency (BLUE) protocol.

LUNG SIGNS

There are five cardinal lung signs to look for when performing thoracic USG. **Table 51.4** describes these and additional signs that are described in LUS and pleural USG. **Table 51.5** summarizes common LUS patterns seen in common disease processes that may be encountered in the CCU.

TABLE 51.4 Normal and Abnormal Signs in Lung Ultrasonography

SIGN	LUNG ULTRASOUND PATTERN	CLINICAL SIGNIFICANCE
A-line	Horizontal reflections or reverberations of pleural line Hyperechoic and equal in distance from skin to pleural line	Present in normal lung, "air" line indicates air in lung or pleural space
B-lines	"Comet tail" or "lung rockets"—vertical hyperechoic reverberation artifacts that arise from the pleural line and extend to the bottom of the screen Move synchronously with lung sliding and efface A-lines; implies fluid-filled subpleural interlobular septa	>3 B-lines = interstitial pathology Multiple diffuse B-lines indicate interstitial syndrome Focal B-line can be seen in pneumonia, infarct, and cancer
Lung sliding	Sliding or shimmering of the pleural line that occurs with respiration Indicates intact visceral and parietal pleura	Present in normal lung Absent in pneumothorax, apnea, fibrosis, ARDS, and pleurodesis

Lung pulse	Subtle rhythmic movement of the visceral upon the parietal pleural with cardiac oscillations	Present in normal lung Rules out pneumothorax
Seashore sign	Normal M-mode image with lines above echogenic pleura and speckled pattern deep to it, indicating normal lung sliding	Normal aeration pattern No pneumothorax
Bar code or stratosphere sign	Abnormal M-mode image showing a linear pattern above and below the pleura	Signifies absence of lung sliding; can be seen with pneumothorax
Lung point	Transition point where visceral and parietal pleura separate—image changes from the intermittent presence and then absence of lung sliding	Pathognomonic sign for pneumothorax
Lung hepatization/consolidation	Loss of aeration of lung leads to a hyperechoic appearance of lung; alveoli are filled with fluid or inflammatory cells or are atelectatic	Can be seen with atelectasis or pneumonia
Dynamic air bronchograms	Dynamic echogenic foci within consolidated lung that fluctuate with the respiratory cycle	Seen with pneumonia
Static air bronchograms	Hyperechoic foci that do not move with respiration	Seen with atelectasis
Shred sign	Border between consolidated and aerated lung	Seen with consolidation but not translobar consolidation
Curtain sign	Intermittent obscuration of underlying organs by intervening air-filled lung	Can be normal finding
Hematocrit sign	Effusion is separated into different echogenicity with a layering effect	Seen in hemothorax or highly cellular effusions (eg, malignant effusion)
Flapping lung (jellyfish sign)	Floating movement of collapsed lung within a pleural effusion	Atelectatic lung in effusion
Sinusoid sign	In a pleural effusion, M-mode appearance of the pleura moving toward and away from the parietal pleura	Can be used to distinguish pleural thickening from effusion
Plankton sign	Particulate matter in lung effusion	Complex effusion

ARDS, acute respiratory distress syndrome.

TABLE 51.5 Lung Ultrasound Patterns

LUNG ULTRASOUND PATTERN	CLINICAL SIGNIFICANCE
A-lines with lung sliding	Normal aeration pattern

A-lines without lung sliding and +lung point	Pneumothorax
B-7 lines	Interlobular septal pathology
B-3 lines	Alveolar-interstitial syndrome
Focal absence of B-lines	Pulmonary embolus, cancer
Lung hepatization + dynamic air bronchograms	Pneumonia
Lung hepatization ± static air bronchograms	Atelectasis
Anechoic collection without septations	Simple pleural effusion
Echogenic fluid with septations	Complicated effusion

Lung Sliding

This is a subtle shimmering of the hyperechoic pleural line (**Figure 51.6**). It represents movement of visceral pleura past the parietal pleura during respiration. It must be present at multiple sites and will be present more often at the lung base. The presence of lung sliding rules out pneumothorax with 100% certainty at that particular site on the thorax.[26,27] The presence of lung sliding strongly suggests that two conditions are met: the pleural surfaces are adjacent (ie, no pneumothorax) and that the lung volume is changing. The examiner can also use a high-resolution linear array transducer because it images the pleura well. A similar analogous sign can be from *lung pulse*, which is produced when cardiac motion causes pulsations of the pleural line. Air in the pleural space (ie, pneumothorax) will cause absence of lung sliding and lung pulse. Other conditions can also cause lack of lung sliding, including apnea or hypoventilation (eg, contralateral bronchial intubation), pleurodesis, and dense lung consolidation.

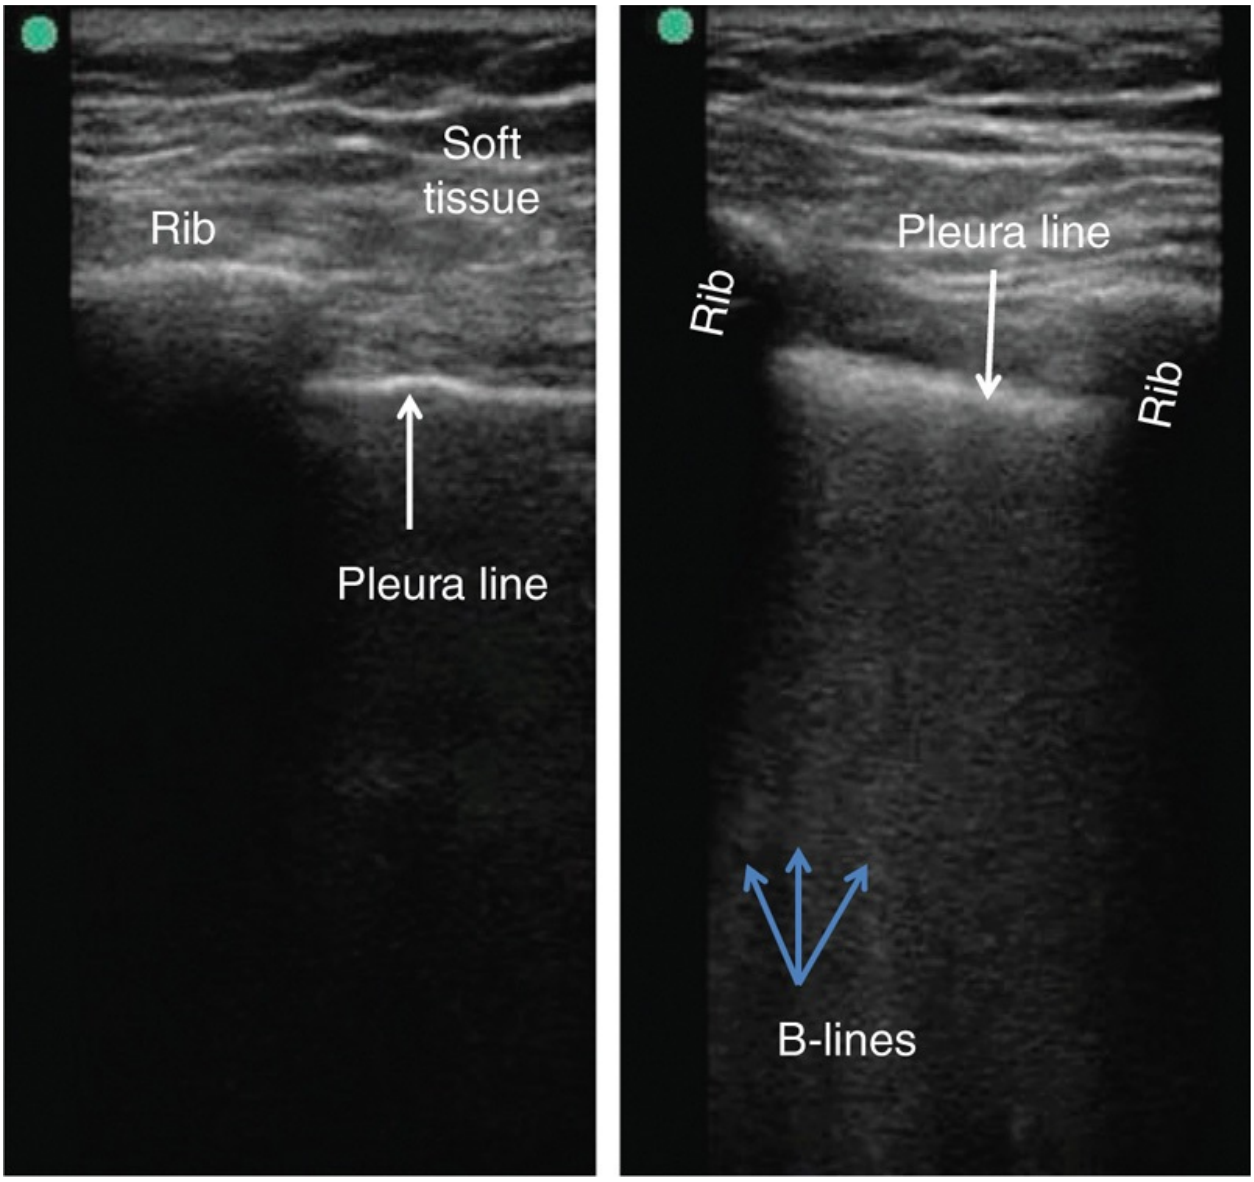

FIGURE 51.6 Normal pleural line with lung sliding imaged with linear array transducer.

A-Lines

Sonographic A-lines are visualized as hyperechoic lines perpendicular to the US beam (**Figure 51.7**). They are reverberation artifacts that arise when the US beam reflects off the pleura; therefore, these lines are below the pleural line. There is equal distance between the transducer, pleural line, and each subsequent A-line. A-lines can be thought of as “air” lines, but the air can be either in the pleural space or in the lung parenchyma. The presence of sliding lung determines that the air is in the lung parenchyma and its absence indicates that the air may be in the pleural space (ie, pneumothorax). Hence, the presence of

A-lines and sliding lung means the lungs are normal at that particular site. The standard view of the upper rib, pleural line, and lower rib has the appearance of a bat flying out of the screen, and hence is called a *batwing sign* (**Figures 51.6 and 51.7**).[10,28]

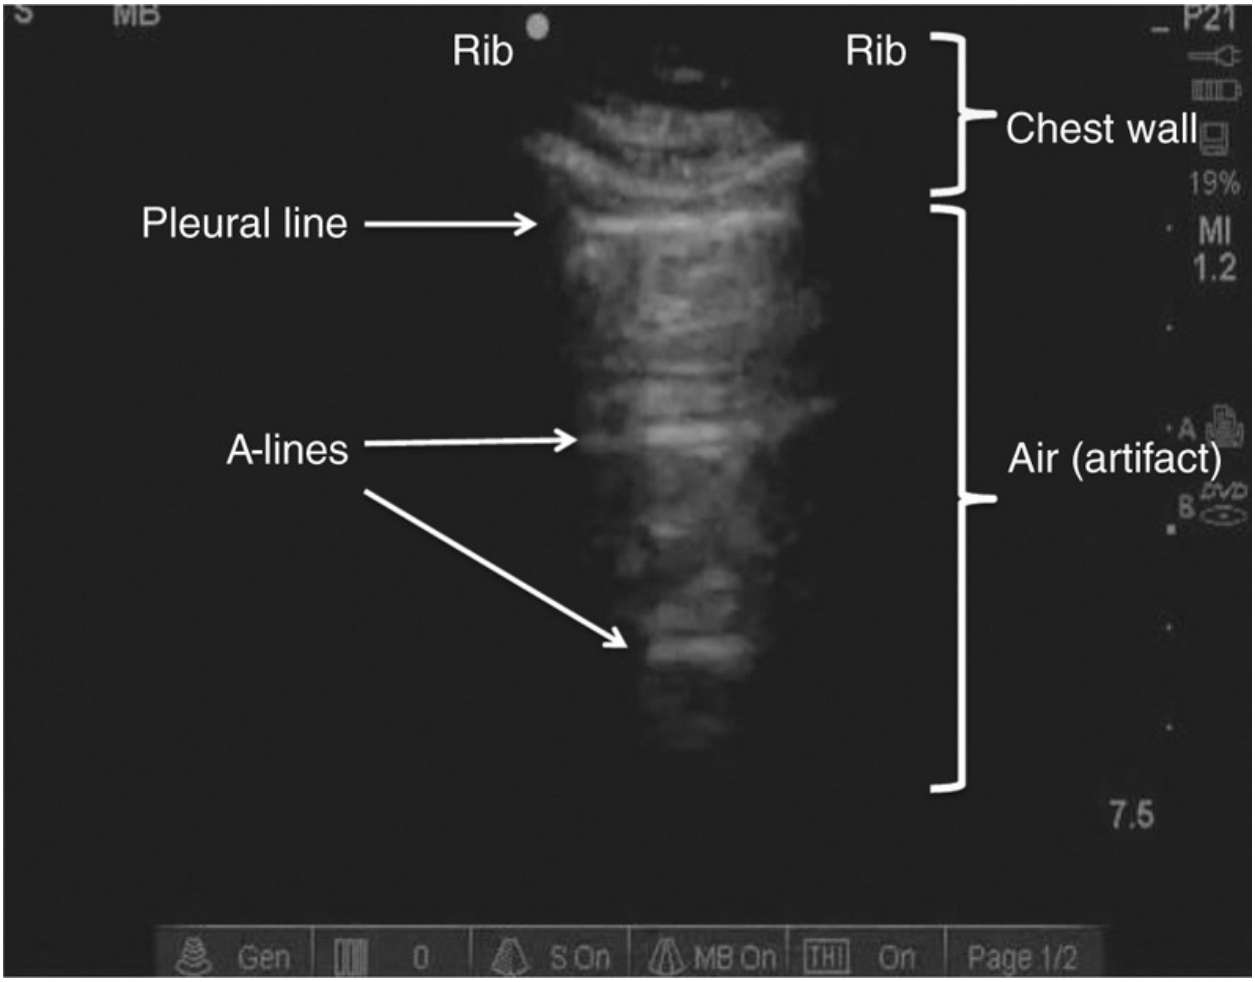

FIGURE 51.7 Standard view of A-line from anterior lung zone imaged with phased array transducer.

B-Lines

B-lines are vertical raylike projections that start from the pleural line and continue to the bottom of the screen (**Figure 51.8**). They are also known as comet tails or lung rockets because of their sonographic similarity with comets and rockets. B-lines follow the motion of the lung sliding and efface the normal A-lines at the point of their intersection. B-lines are generated when the interlobular septa become abnormally thickened with fluid or when the alveoli become abnormally filled with fluid, blood, or purulent material. Although

isolated B-lines in any given region may be a normal finding, seeing more than three lines is considered abnormal. It is not uncommon to find B-lines at the lung bases in the hospitalized patient; however, the presence of >3 B-lines in the anterior lung zones is abnormal. The focal location of B-lines may be suggestive of local infiltration (eg, focal pneumonia). A generalized B-line pattern represents an interstitial syndrome such as pulmonary edema, pneumonia, acute respiratory distress syndrome (ARDS), or interstitial lung disease.[10,23,24]

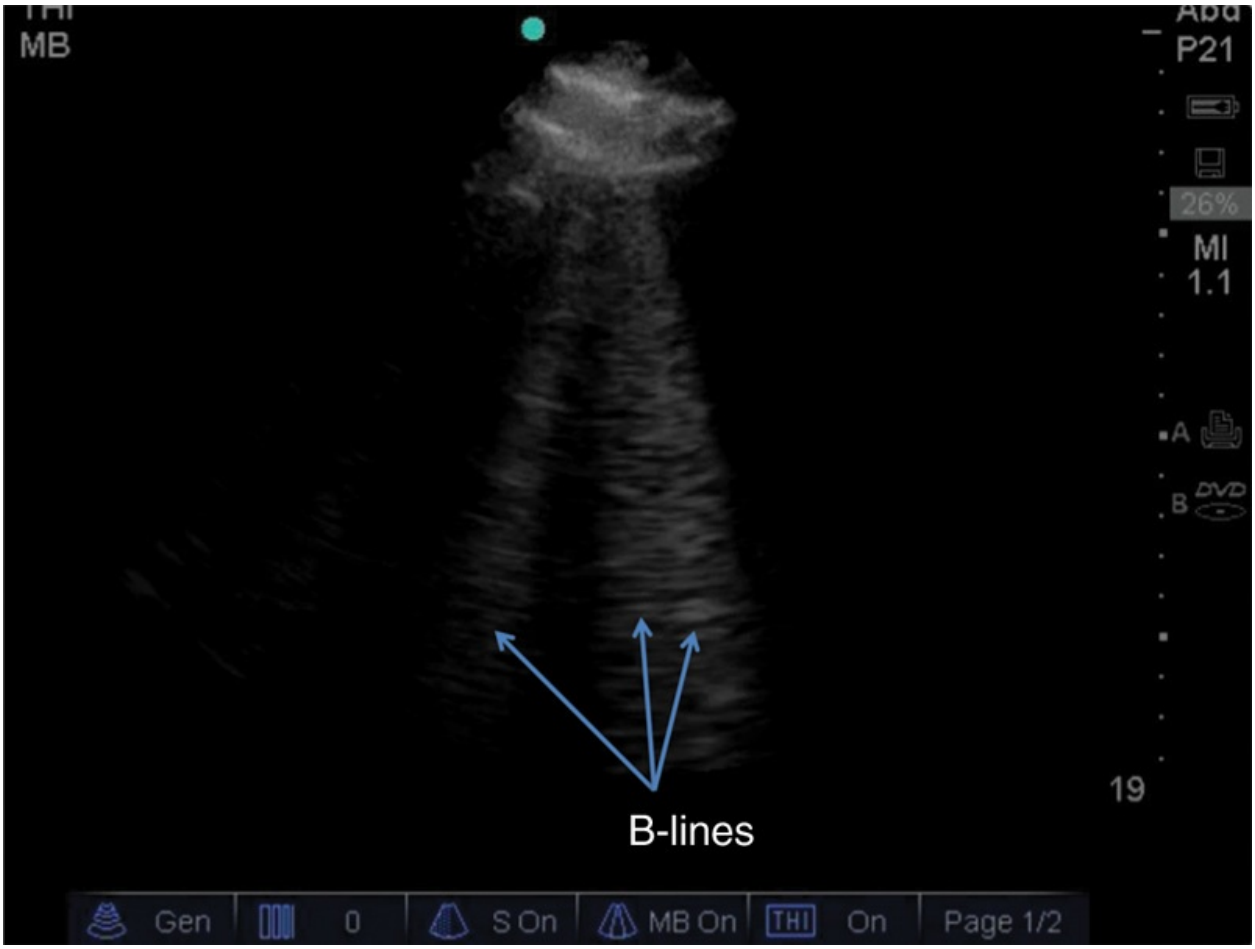

FIGURE 51.8 B-line pattern.

Alveolar Consolidation

When the alveoli become devoid of air and are filled with pus, fluid, or blood, the lungs develop echogenicity. Consolidated lung adjacent to the pleura will permit the transmission of US waves. In the circumstance of lung consolidation, the lung appears sonographically similar to the liver; therefore, the term “lung

hepatization" has been descriptively utilized.[10,27] In addition, sonographic air bronchograms or punctate hyperechoic foci within the consolidated lung may be visualized, which indicates that air still remains in the bronchioles. The presence of mobile or dynamic air bronchograms has high specificity (94%) for the diagnosis of pneumonia, as compared to static air bronchograms, which is seen in resorptive atelectasis.[29] **Figure 51.9** shows an example of a patient with lung consolidation as a result of severe pneumonia with parapneumonic effusion.

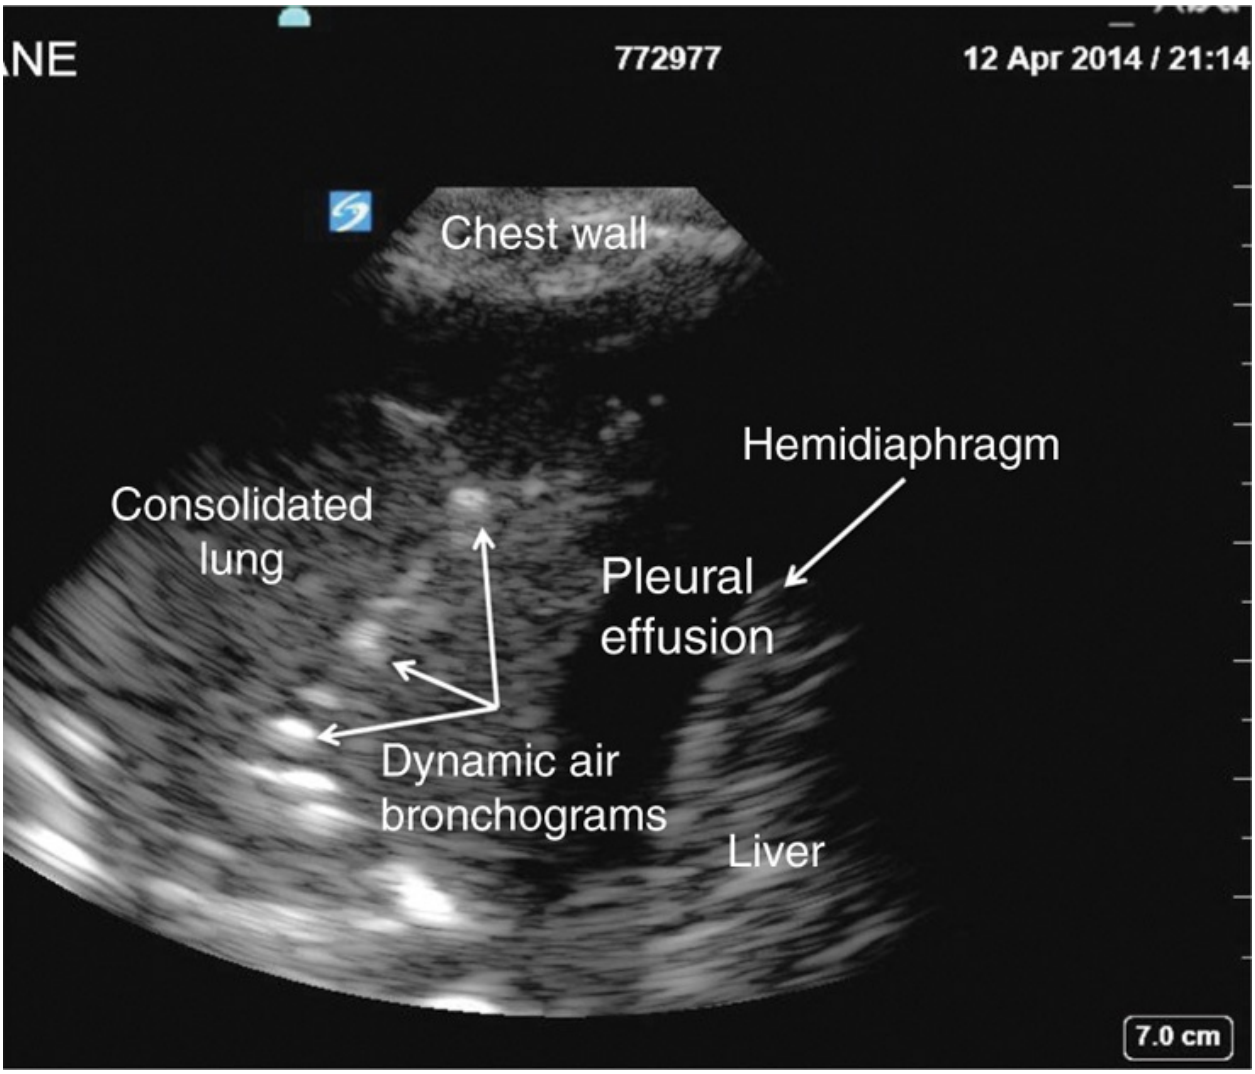

FIGURE 51.9 Lung consolidation with sonographic air bronchograms.

Pleural Effusion

One of the most important uses of US in thoracic pathology is the ability to detect, quantify, and characterize pleural effusion. Pleural USG is superior to

standard upright chest radiography and supine chest radiography for detecting pleural effusions.[30] On a portable chest radiograph in the patient in the CCU, both lung consolidation and pleural effusion will appear “white.” POCUS is particularly helpful in these patients, because it will help differentiate the two. Pleural fluid is typically anechoic, whereas consolidated or atelectatic lung is echogenic. It is important to also distinguish pleural effusion from pericardial effusion in such patients. In the PLAX view, pleural effusions lie posterior to the descending aorta and pericardial effusions anterior and within the pericardium. In addition, scanning the lateral or posterior lung zone (**Figure 51.4**) further helps differentiate the two effusions. The use of US also allows for the identification of a safe puncture site to perform thoracentesis, even in mechanically ventilated patients in the CCU.[8] Before thoracentesis, ensure the three cardinal features of a pleural effusion: an anechoic space; anatomic boundaries of chest wall, diaphragm and lung; and dynamic changes of the atelectatic lung and diaphragm related to respiration and cardiac motion.[28]

Pleural USG can further help characterize the pleural effusion and can even identify septations within it. Simple anechoic fluid suggests a noncomplicated pleural effusion, which may or may not be a transudate. The *flapping lung* or *jellyfish sign* is the oscillating movement of a collapsed lung in a pleural effusion (**Figure 51.10**). Strands of echogenic floating matter suggest complex fluid; this is called the *plankton sign*.[31] Septated or loculated effusions imply complicated effusions that require sampling of the fluid and usually warrant a chest tube placement or surgical drainage. **Figure 51.11A** demonstrates the multiple septations within the pleural fluid of a patient with pneumonia and empyema. This patient was a poor surgical candidate, and so was treated with a small-bore chest tube and intrapleural alteplase and deoxyribonuclease (DNase). Similarly, pleural effusions can demonstrate the *hematocrit sign*, where an echogenic or highly cellular effusion (ie, blood) has gravity-dependent fading of echogenicity.[31] **Figure 51.11B** is that of a patient with trauma who presented with a hemothorax.

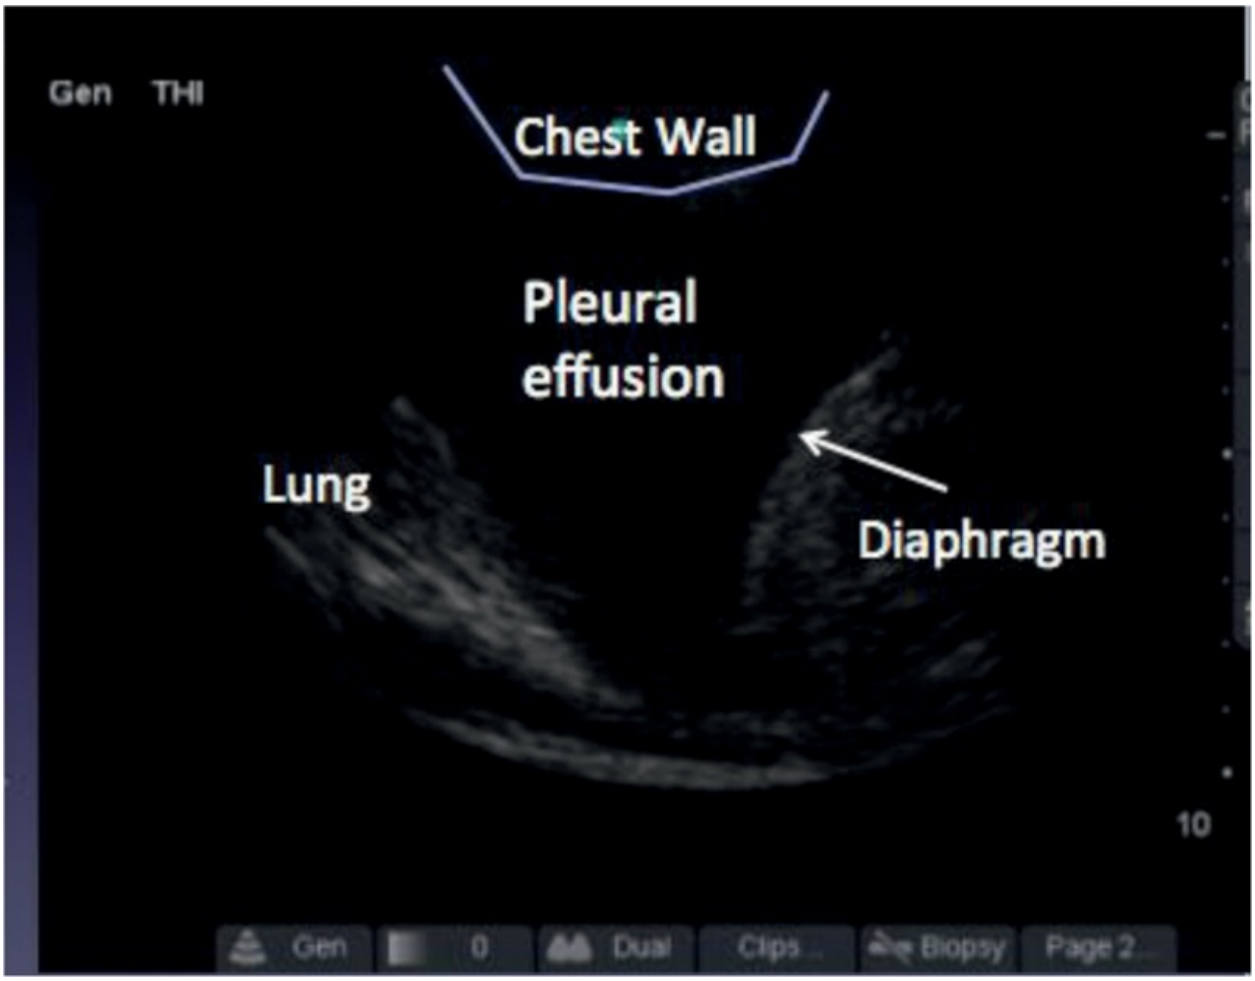

FIGURE 51.10 Moderate pleural effusion with flapping lung.

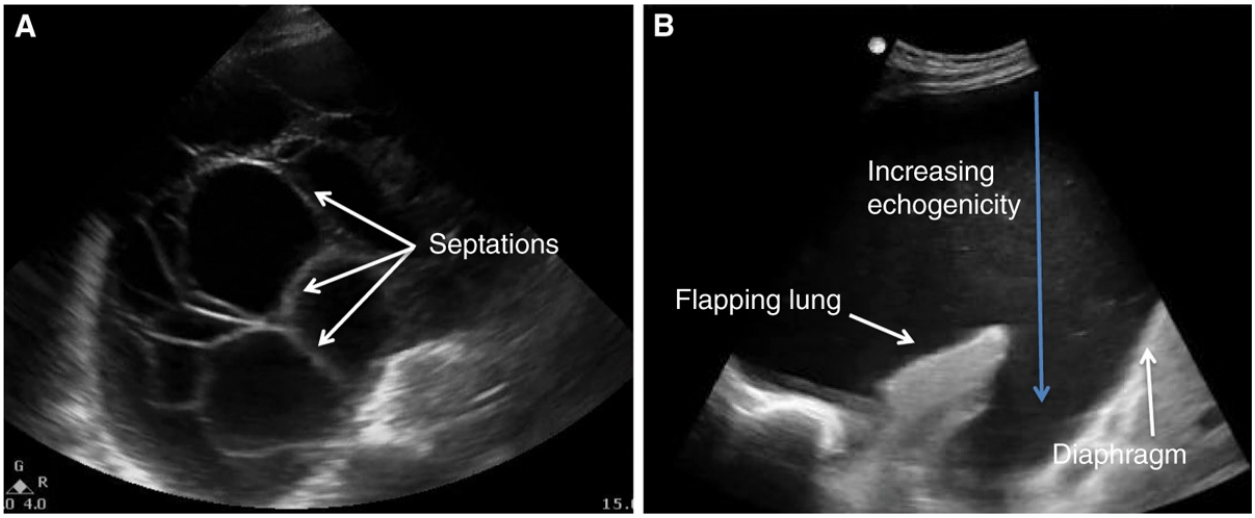

FIGURE 51.11 A, Empyema with thickened pleura and multiple septations within pleural effusion. B, Hemothorax with increasing echogenicity of fluid in the pleural space.

CLINICAL SCENARIOS ENCOUNTERED IN THE CCU

Detection of Pneumothorax

Pneumothorax can occur spontaneously in the CCU and is potentially fatal. Patients on mechanical ventilation with underlying emphysema or those undergoing central line placement are at risk for pneumothorax. Lung ultrasonography carries a >95% sensitivity in the detection of pneumothorax.[32] The examination requires, on an average, 2 to 3 minutes. The transducer is placed longitudinally in the mid-clavicular line at the level of the second to third intercostal space. Sequential movement of the transducer inferior and lateral across multiple rib interspaces will allow for a comprehensive examination of the pleural space.[27] The presence of lung sliding is characteristic of normal visceral and parietal pleural layers and carries a 100% negative predictive value in the diagnosis of pneumothorax.[26] In contrast to normal lung, when air is trapped between the visceral and parietal pleural layers, lung sliding will not be detected. Nevertheless, absence of lung sliding may not always be due to the presence of pneumothorax because it has also been observed in massive atelectasis, ARDS, pleural adhesions, and severe lung fibrosis. The presence of B-lines or lung pulse also rules out pneumothorax.[24,33]

In the occasion that lung sliding is difficult to visualize, additional information is obtained with the assistance of M-mode analysis. Characteristically, M-mode analysis of normal lung tissue demonstrates the *seashore sign*, a characteristic linear wave pattern representing the motionless chest wall, and below the pleural line a granular pattern represents normal lung motion (**Figure 51.12**A). If present, it confirms the presence of lung sliding and therefore the absence of pneumothorax. When there is air in the pleural space, this morphology is replaced on M-mode imaging by parallel linear lines called the *stratosphere sign* or *bar code sign* (**Figure 51.12**B*)*.[32] The visualization of the *lung point* may also be used in the diagnosis of pneumothorax, having a specificity of 100%. The lung point represents the transition point between normal lung sliding and to an area of absent lung sliding (**Figure 51.13**).[25] Lung point is helpful to also quantify how large a pneumothorax is and helps with procedural guidance for chest tube placement. One approach during central line placement would be to check for lung sliding before and after line placement to quickly rule out a pneumothorax. These concepts can be applied within seconds to the patient in the CCU who is quickly decompensating to rule out pneumothorax.

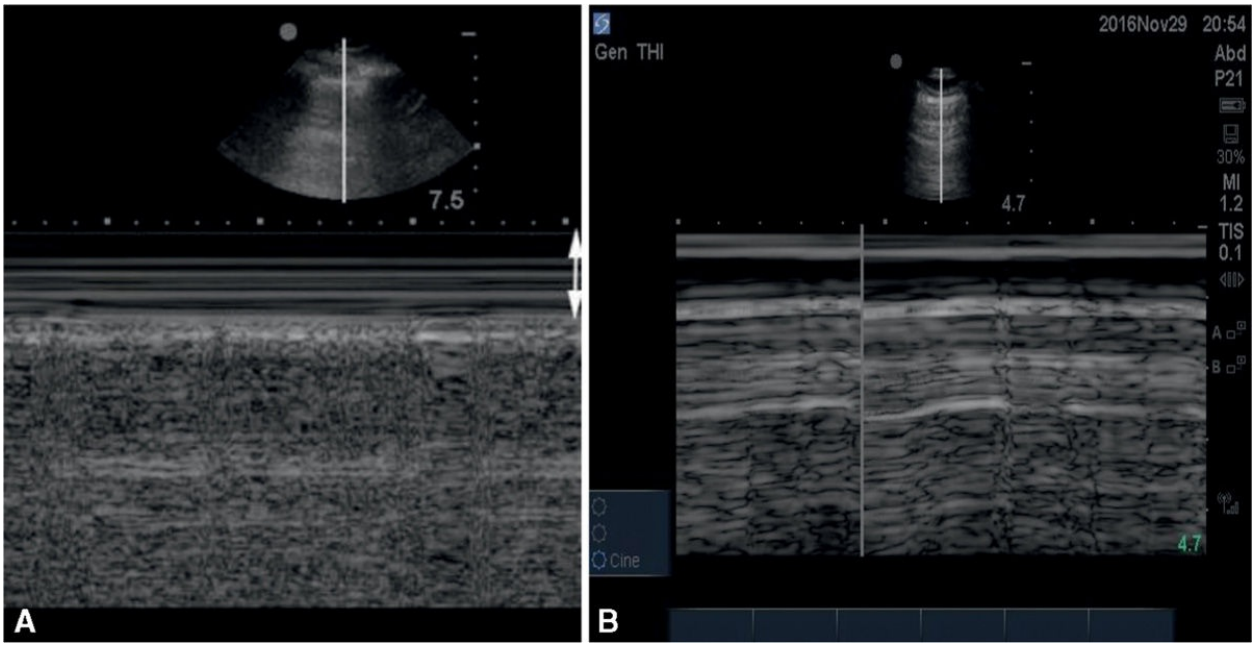

FIGURE 51.12 A, Seashore sign. B, Stratosphere or bar code sign.

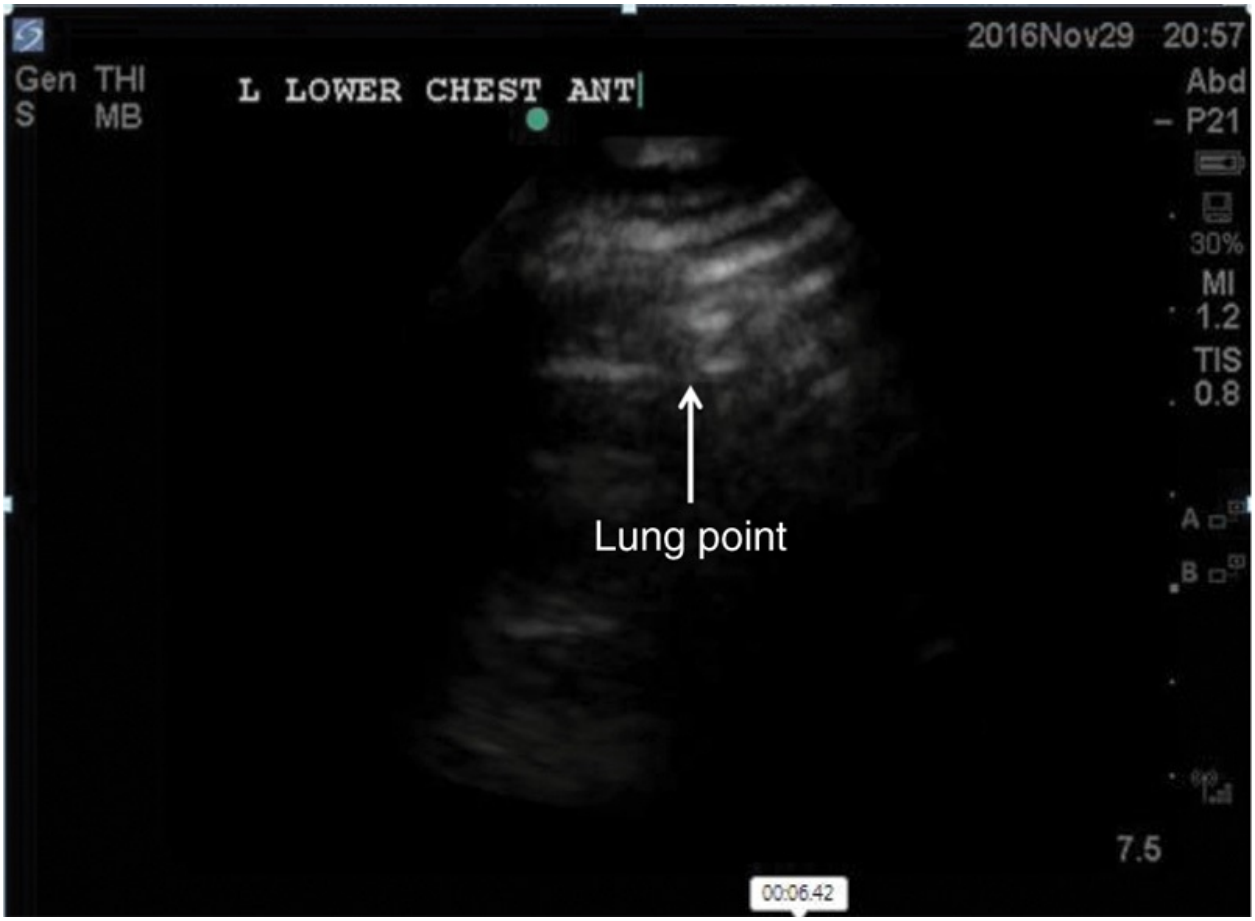

FIGURE 51.13 Lung point.

Detection of Lung Alveolar-Interstitial Syndrome

Alveolar-interstitial syndrome is a common entity in the CCU, caused by a variety of conditions, including acute pulmonary edema, ARDS, and interstitial pneumonias. B-lines 7 mm apart, called *B-7 lines*, correspond to edematous or thickened interlobular septa and extravascular lung volume (similar to Kerley B-lines on a chest radiograph). Lichtenstein also described *B-3 lines*, which are B-lines that are 3 mm apart and more confluent, indicating alveolar edema or an alveolar process such as pneumonia. The more B-lines that are present anteriorly, the lower the air to fluid and the more severe the lung pathology.

LUS is very sensitive in detecting early pulmonary vascular congestion, much more than a chest X-ray. In an acutely dyspneic patient, the detection of diffuse B-lines allows the intensivist to immediately differentiate acute pulmonary edema from chronic obstructive pulmonary disease (COPD).[23] Even while administering fluids in the CCU, the appearance of new B-lines corresponds to early pulmonary edema and correlates to elevated pulmonary artery occlusion pressures (>18 mm Hg).[14] Similarly, while administering diuretics in patients with acute pulmonary edema, one can assess for reduction in the number of B-lines and also reduction in the volume of pleural effusions.

Differentiating Between Types of Lung Alveolar-Interstitial Syndrome

Diffuse B-lines suggest an interstitial pattern, and the presence of a diffuse B-line pattern in both lungs suggests a diffuse alveolar interstitial syndrome such as pulmonary edema, pulmonary fibrosis, or ARDS. The presence of a smooth pleural line may be seen in pulmonary edema, whereas with lung fibrosis, an irregular or "lumpy bumpy" pleural line may be visualized with a high-frequency linear array transducer. In ARDS, subpleural consolidation may be visualized below the pleural line with sparing of certain areas.[28] **Table 51.6** summarizes the main characteristics that can be used to distinguish these entities.

TABLE 51.6 Differentiating causes of the interstitial syndrome

	ACUTE PULMONARY EDEMA	CHRONIC HEART FAILURE	ARDS	PULMONARY FIBROSIS
Clinical setting	Acute	Chronic	Acute	Chronic

B-lines number	++++	+/++/+++	++++	+/++/+++
B-lines distribution	Multiple, diffuse, bilateral	Multiple, diffuse, bilateral following dependent regions	Non-homogenous distribution, spared areas	More frequently posterior at lung bases
Other Lung US signs	Small bilateral pleural effusions	Bilateral pleural effusions	Subpleural consolidations, possible effusion	Irregular pleural line
Echo	Abnormal	Abnormal	Likely normal	Likely normal

Assessing Diaphragmatic Function

The diaphragm is hyperechoic and easily visualized by USG. Diaphragmatic function can be quickly assessed in the patient in the CCU or the patient post cardiac surgery with acute respiratory failure or inability to wean from mechanical ventilation, obviating the need for fluoroscopy. The technique involves scanning the lateral lung zone, along the anterior or mid-axillary line, and identifying the liver or spleen. M-mode imaging can be utilized to obtain a quantitative measure of diaphragmatic excursion. Normal diaphragmatic excursion for a male in quiet breathing is 1.8 and 7.5 cm during deep breathing. Sonographically detected diaphragmatic dysfunction, defined as <10 mm or paradoxical motion, can identify patients who are difficult to wean. **Figure 51.14** represents 2D and M-mode imaging of the left hemidiaphragm in a patient with amyotrophic lateral sclerosis who presented with Takotsubo cardiomyopathy and acute respiratory failure.

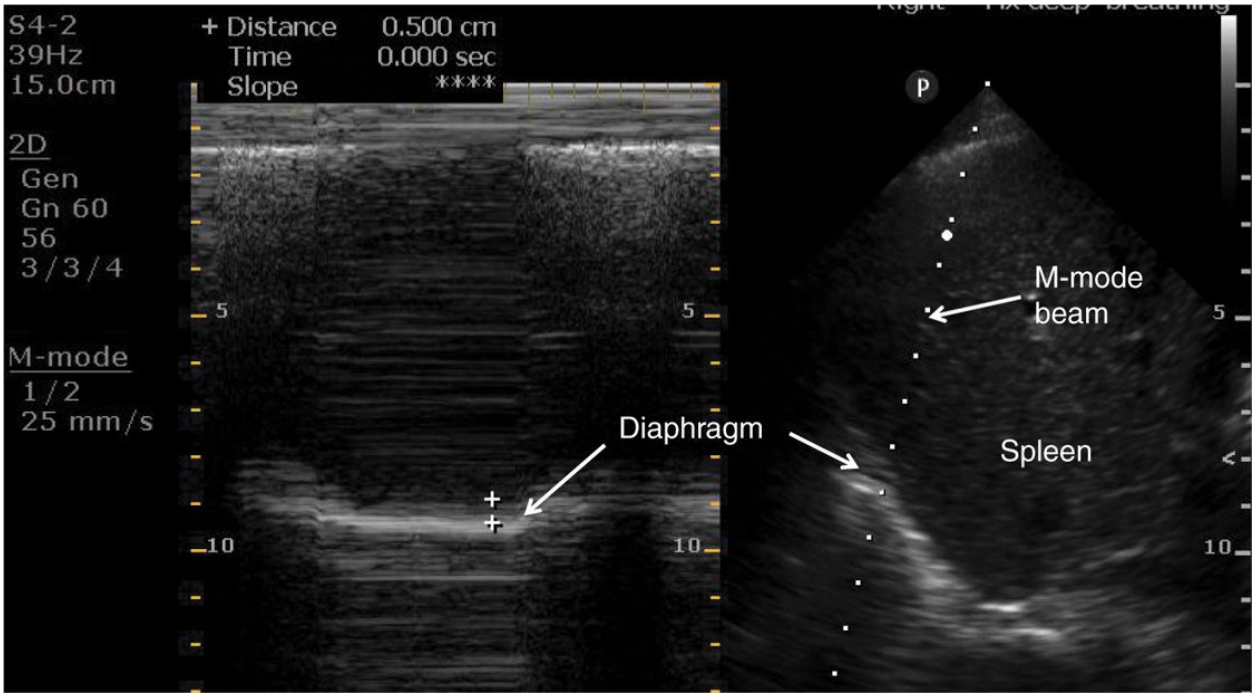

FIGURE 51.14 Decreased diaphragmatic excursion on M-mode.

Rapid Assessment of the Acutely Decompensating Patient in the CCU

Using the concepts described in this section, the CCU practitioner can rapidly assess the patient with acute respiratory failure and find the etiology of the decompensation. If there is an A-line pattern and absence of lung sliding, then pneumothorax has to be ruled out. Presence of diffuse B-lines and pleural effusions bilaterally detected on POCUS points to a pulmonary edema picture. Unilateral B-lines or a consolidation pattern can be seen with pneumonia. If lung sliding is present with a normal A-line pattern in all the lung zones, then the etiology of the respiratory decompensation has to be either due to airways disease (ie, asthma/COPD) or pulmonary vascular disease (ie, PE). Combining thoracic US with GDE can detect findings such as right ventricular (RV) strain or clot-in-transit, leading to a diagnosis of acute PE.[34]

Lichtenstein summarized these concepts in what he called the BLUE protocol, a simple, goal-directed LUS examination combined with a DVT study for acute respiratory failure. Blinded investigators scanned the four BLUE points (**Figure 51.5**) and performed compression US of the lower extremities, following a standardized algorithm (**Figure 51.15**). They were able to rapidly make an accurate diagnosis in 90% of the cases. In addition, the profiles described had very good sensitivity and excellent specificity to diagnose the conditions

correlating with each profile.[10] The concepts of thoracic USG can be easily learned by house staff and other clinicians and utilized to make accurate diagnosis in patients presenting with dyspnea.[35]

FUNDAMENTALS OF ULTRASONOGRAPHY IN UNDIFFERENTIATED SHOCK: MULTIORGAN POINT-OF-CARE ULTRASONOGRAPHY

Shock is a commonly encountered condition in the CCU but is not always associated with cardiac causes. Physical examination and laboratory parameters, along with multiorgan POCUS, guide the evaluation and management. POCUS techniques involving the heart, lungs, abdomen, and vasculature are performed on the basis of the appropriate clinical setting in an attempt to identify the cause of hypotension and optimize management. The goal-directed evaluation of a new, unexpected, or unexplained shock state in a patient in the CCU requires a

structured approach that will diagnose or rule out reversible causes such as cardiac tamponade, tension pneumothorax, pulmonary embolus, ruptured aortic aneurysm, and intra-abdominal hemorrhage.

GDE allows the intensivist to assess for RV or left ventricular (LV) failure, pericardial effusion, major valvular failure, and fluid responsiveness. The statement on training in CCUS makes the recommendation that training in critical care includes training in basic critical care echocardiography.[1–3] GDE can be learned and performed well by non-cardiologists with adequate training.[36–38] Combining GDE with sonography of other organs (multiorgan or whole-body USG) adds to the diagnostic yield when evaluating the patient in shock.[4,13] One can perform a goal-directed multiorgan POCUS examination in an efficient and systematic way to discern the etiology of shock:

1. Basic critical care echocardiography to evaluate LV and RV function; rule out tamponade and valvular failure
   a. PLAX, parasternal short-axis (PSAX), apical four-chamber, and SC views
2. IVC imaging to assess volume status in the setting of hypovolemia or sepsis
3. Thoracic US to rule out pneumothorax, hemothorax
4. Limited abdominal examination
   a. Right and left flank to rule out hemoperitoneum
   b. Abdominal aorta to evaluate for dissection
   c. Kidneys and bladder to rule out hydronephrosis in the setting of sepsis or renal failure
5. Compression US of lower extremities to evaluate for DVT

A systematic approach to the patient with shock in the CCU also employs the following questions while performing POCUS[22]:

1. Is there an imminently life-threatening cause of shock?
2. Is there evidence of pump failure: LV or RV failure?
3. Is the shock state likely to be fluid responsive?
4. Is there more than one cause for the shock state?
5. Is it noncardiac in origin?
6. Is there evidence of life-threatening hemorrhage?

Figure 51.16 illustrates an algorithmic approach to the patient in the CCU who is hypotensive. Many POCUS protocols exist for the evaluation of shock.

Essentially, they all incorporate multiorgan POCUS to evaluate the etiology of shock. **Table 51.7** summarizes a few of these protocols and the organs that are assessed.[39–41] Further discussions on cardiac etiologies of shock are found in other sections of this textbook.

INFERIOR VENA CAVA IMAGING: EVALUATING FLUID STATUS AND FLUID RESPONSIVENESS IN SHOCK

The IVC caliber is altered by respiration, blood volume, and right heart failure. The IVC can be used to assess intravascular volume status. Fluid responsiveness is by definition an increase in cardiac output (generally >15%) after an adequate volume challenge. Interpretation of IVC size and variability is dependent on whether a patient is spontaneously breathing or on mechanical ventilation. In the

spontaneously breathing patient, IVC imaging helps estimate right atrium (RA) pressures (ie, as a “noninvasive” central venous pressure [CVP] reading). In the patient on mechanical ventilation in the CCU, respiratory variation of the IVC can predict fluid responsiveness, in the appropriate settings.

TECHNIQUE

Multiple ways have been described to image the IVC. With the patient in supine position (and knees bent if possible), the IVC can be visualized from the SC cardiac view by placing the phased array transducer in the SC space with the marker facing the patient’s head. Alternatively, obtain an SC four-chamber view by positioning the probe flat just below the xiphoid, with the probe marker facing the patient’s left side (**Figure 51.17**). Identify the RA at the top of the screen and track it while turning the probe counterclockwise and slightly perpendicular to the body such that the marker is facing the patient’s head. The IVC will appear within the liver with a hepatic vein joining it and emptying into the RA. **Table 51.8** delineates basic characteristics used to identify the IVC and differentiate it from the aorta, which runs alongside the IVC. The IVC can be measured using 2D imaging or via M-mode imaging using the caliper feature. The “sniff” maneuver can be used in spontaneously breathing patients to estimate RA pressures. In patients on mechanical ventilation, the maximal and minimal diameter can be calculated to assess for respiratory variability.

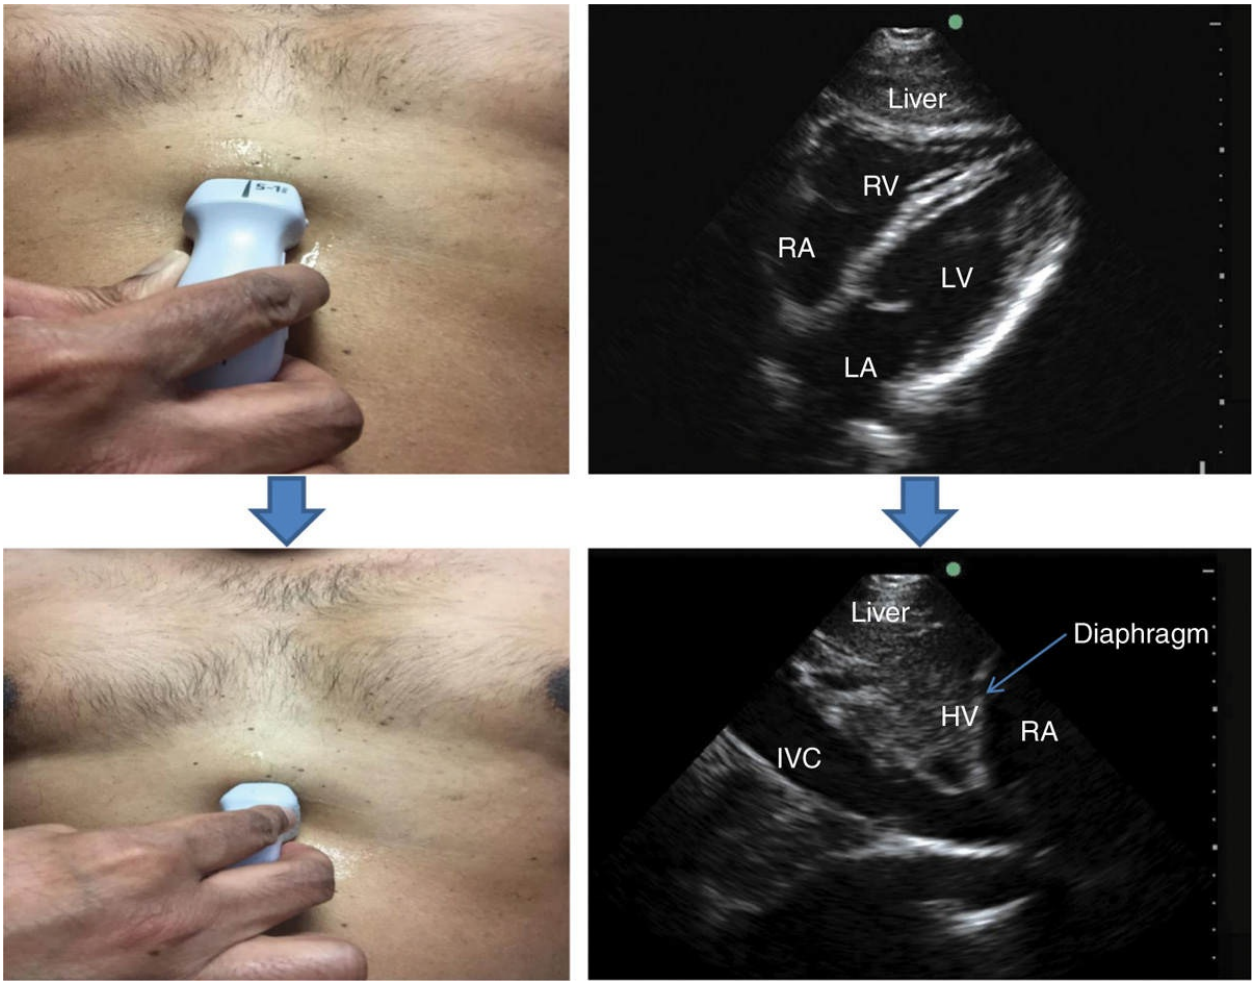

FIGURE 51.17 Technique for IVC image acquisition. HV, hepatic vein; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

TABLE 51.8 Distinguishing IVC from Aorta

	IVC	AORTA
Direction	Goes through the liver	Goes through the liver
Relation to heart	Merges with right atrium	Continues down the heart
Flow	Continuous, changes with respiration	Pulsatile
Walls	Thin-walled, may not be visible	Thick-walled, hyperechoic
Respiratory variations	May be present	No
Collateral vessels	Sub-hepatic veins merge with the IVC	Not visible from this approach

IVC, inferior vena cava.

SPONTANEOUSLY BREATHING PATIENT

In the spontaneously breathing patient, IVC size and the degree of collapse correlate to CVP. An IVC >2 cm in diameter, with inspiratory collapse <50% approximates a CVP of 15 cm H_2O. When the IVC is narrow (<1.5 cm) and collapses a large amount (>50%), the CVP will be low and a hypovolemic (dehydration, hemorrhage) or distributive (sepsis, anaphylaxis) cause of shock is likely (**Table 51.9**).[42] When the IVC is dilated (>3 cm) and non-collapsing, it usually indicates volume unresponsiveness unless the patient has right heart strain. On the other hand, when the IVC is extremely small or a "virtual IVC," it likely indicates that the patient is fluid depleted (**Table 51.10**).

TABLE 51.9 IVC Size, Collapsibility, and Estimation of CVP in Spontaneously Breathing Patients

IVC DIAMETER (cm)	INSPIRATORY COLLAPSE (%)	CVP (mm Hg)
Normal: <2.1	>50	0–5 (mean 3)
IVC findings other	±	5–10 (mean 8)
High: >2.1	<50	10–20 (mean 15)

CVP, central venous pressure; IVC, inferior vena cava.

TABLE 51.10 IVC Variability and Fluid Responsiveness in Critically Ill Patients

EVALUATING FLUID STATUS VIA INFERIOR VENA CAVA SIZE AND VARIABILITY
Fluid responsiveness: clinically relevant increase in cardiac output (>15%) after a volume challenge

Spontaneously breathing patients
• Measure IVC size 2–3 cm from the right atrium using M-mode:
• Static:
  • <1 cm → likely volume depleted
  • >3 cm → sufficient volume status

Patients on mechanical ventilation (criteria) • On mechanical ventilation • Tidal volume >8 mL/kg ideal body weight • Passive on ventilator support (no spontaneous breaths) • Normal sinus rhythm
Patient is fluid responsive if: • (Maximum diameter–minimum diameter)/minimum diameter >18% OR

- (Maximum diameter–minimum diameter)/average diameter >12%

IVC, inferior vena cava.

MECHANICALLY VENTILATED PATIENT

Studies have shown that dynamic measures of fluid responsiveness (eg, IVC variation) are more reliable than static measures (eg, CVP).[43] During mechanical ventilation of a sedated or paralyzed patient, pleural and juxtacardiac pressures increase during inspiration, causing RA pressures to rise and decreasing filling of the right heart. This causes a reduction in RV stroke volume (SV) and less filling of the left ventricle, thus reducing LV SV several cardiac cycles later. These respiratory changes are exaggerated in the hypovolemic patient and these variations in SV can be used to predict fluid responsiveness.[22] Respiratory variation of the IVC diameter has been shown to accurately predict fluid responsiveness.[17,44] **Tables 51.9** and **51.10** summarize interpretation of IVC size and variation. **Figure 51.18** shows examples of measurement of IVC diameter and respiratory variability using M-mode. **Figure 51.19** show examples of small and dilated IVCs.

FUNDAMENTALS OF ABDOMINAL ULTRASOUND IN CRITICAL ILLNESS

Abdominal USG has several applications in the evaluation of the critically ill patient in the CCU. Intraperitoneal or retroperitoneal bleeding may be the etiology of hemorrhagic shock in a patient who recently underwent a cardiac catheterization, an intra-aortic balloon pump placement, or an intravascular cooling catheter placement. Not uncommonly, patients get subjected to invasive procedures involving femoral venous or arterial sheath placement and are at risk for hemorrhage both during insertion and after removal. In addition, patients in the CCU are frequently on dual antiplatelet agents and anticoagulation, and are at high risk for intra-abdominal bleeding.

FOCUSED ASSESSMENT WITH SONOGRAPHY IN TRAUMA

EXAMINATION

The FAST examination has been demonstrated to have 90% sensitivity in the detection of intra-peritoneal free fluid.[12] An approximate volume of at least 200 mL of free fluid is required for the test to have high sensitivity. In other words, a smaller volume of free blood may not be demonstrated on initial FAST examination; therefore, repeat testing may be warranted.[7]

A curvilinear transducer or, alternatively, a low-frequency phased array transducer is used for the FAST examination. The duration of the examination averages <3 minutes and is best performed in the supine position. These windows used serve to conduct the sound wave to the three most dependent areas of the peritoneal cavity in the supine patient as well as to the costophrenic angles bilaterally. The fourth view provides a view of the heart and pericardium, typically obtained from the subxiphoid region. The order of obtaining these views is not as important as systematically evaluating each quadrant for pathology.

For the right-sided evaluation, the probe is placed in the right mid-axillary line at the level of the xiphoid process in the longitudinal view (probe marker pointing cephalad and slightly posterior). This obtains a coronal view of the right hemidiaphragm, liver, and kidney. Morrison's pouch or the hepatorenal space is a site where free fluid can be detected very early (**Figure 51.20A**). Scan above the diaphragm to evaluate for a pleural fluid collection as well. For the left-sided evaluation**,** the probe is placed in the posterior axillary line at the level of the xiphoid process, in the longitudinal view. The left hemidiaphragm, spleen, kidney, and splenorenal space can all be identified from this view. The suprapubic region should be scanned for free fluid in the pelvis by placing the transducer in the midline of the pubic symphysis and tilting down (**Figure 51.20B**). A transverse (probe marker pointing to patient's right) and longitudinal view (probe marker facing cephalad) should be obtained to assess for free fluid in the pelvis. An SC echocardiographic view should be obtained to evaluate for pericardial fluid. The extended FAST examination also includes an examination of the anterior lung zone to rule out pneumothorax (**Table 51.7**). **Figure 51.21A** and **B** shows examples of hemoperitoneum where blood is seen as layering with increasing echogenicity, and echogenic material in the retroperitoneum (hematoma). USG does not have high sensitivity to detect retroperitoneal bleeding; hence, a computed tomography of the abdomen should be performed.

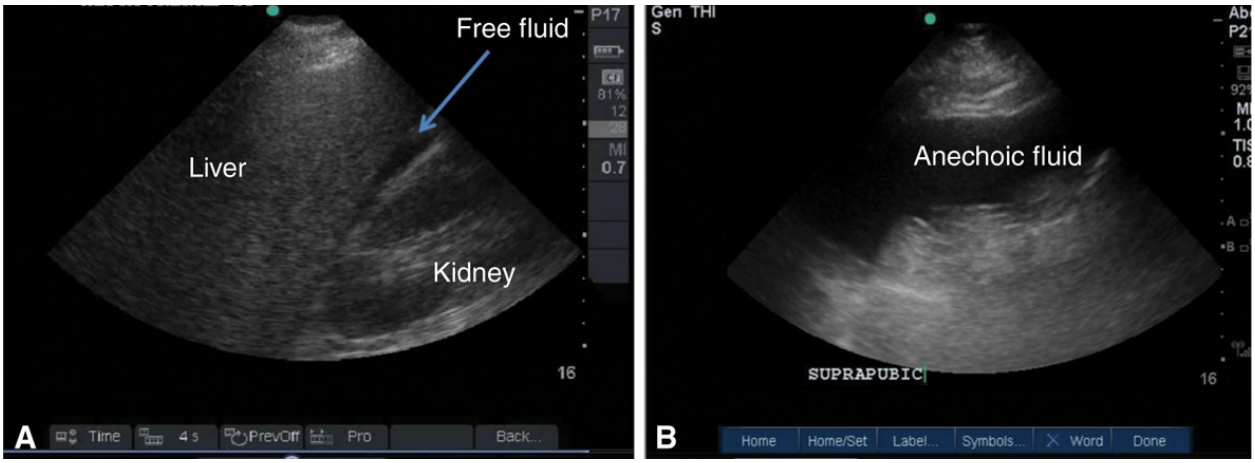

FIGURE 51.20 A, Early ascites—fluid in hepatorenal recess. B, Ascites—simple anechoic fluid in pelvis.

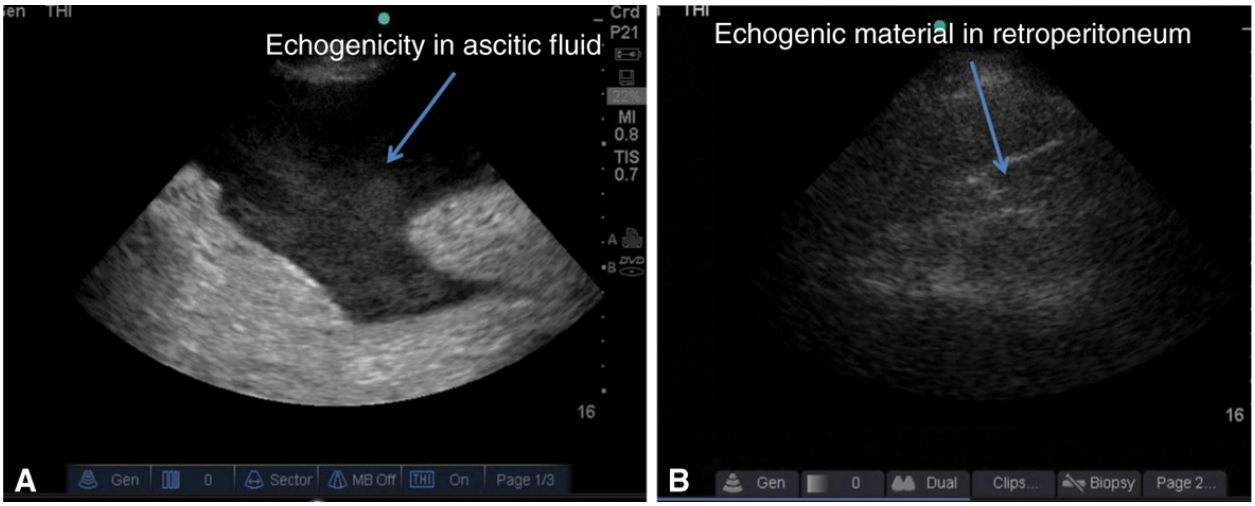

FIGURE 51.21 A, Hemoperitoneum. B, Retroperitoneal hematoma.

ABDOMINAL AORTIC ULTRASONOGRAPHY

Aortic sonography allows for detection of aortic syndromes such as thrombosis, dissection, or rupture. Abdominal USG serves as a rapid noninvasive test that provides important clinical information without the need for radiation or intravenous contrast. Conventionally, an abdominal aortic aneurysm (AAA) is diagnosed when the diameter of the aorta exceeds 4 cm. The risk of rupture at this level is <4% within a year, but it exponentially increases for AAA of larger diameter (>5 cm). The presence or absence of AAA can be evaluated with POCUS with high sensitivity and specificity; however, it has poor sensitivity for extraluminal blood. Nevertheless, in one ED study it was shown to improved diagnosis of ruptured AAA in the appropriate clinical setting and resulted in the

correct decision to perform surgery.[45]

Sonographic visualization of the abdominal aorta is achieved through a transabdominal approach. The proximal aorta can be visualized with a curvilinear transducer. Ideal conditions for scanning are a thin body habitus and a non–gas-filled transverse colon. Scanning of the aorta is done between the xiphoid process and the umbilicus, because these two areas correspond to the 12th thoracic and 4th lumbar vertebral bodies where the aorta enters the abdominal cavity and bifurcates to the iliac arteries. This area below the diaphragm within a distance of 1 cm is where the aorta gives rise to its three major branches: the celiac trunk (immediately below the diaphragm) giving rise to the common hepatic artery and splenic artery (called *seagull sign*), the superior mesenteric artery, and the renal arteries. The majority (>90%) of all aortic aneurysms occur distal to the point of the renal arteries. **Figure 51.22** shows examples of the appearance of the aorta at different branch points in the abdominal aorta.

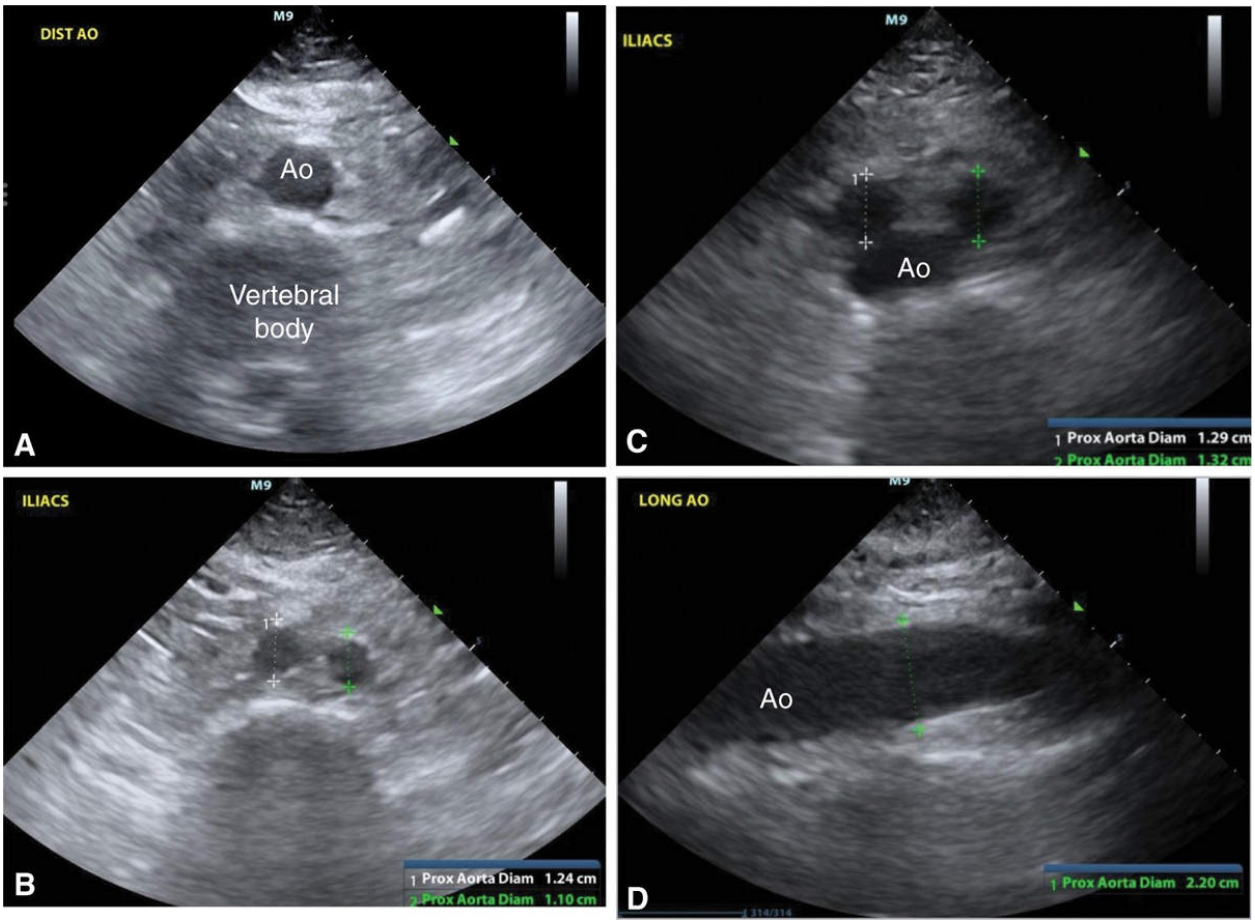

FIGURE 51.22 A, Distal aorta. B, Aorta bifurcating in iliacs. C, Aorta at the level of bifurcation to the common iliac arteries. D, Proximal aorta; longitudinal view. Ao, aorta.

ASCITES

Bedside USG is an easy way to assess for ascites in the patient with cirrhosis or right heart failure. US also facilitate paracentesis by assisting in selection of the best pocket for sampling and by avoiding nearby structures such as bowel and vasculature. US guidance has shown to lead to successful paracentesis with up to a 95% success rate in one study as compared to traditional methods (61% success rate).[46] Similarly, simulation-based training on US guidance using a paracentesis trainer has been shown to improve procedural competence of medical residents.[47]

KIDNEY AND BLADDER

In the patient with acute renal failure or abdominal pain in the CCU, bedside POCUS can serve to quickly eliminate a post-obstructive etiology. The normal kidney has a hyperechoic medulla and a relatively hypoechoic cortex. With increasing obstruction, the collecting system will become dilated and extend to the major and minor calyces and eventually thin the cortex of the kidney. Fluid is anechoic; so if the center of the kidney becomes dilated with anechoic fluid, suspect hydronephrosis. Similarly, in a post-obstructive state, one can visualize a dilated, fluid-filled (anechoic) bladder (**Figure 51.23A** and **B).** It is not uncommon to see a Foley balloon in a dilated anechoic bladder, indicating the catheter itself is obstructed.

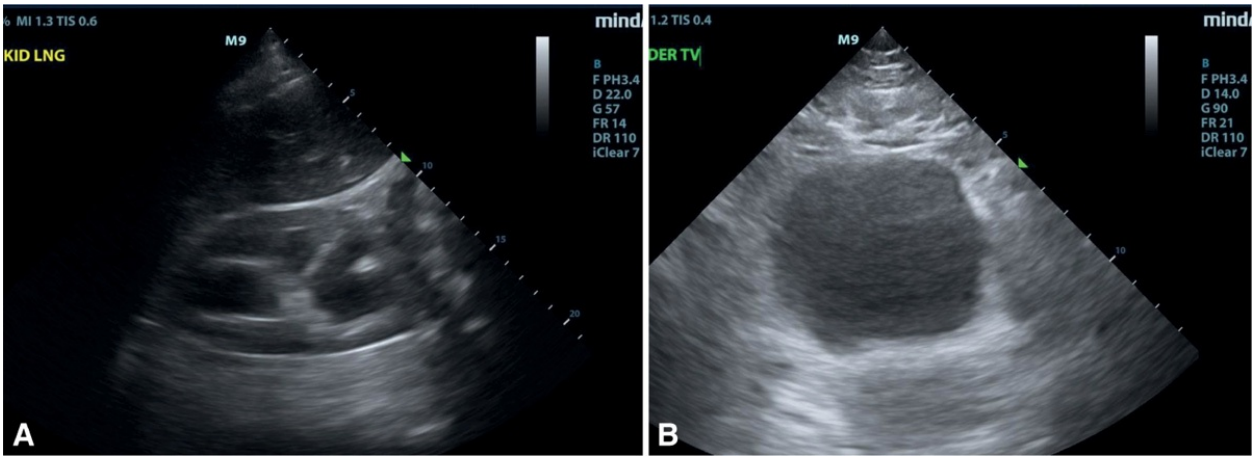

FIGURE 51.23 A, Hydronephrosis. B, Full bladder.

Using a low-frequency phased array or curvilinear probe, obtain transverse

and longitudinal views of the kidneys and bladder. The landmarks for scanning are the same as those for the FAST examination, described earlier. Fan the probe anteriorly and posteriorly through each kidney, assessing for any dilation of the collecting system. Color Doppler can be used to ensure that an anechoic duct is not a blood vessel. Rotate the probe 90° counter clockwise and fan the probe superior to inferior to scan through the entire kidney. Place the transducer over the pubic symphysis and evaluate the bladder in the transverse and longitudinal views.[48]

DIAGNOSTIC VASCULAR ULTRASOUND

DEEP VENOUS THROMBOSIS

Critically ill patients are at higher risk for development of venous thromboembolism due to risk factors such as immobility, indwelling central venous catheters, cardiac failure, dehydration, and inflammatory states. The examination for lower extremity DVT is performed with a high-frequency linear transducer. US evaluation of venous thrombosis consists of verifying vein patency or the lack thereof. The gold standard for venous patency is the ability of a vein to collapse completely under pressure, with the lumen disappearing entirely under direct visualization with US. The diagnosis is confirmed when echogenic thrombus is observed in the vascular lumen or when the vein is not completely collapsible during compression.

To allow for better visualization of the vessels, the patient is supine, with the leg externally rotated and with the knee slightly bent. Once the common femoral vein (CFV) is identified, compressions should begin above the inguinal ligament at the proximal portion of the external iliac vein. Downward pressure should be applied to the transducer and the vein should collapse completely. The operator should then compress every 1 to 2 cm while moving distally along the CFV, the greater saphenous vein, over the lateral perforator-CFV junction until the CFV is seen branching into the superficial and deep branches (**Figure 51.24**). The examination then moves to the popliteal region. The knee is flexed 45 degrees and externally rotated, with the transducer placed transversely over the mid-fossa. The popliteal vein is identified overlying the artery. Even minimal pressure can compress the popliteal vein. Sequential compression at approximately 1-cm intervals should occur while moving distally to the trifurcation of the popliteal vein. Color Doppler and pulse-wave Doppler give

the traditional venous US examination its name, “duplex.” Studies have shown that using compression US alone, nonradiologists such as EM physicians and intensivists can accurately diagnose DVT with 95% accuracy and reducing the time to diagnosis.[18,19]

PROCEDURAL GUIDANCE FOR VASCULAR ACCESS

This is one of the highest utilization indications for POCUS in the CCU. The topic is discussed in detail with regard to both CVC placement and arterial line placement in Chapter 48 of this volume from the same authors.

LIMITATIONS OF POINT-OF-CARE ULTRASONOGRAPHY

USG has developed as an irreplaceable tool in for the critical care physician in the management of a critically ill patient. Patient factors such as obesity, body habitus, rib shadows, artifacts, the presence of edema, subcutaneous emphysema, or suboptimal patient position can be a limitation. It is also operator dependent, so adequate training and a proper certification process is required.

EDUCATION IN POINT-OF-CARE ULTRASONOGRAPHY

Studies have shown that bedside sonography can be taught to both early and advanced learners. With the popularity of POCUS, many medical schools are now adopting US education into undergraduate medication education, as early as in first year anatomy courses to fourth year electives.[49,50] Basic cardiac echocardiography, which may seem intimidating to the novice, can be easily learned with proper training and supervision. Resident physicians, after 12 hours of didactic teaching and image interpretation, were able to accurately identify LV failure, RV dilatation, pericardial effusion, and IVC dilatation.[38] Similarly, intensivists were able to successfully obtain and interpret images after 10 1-hour tutorial sessions by cardiologists.[36] Large 3-day hands-on educational courses led by Dr Paul Mayo and the American College of Chest Physicians, in which the authors have been course faculty (GN, JM), have trained thousands of physicians (eg, pulmonologists, intensivists, cardiologists, anesthesiologists, hospitalists, critical care fellows, advance care practitioners, etc) since its inception in 2007. This multiday format has been shown to be an effective way to train a large group of clinicians in POCUS with excellent performance in image acquisition, interpretation, and subject knowledge.[51]

CONCLUSIONS

POCUS has evolved into an invaluable tool in facilitating the diagnosis and treatment of acutely ill patients. With the advent of portable US machines, POCUS has revolutionized the way that patients are managed and has drastically improved the safety of procedures. Goal-directed USG readily answers clinical questions in the management of critically ill patients in the CCU with conditions such as shock, acute respiratory failure, and multiorgan failure. With proper training and supervision, POCUS is easily learned both by early and advanced learners. Challenges that remain in further dissemination of the use of POCUS include appropriate training, credentialing, and reimbursement. As medical societies make inroads into these hurdles, POCUS will continue to diffuse into medical education and daily practice.

End-of-Life Care in the CCU

Patients in the cardiac care unit undergo intensive and heroic treatments intended to save and prolong life. The cardiac care unit has evolved over the past several decades such that the current CCU provides care to patients with advanced age and increasing cardiac and noncardiovascular critical illness, including sepsis, acute renal injury, and acute respiratory failure.[1] Patients in the CCU are frequently managed with life support measures including mechanical ventilation, cardiovascular support, and renal replacement therapy. Thus, the CCU clinician is faced with critically ill patients on life support measures, some of whom may be at the end of life. The major cardiology societies encourage provision of supportive and palliative care in cardiac patients at the end of life. The goal of this chapter is to provide practical information about end-of-life decision making and the process of withdrawal of life-sustaining treatments in the CCU.

Decision making about end-of-life care in the CCU is challenging for several reasons. Many patients do not have an advance directive. Even in cardiac patients with advanced interventions, including implantable electronic devices, discussions about advance directives are uncommon.[2] Clinicians face difficulty in prognostication for critically ill patients in general. In patients with heart failure, variability in the course makes identifying the end of life especially complicated. The guidelines of the Heart Failure Society of America and the American College of Cardiology/American Heart Association promote consideration of end-of-life care in patients with advanced heart failure,

including decisions about inactivation of implantable defibrillators.[3,4] Aggressive and invasive treatments are often initiated for patients in the CCU in the hope of restoring life, and this initial aggressive support is construed by the family as the optimistic expectation that the patient will recover. This is especially true for patients following cardiac arrest, in whom therapeutic hypothermia is initiated. The hope from this treatment must be tempered with the reality that the majority of patients still suffer neurologic injury. The need for sedation and the post-arrest state require time for neurologic prognostication. During this time, communication with the family about uncertain prognosis and the possibility of anoxic encephalopathy is important. A multidisciplinary team approach must include the neurologist for prognostication and decision making.

GOALS OF CARE

As clinicians, our goals for patients are to save lives, return to health or an acceptable existence, alleviate suffering, and provide the dying with a peaceful death. The transition of the goal from curative treatment to comfort care is one of the most challenging aspects of critical care. It is possible to combine a palliative approach even when life-sustaining treatments are in place, so that clinicians may still focus on alleviation of symptoms and overall goals of care.

The goals of palliative care can be applied to many patients, even those receiving aggressive interventions: control of symptoms such as pain, dyspnea, and discomfort; effective communication about appropriate goals of treatment and concordance of treatment with patient preferences; and enhancing quality of life. The role of palliative care in the CCU includes providing guidance and support, so that care will be consistent with the patient's values.[5]

Effective communication is the means to achieving patient preferences in end-of-life care. The landmark SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) revealed that the wishes of dying patients were often unexplored by physicians and those patients received potentially undesired treatments at the end of life.[6] Clinicians must also recognize that their own wishes may not coincide with those of their patients, because physicians and nurses may be less likely to desire life support than patients and families. Decision making that is shared between the patient/family and the clinicians is the model process supported by American and European critical care societies.[7,8] The evolution of critical care decision making from a

paternalistic model to the current standard of shared decision making is predicated on respect for patient autonomy and values. In the cardiac care unit, the majority of patients may be unable to participate in decisions owing to the severe illness, need for life support, and sedative medications. Therefore, the legally recognized appropriate surrogate often assumes the decision-making role to represent the patient's values and preferences. The family-centered approach respects the patient's values, and also acknowledges that many patients would want their family members to participate in decision making.

ETHICAL PRINCIPLES IN END-OF-LIFE DECISION MAKING

Patient *autonomy* is a foundation ethical principle for patient care. U.S. Supreme Court cases such as the Quinlan and Cruzan cases established that patients have a right to determine which medical treatments to accept or refuse, even when refusal leads to death.[9] Often, in the critical care unit, the patient is incapable of participating in the decision making. However, the patient may have left guidance in the form of an advance directive, such as a proxy, living will, or oral statements articulating his or her wishes concerning life support at the end of life. The patient may have assigned a health care proxy to make decisions if he or she becomes unable to do so. If no proxy has been assigned, the surrogate decision maker is chosen from the patient's close relatives or friends based on a priority order. In this way, the patient's values and preferences can still guide the decision-making process when decision-making capacity is lost.

The principle of *beneficence* maintains that physicians will work to provide the best course of treatment for the patient. Physicians see the goal of preserving life, but beneficence also means the support of the patient's informed decision even when refusal of therapy may lead to death. *Nonmaleficence* means not inflicting harm. This principle instructs the physician to weigh potential harms of treatments against potential benefits and not provide interventions that will not benefit the patient.

Conflict may arise when the patient, family, and clinician disagree about the appropriateness of an intervention. Nonabandonment is an important principle that obliges the physician to help the family understand the situation and support the family's decision. Physicians are not obligated to disregard their own beliefs and so, if the physician disagrees with the patient and family decision, the

principle of nonabandonment requires the physician to try to transfer care to another physician who will pursue the desired plan of care. The hospital administration or ethics committee may be involved to assist in resolution of these complicated situations.

ADVANCE DIRECTIVES

As stated, patient autonomy is the strongest ethical principle driving medical decision making, so that patients have the right to make decisions for themselves; and when conscious capacity is lost, this right remains protected. Advance directives, such as the health care proxy and living will, provide for decision making based on patient values and preferences when the patient loses decision-making capacity. Respect for patient autonomy underlies the federal Patient Self-Determination Act of 1990, which requires hospital personnel to ask patients whether they have an advance directive and inform patients of their right to accept or refuse medical treatments and to create an advance directive.[10] A Do Not Resuscitate (DNR) order is one kind of advance directive that addresses interventions in the setting of a cardiopulmonary arrest. A DNR order means that if the patient suffers a cardiopulmonary arrest, the interventions of intubation, cardiopulmonary resuscitation (CPR), and advanced cardiac life support will be withheld. A DNR order is often issued for patients at the end of life, and in patients with chronic or terminal illnesses. In some patients with DNR orders, the patient may be expected to benefit from and will receive intensive care interventions, but CPR will be withheld in the event of cardiac arrest. A DNR order is often a first step in the family's decision-making process.

COMMUNICATION

Achieving appropriate decision making is based on effective communication, family comprehension of the information, and sharing of the patient's values. It should not be assumed that families grasp the severity of their relative's illness or the ramifications of life support measures. Family understanding of critical illness and intensive care treatments has been shown to be inadequate. Knowledge about CPR is especially poor, with a prevalent unrealistic expectation of survival among patients with serious medical illness and their

families.[11] Accordingly, assessing family members' understanding of the patient condition is vital and will be part of the communication strategy in a family meeting.

FAMILY MEETING

Communication with the family occurs in several venues: bedside discussions, conversations with the nurse, telephone updates, as well as a formal family meeting. The contributions of the entire team are invaluable. The bedside nurse usually has important insight into the patient's condition and the family understanding of the patient's condition. A family meeting is an opportunity to present and review the situation and treatments, provide information on short-term and long-term prognoses, answer questions, explore patient and family values and wishes, and assess the family's understanding of the patient's condition. Investigators have examined family meetings and found missed opportunities in time allotted for family speech, articulating a prognosis, emphasizing the process of surrogate decision making, supporting the decision, and assuring nonabandonment. Family satisfaction with the meeting was associated with increased time for family speech; presumably this is their opportunity to make the patient and his values known.[12] Prognostication is important for family members, but the meetings often lacked discussion of prognosis for survival. Although families may doubt the accuracy of the prognosis given by physicians, that prognostic information is desired and important in the family's understanding and deliberation.[13]

Here, we can make some points about the family meeting.

- The medical team should prepare for the family meeting. The clinicians should discuss the goals of the family meeting, review the patient's condition, and achieve consensus concerning prognosis and treatments to be administered. The team should be aware of specific issues or problems related to the family situation. The bedside nurse may have great insight into the patient's condition and family situation and should be included in the meeting. It may be helpful to include team members such as the neurologist, and primary cardiologist, if applicable.
- The physician will lead the discussion in a private, quiet place. All participants should be introduced. The family should be asked their understanding of the condition and treatments. The physician should provide information about the illness, treatments including life support measures, and prognosis in a

meaningful and compassionate manner, avoiding excessive medical jargon. The clinicians should explain surrogate and shared decision making.

- The clinicians should allow time for the family to speak about the patient's values and preferences, to demonstrate their understanding of the situation, and to ask questions.
- The physician leader should judge how the family has understood the information and whether they are ready to discuss goals and end-of-life decisions. For some meetings, it is sufficient to provide the medical information and it may be better to discuss end-of-life decisions in a subsequent meeting.
- Often, the family members report that they never discussed end of life with the patient. Some ways to elucidate patient wishes include asking whether they ever had a conversation about the patient's own wishes, in the setting of another family member's illness or even related to a topic in the news; how the patient lived life, what it may mean to be dependent in all aspects of care; and what they think the patient might say about life support measures if he or she were in this meeting. The leader may ask the family what they believe is a meaningful and acceptable quality of life for the patient.
- If withdrawal of life support is discussed, the clinicians should emphasize that this does not mean withdrawal of *care* and that supportive and comfort care will be provided.
- The staff should offer support for the decision of the family, whether the decision is to withdraw or not withdraw life support. The team should assure the family that the patient will not be abandoned and all measures will be taken to prevent suffering.
- The family cannot be rushed to make a decision. The clinicians should understand that the family may not yet accept the expressed prognosis.
- The meeting may conclude with a plan to reconvene in the following days to review the situation.

It is important that clinicians do not relinquish medical decisions to the family. The physicians must give information, prognosis, and advice on how to proceed. The family provides information about the values and preferences of the patient. The transition from aggressive CCU care to comfort care is often made quickly by clinicians who have the benefit of medical knowledge of disease and prognosis, but families may need time for this adjustment and should not be rushed to make a decision. Planning a follow-up conversation within a specified

time period allows the clinicians to further assess the patient's trajectory and permits the family time to grasp the information and condition. Families need ongoing contact and communication. Families need assurances that all efforts will be made to maintain comfort. Involving the palliative care service may be beneficial in optimizing the medical and nursing treatments for palliation.

Cultural values and beliefs may exert a profound influence on decision making. Domains affecting decisions include attitudes about truth telling concerning illness and prognosis, religious and spiritual beliefs, historical and political context, perception of illness, and the decision-making process in the group. The not uncommon clinician impression that the family is not accepting a dire diagnosis and prognosis may therefore at times be explained by cultural factors.[14] Recognizing the influence of cultural factors may lead to enhanced understanding and compassionate and effective communication.

Conflicts may develop between family and physicians, within families, as well as among the health care team. Given physicians' inability to be certain of the outcome, the family may be reluctant to accept a poor prognosis. The CCU team may involve other disciplines such as the patient's primary care physician, other involved subspecialties, palliative care, pastoral care, and social work. For conflicts that reveal marked differences in desires among the patient, family, and physicians, the hospital ethics committee may be involved. Ethics committee consultations may be beneficial in resolving conflicts, establishing desired care, and limiting non-beneficial life support measures. In addition, legal affairs involvement may be required in rare, complicated situations.

WITHDRAWAL OF LIFE SUPPORT

Ethical principles described previously support the decision to withdraw or withhold life-sustaining treatments. The U.S. Supreme Court cases confirmed that patients or surrogates can refuse life-sustaining therapies.[9] The decision to withdraw life support is based on patient values and preferences as articulated by the patient or his proxy or surrogate. Withdrawal of life support would be allowing the patient to die from the underlying disease. Withholding and withdrawing life support are considered equivalent, although clinicians may be more uncomfortable with the withdrawal of treatment.

Decisions to withhold or withdraw life support are common among critically ill patients, and frequently precede intensive care unit (ICU) deaths. All forms of

life support may be withheld or withdrawn, including mechanical ventilation, vasopressors, antibiotics, blood product transfusions, hydration, and nutrition. Sometimes all treatments are discontinued at once, sometimes in a stepwise manner. With the exception of the withdrawal of mechanical ventilation, withdrawing these other treatments does not often lead to an evident clinical change. The decision to withdraw mechanical ventilation may be a more difficult decision for families as well as for clinicians. With the assurance that withdrawal would be the patient's wish and that medications will be provided for comfort, withdrawal of mechanical ventilation is often desired at the end of life.

At the time of withdrawal of life support, there should be written documentation of the prognosis, discussion, and decision making with the patient/surrogate, goals of care and plan, including orders to discontinue specific therapies. In particular, an order for removal of mechanical ventilation or deactivation of an implantable device should be entered.

The process of withdrawal of life support is delineated in **Table 52.1**. This process involves the actual withdrawal of life support measures as well as the palliative medications that may be required.

TABLE 52.1 Withdrawal of Life Support: Process of Withdrawal of Mechanical Ventilation in the Cardiac Care Unit

Ask if family wishes to be present for extubation. Explain the process. May request chaplain presence, palliative care, and hospice services
Do Not Resuscitate Order is placed. Documentation in the medical record should reflect the discussions and decision to withdraw life support
If patient has an ICD, discuss inactivation of device
Discontinue previous orders for routine vital signs, routine laboratory tests, and radiographs
Discontinue enteral tube feedings several hours before extubation
Discontinue nonessential medications Continue only palliative medications and necessary medications (such as anticonvulsants)
Change ventilator setting to spontaneous breathing mode (such as pressure support 5 cm H_2O) to assess palliative medication needs. Adjust palliative medications to goal of comfort and unlabored breathing. Consider opiates for dyspnea, benzodiazepines for seizures, anticholinergics for secretions, acetaminophen for fever, and antipsychotic medications for delirium.
Optimize the environment: • Remove unnecessary equipment, provide space for family • Discontinue monitor alarms • Discontinue inappropriate television

Extubate patient with respiratory therapist assistance
Room air or 2–4 L of oxygen by nasal cannula if this improves comfort

ICD, implantable cardioverter defibrillator.

ORGAN DONATION

A minority of deaths in the CCU is determined by brain death criteria. Most deaths in CCU are expected and are due to progression of the cardiac and other organ failures.

Patients in the CCU may be candidates for organ donation based on brain death criteria or donation after cardiac death.[15] Institutions have policies for determination of brain death, organ donation following brain death, and organ donation after cardiac death. Patients who are admitted following cardiac arrest who suffered anoxic encephalopathy may progress to brain death. Patients should be referred to the organ procurement organization if they meet specific triggers. The actual brain death determination is performed by a qualified attending physician. In patients who have undergone therapeutic hypothermia following cardiac arrest, additional vigilance is recommended in initiating the brain death determination.

For patients who have a nonrecoverable neurologic injury but not brain death, the family may make the decision to withdraw life support. These patients may be candidates for organ donation following cardiac death. Institutional policies address the referral, process, and management of patients. The cardiac team will generally involve specialists including intensivists and neurologists to confirm the neurologic prognosis. Only after the decision to withdraw life support will the organ donor network approach the family concerning organ donation.

WITHDRAWAL OF MECHANICAL VENTILATION

Communication with the family about the process of withdrawing ventilation and what to expect is essential. Although it is difficult to be certain, the physician should provide an estimation of duration of survival following extubation. The family may want to be present and may desire pastoral care to be present for support. All nonbeneficial treatments, including vasoactive medications, should be discontinued, and alarms should be silenced. Palliative medications should be adjusted before extubation while the patient is on a spontaneous breathing mode. The endotracheal tube is removed and the family

should remain with the patient for as long as desired.

WITHDRAWAL OF CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICE THERAPY

Implantable defibrillation and pacing devices provide life support that can be declined or withdrawn based on patient values and preferences.[16] The dying patient or surrogate may request inactivation, if the device effectiveness is outweighed by burdens experienced by the patient: prolonging the dying process, preventing a natural death, and suffering the loss of dignity and quality of life. The Heart Rhythm Society published a consensus statement on the management of cardiovascular implantable electronic devices in patients nearing the end of life.[16] This document sets out the ethical principles, concerns, and practical management of withdrawal of cardiovascular implantable electronic device therapy. Deactivation may prevent uncomfortable shocks in dying patients. In pacemaker-dependent patients, the device sustains life and may, like other life-sustaining treatments such as mechanical ventilation, be discontinued on the basis of the patient's right to decline therapy. If cardiac resynchronization is aiding cardiac function, then inactivation may lead to increased symptom burden. So each therapy must be addressed in light of the overall goals. The Heart Rhythm Society consensus statement offers practical advice for communication, assessing patient understanding of the device, and utilizing the overall care goals to guide management of the cardiac device. The patient's cardiologist and electrophysiologist should be involved in these discussions about deactivation.

NONINVASIVE VENTILATION

Many physicians use noninvasive ventilation for respiratory failure near the end of life.[17] Its use should be guided by the goals of care. A patient who declines mechanical ventilation may receive noninvasive ventilation with the goal of survival: in patients with heart failure, noninvasive ventilation may successfully prevent intubation and the patient may survive the episode. In patients at the end of life, noninvasive ventilation has been used for palliation of dyspnea as well as a means to give more time for family to arrive and communicate with the patient. However, if noninvasive ventilation becomes uncomfortable or burdensome, it should be removed. Noninvasive ventilation should be addressed with the patient and family as a life support measure that can be continued or

discontinued based on the goals of care. Use of high-flow nasal cannula may be a good choice for patients who require O_2 support for comfort and have high ventilatory requirements.

SYMPTOM MANAGEMENT

Most critically ill patients experience pain and discomfort related to procedures and nursing care in the ICU. The possibility of pain in patients unable to report their symptoms is a great concern for families and clinicians. Dyspnea is a common symptom in critically ill patients. When withdrawal of mechanical ventilation is being discussed, a frequent concern of the family is that the patient will experience respiratory distress. The clinicians should assess the patient with input from the bedside nurse and family.

Management is individualized, based on the patient's level of consciousness, underlying disease, and reason for respiratory failure. The patient's prior use of and response to opiates is important in dosing this medication. Route of administration and dosages must be adjusted, often with the assistance of the critical care pharmacist and palliative care specialist. **Table 52.2** shows common medications used during withdrawal of life support in the critical care unit. The intravenous route of administration is often used for these patients; however, enteral, sublingual, subcutaneous, rectal, and transdermal routes can also be used for medications. **Table 52.2 s**hows initial doses. Patients with severe dyspnea or pain at the end of life may require much higher dosages and infusion rates. It is important to provide these medications, even at high rates, for the goal of comfort. Goals are relief of dyspnea, resolution of tachypnea and tachycardia, and lack of indication of pain by verbal response or clinical appearance.

TABLE 52.2 Withdrawal of Mechanical Ventilation: Initiation of Palliative Medications

PAIN OR DYSPNEA[a]	
Morphine 1–4 mg intravenous every hour as needed Continuous infusion start at 2 mg/h	If requiring continued hourly dosing, change to continuous infusion For continued symptoms, administer bolus doses of 2x hourly rate, increase infusion (range: 2–30 mg/h)
Hydromorphone 0.5–1 mg intravenous every 3 h as needed	If requiring continued dosing, change to standing or continuous infusion For continued symptoms, increase infusion to 3 mg/h

Continuous infusion 0.5–1 mg/h
ANXIETY OR AGITATION
Lorazepam 0.5–1 mg intravenous every hour as needed Continuous infusion start at 2 mg/h Haloperidol 0.5–1 mg intravenous every 4 h as needed
TERMINAL SECRETIONS
Scopolamine patch 1.5–3 mg every 3 d Glycopyrrolate 0.2 mg subcutaneously every 4–6 h

[a]If patient is comfortable on stable doses of opioid, continue current dose when starting withdrawal of ventilation. If the patient is not already receiving these medications, consider starting before extubation.

Opioid analgesia is a basic medication class for patients at the end of life. The desired effects are analgesia and sedation, but there is also a respiratory depressant effect on the medullary respiratory center. Opioid medications are useful in management of the symptoms and signs of respiratory distress. Morphine is often chosen for management of pain or dyspnea. In patients with renal failure, there may be accumulation of active metabolite. In these patients, hydromorphone is often used. It is important to remember that hydromorphone is 5 to 10 times as potent as morphine. These medications are given at the dosages necessary to relieve symptoms.

The concern about hastening a patient's death by administering opiate analgesia is overridden by the intention of providing comfort and relieving suffering. Studies have demonstrated that the use of palliative medications at the end of life does not hasten death.[18,19] In fact, adequate pain management may mitigate the systemic effects of severe pain. In addition to respiratory depression, attention must be directed to several effects of opioid analgesia: inhibition of peristalsis with constipation, nausea and vomiting; and myoclonus and seizures.

Benzodiazepine medications provide sedation and anxiolysis. These medications do not provide analgesia but may be useful in combination with an opioid to prevent the anxiety related to pain. Side effects also include depressed level of consciousness and respiratory depression. Delirium, in the form of either an agitated or a calm state, is a common symptom in dying patients in the ICU. Although haloperidol is the standard medication for the management of delirium, the team should implement nonpharmacologic measures such as removing restraints, reducing activity and noise, and having family members at

the bedside to calm and orient the patient.

AT THE TIME OF DEATH

Notification to the family, optimally in person, using unambiguous language that the patient died is the initial duty. A minority of deaths is determined by brain death criteria and selected patients undergoing withdrawal of life support may be candidates for organ donation following cardiac death. This process requires a specialized protocol for the withdrawal of life support and management in collaboration with the organ donor organization. The staff may assist the family by providing information about the next steps, including autopsy, funeral, and bereavement services.

The critical care unit staff can also benefit from a debriefing about the patient's course, the end-of-life care, and the death. Physicians and nurses have different perspectives on end-of-life decision making, intensity of interventions, symptom management, and the quality of death and dying.[20] The burdens experienced by ICU nursing staff may lead to burnout, moral distress, and post-traumatic stress disorder. Communication to improve collaboration and the ethical climate may improve the environment for clinicians as well as the care of dying patients.

CONCLUSION

Patients and their families should expect excellence in all treatments in the cardiac care unit, including care at the end of life. Patients deserve humanity, compassion, and respect for autonomy. End-of-life care in the cardiac care unit requires expertise on many levels: assessing prognosis, communicating information, understanding patient values and preferences for life support, and implementing a patient's end-of-life decision. The CCU team can utilize the expertise of consultants, including palliative care specialists, in optimizing end-of-life care. Clinicians' management will be rewarded by alleviating a patient's suffering, facilitating a peaceful and dignified death, and providing peace and satisfaction for the patient's family.

Patient and Family Information for: END-OF-LIFE CARE IN THE CCU

The doctors, nurses, and the entire CCU team treat patients with the goal of curing disease, prolonging life, and making the patient better. The team also works to relieve pain and suffering. Even with all the medical care, technology, and life support machines, patients may not get better or survive. Sometimes, the patient has an incurable illness, such as advanced heart disease, which has led to damage to all the vital organs and also led to coma. These patients are in a terminal condition and the use of life support may only postpone death. For patients and families, it is very important to communicate with the cardiac care unit team to understand the illness and outlook (prognosis) and to make decisions so that the patient's wishes and values are respected.

HOW ARE END-OF-LIFE DECISIONS MADE?

Decisions in the cardiac care unit are based on shared decision making between the physicians and the patient and family. Communication is the key to decision making for a critically ill patient. The wishes of the patient are most important. If the patient does not want life-sustaining measures, they can be stopped. This is respect for the patient's autonomy, which means control over his/her own body. The law states that the patient has a right to agree to or refuse treatments, including life support.

The decision to limit or stop life support measures is based on the wishes of the patient, as well as the patient's best interest if the exact wishes are unknown. Often, patients in a critical condition cannot communicate or participate in making decisions and trust their closest relatives to make the decisions. The patient may have prepared for this by appointing a health care proxy to make

medical decisions if the patient is unable to speak. A surrogate is a close relative or friend who will make decisions if a proxy has not been appointed and the patient is unable to make decisions. If the patient has not assigned a proxy, a surrogate is chosen from the patient's close relatives or close friends based on a priority order. Some patients have filled out a proxy or living will; these documents can spell out the care or treatment that the patient wants or does not want in the case of a terminal illness or condition.

Remember that decisions about life support are made on the basis of careful, thorough discussions with doctors, patient, and family/proxy/surrogate. Patients and family members should be sure that the doctors and nurses are aware of wishes concerning the end-of-life care.

FAMILY MEETING

The CCU team will provide information to the patient and family about the patient's condition and treatment. Often, the patient is very ill and unable to understand or participate, and so the physicians will speak with the family and health care proxy. A family meeting is often convened to talk about the patient's condition, treatments, and obtain information about the patient's wishes and values. It is often very difficult to be sure of the patient's outcome (prognosis); however, the physicians should give some information about whether the patient is expected to survive and what the function might be if he/she survives. If one member of the family becomes the contact person for the CCU staff, this will help the communication process.

WHAT IS LIFE SUPPORT?

Life support measures are treatments or procedures that support or replace body functions that are failing. When patients have curable or treatable conditions, life support is temporary until the organ function improves. With advanced illness and advanced age, certain diseases lead to a continued decline in function of the organs and of the entire person. Sometimes, the body never recovers and the patient would not be able to survive without life support.

It is important to understand the benefits and burdens of life support treatments. A treatment may be beneficial if it restores functioning, improves quality of life, and relieves suffering. The same treatment could be a burden if it causes pain, prolongs the dying process, or decreases the quality of life. The

decision about whether a treatment is a benefit or a burden is a personal decision based on the patient's preferences and values. If the patient is able to tell the doctors, his/her decision will be respected. If the patient is unable to express his/her wishes, the doctors will meet with the family and proxy/surrogate to learn the patient's preferences and values.

WHAT ARE LIFE SUPPORT MEASURES?

CPR (Cardiopulmonary Resuscitation) is a set of treatments given when a patient's heart and breathing stop in order to restart the heart and breathing. It involves breathing for the patient using a mask or tube placed into the patient's airway. The team will compress the chest and may apply electric shocks to get the heart beating again.

In certain conditions, CPR can be very effective, for example, if a patient has a sudden heart attack. However, in patients at the late stages of a terminal illness who are at the end of life, CPR is usually not successful. Even if the heart does start beating, often the patient remains in a coma or dies within a short period of time. Making a decision about whether the patient should go through CPR is an important decision. In patients at the end of life, when the heart stops, this would be a natural death. A DNR (Do Not Resuscitate) order means that if the heart stops, CPR will not be done and the patient would die a natural death.

Mechanical ventilation is the use of a *ventilator* to support the breathing function of the lungs. Ventilator and *respirator* both mean the same machine. A tube is inserted through the mouth into the trachea (windpipe) and this tube is connected to a ventilator that gives the breaths to the patient. Patients on a ventilator are not able to speak, sometimes are awake enough to communicate, and often require sedation so that they are not anxious or uncomfortable. Mechanical ventilation may be used for a short period, such as in heart failure or pneumonia, and can also be used for a long time in patients with neurologic disorders, who may still be satisfied with the quality of their life. However, in a dying patient, mechanical ventilation will not improve the condition or the quality of life. In a patient who is dying, being on a respirator may prolong the dying process.

Noninvasive mechanical ventilation is the use of a ventilator machine that is attached to a special face mask. The ventilator will force air through the mask so the patient will feel some pressure of air moving in. Some patients can work well

with the mask and even speak; for others, it is uncomfortable. This is a kind of life support that can be used if helpful; if it becomes uncomfortable and is not beneficial, it can be stopped.

Hemodialysis is used to replace the function of failed kidneys, which will clean the blood of wastes that normally accumulate. Dialysis requires placement of a large catheter and long periods on the dialysis machine. Some patients with kidney failure can live for years while receiving dialysis treatments several times each week. For patients at the end of life, dialysis cannot be expected to restore health.

Artificial nutrition and hydration can be given by a feeding tube placed into the stomach, which replaces normal eating and drinking. Artificial feeding may be necessary in some patients undergoing a prolonged illness until their bodies recover. In patients at the end of life, artificial nutrition and hydration still cannot restore health.

WHAT HAPPENS IF THE DECISION IS MADE TO WITHDRAW LIFE SUPPORT?

The decision to withdraw life support is made after careful discussion of the prognosis and patient preferences and values. All forms of life support can be withdrawn. The doctors may suggest placing an order for no CPR—a DNR order and not administering certain medications.

The mechanical ventilator can be removed, based on patient desires and values. The physician and nurse will assure that the patient is comfortable. The family can be present during this process if they wish.

HOW WILL THE DYING PATIENT BE TREATED?

The goal of the health care team is to provide the desired and beneficial care. In a dying patient, p*ain management and comfort care* will always be provided. Pain and discomfort can be managed by medications and also by working on the environment, such as having family present. Certain medications such as morphine are used to relieve pain and can also make the patient sleepy. All medications and treatments have other effects, so the overall goal of comfort must be a priority. The physicians and nurses will monitor the patient and also

rely on the family to tell the staff whether the patient is comfortable.

There are clinicians who specialize in palliative care who may be consulted to assist the team with care. Patients and families may want the services of pastoral care.

The overall goal is for the cardiac team to work with the patient and his/her family, health care proxy, and surrogate to provide care that is beneficial and desired. Comfort and respect are priorities. It is important that there is communication and understanding in the shared responsibility for decision making and care for each patient.

VI

RISK FACTORS: FROM THE ACUTE SETTING TO CHRONIC MANAGEMENT

Hypertension in the Cardiac Care Unit

The Committee on Public Health Priorities to Reduce and Control Hypertension in the U.S. Population concluded that "the Centers for Disease Control (CDC)'s cardiovascular disease program in general, and the HTN program in particular, are dramatically under-funded relative to the preventable burden of disease."[1] The global burden of hypertension (HTN) is tremendous. HTN is a risk factor for essentially every medical condition that would warrant admission to a hospital's cardiac care unit (CCU); in fact, the CCU is where the most severe forms of the HTN burden can be seen. HTN can be defined as a sustained rise in blood pressure (BP) that increases the risk of cerebral, cardiac, and renal events. In industrialized countries, the risk of becoming hypertensive during a lifetime exceeds 90%. The clinical spectrum of HTN ranges from mild elevations in BP to hypertensive emergencies requiring immediate therapy. Patients may be asymptomatic despite marked elevation in systemic BP, yet the resultant end-organ damage is a major cause of morbidity and mortality; hence the designation of HTN as the "silent killer."

At our institute, we have created a pathway for the management of in-hospital HTN, with a particular focus on the management of HTN in the CCU (**Figure 53.1**).

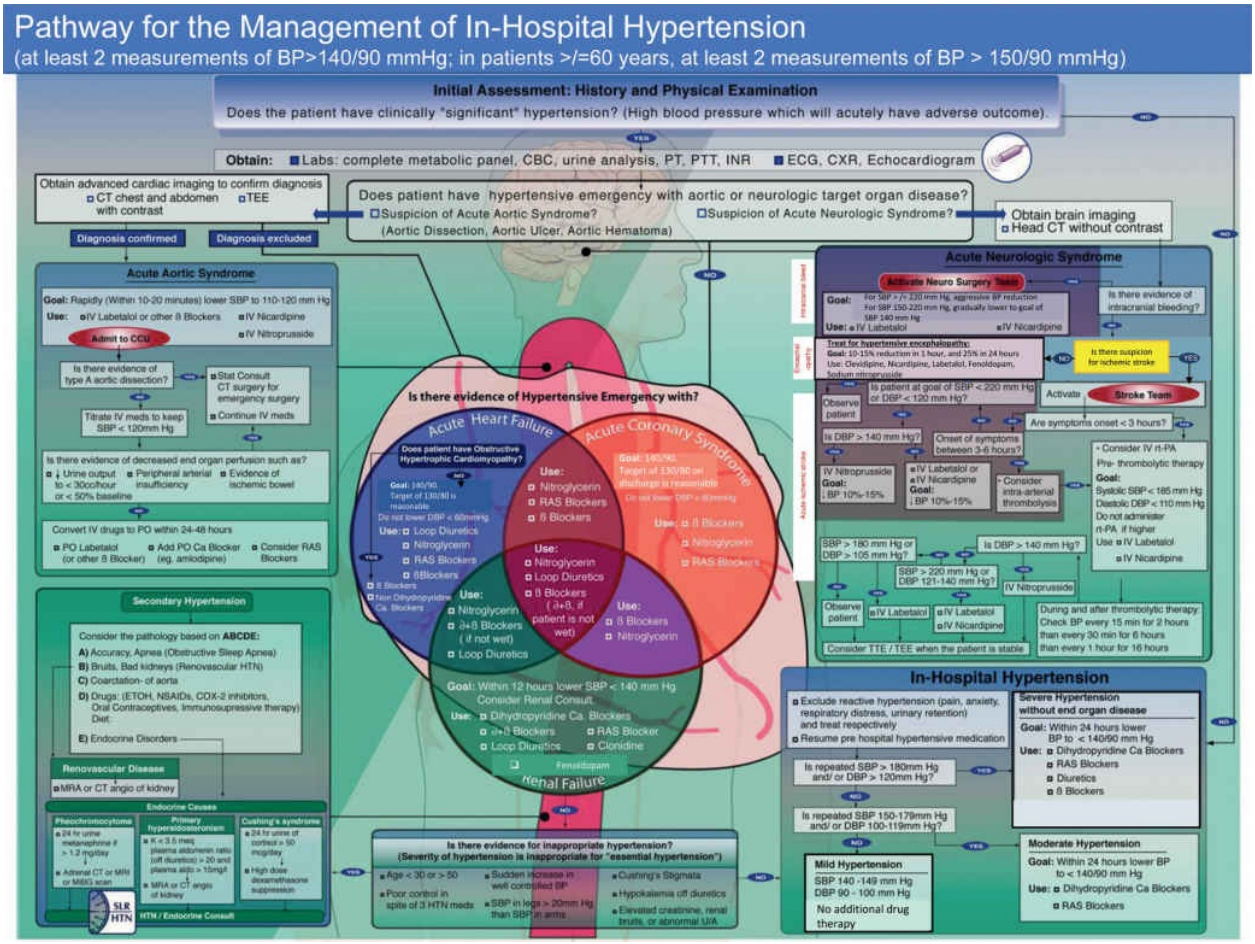

FIGURE 53.1 Pathway for the management of in-hospital hypertension. BP, Blood pressure; CBC, complete blood count; CCU, cardiac care unit; COX-2, Cyclooxygenase-2; CT, computed tomography; CXR, chest X-ray; DBP, diastolic blood pressure; ECG, electrocardiogram; ETOH, ethanol; HTN, hypertension; INR, international normalized ratio; MIBG, metaiodobenzylguanidine; MRA, magnetic resonance angiogram; MRI, magnetic resonance imaging; NSAIDS, non-steroidal anti-inflammatory drugs; PT, prothrombin time; PTT, partial thromboplastin time; PO, Per Os (Oral); RAS, renin–angiotensin system; SBP, systolic blood pressure; TEE, transesophageal echocardiogram; TTE, transthoracic echocardiogram.

HYPERTENSION: DEFINITION AND PATHOPHYSIOLOGY

The 2014 Guidelines of the Eighth Joint National Committee (JNC 8) and the 2013 European Society of Hypertension (ESH)/European Society of Cardiology (ESC) define hypertension in a non-elderly (<60-year-old) patient without diabetes and chronic kidney disease (CKD) as BP of ≥140/90 mm Hg.[2,3] JNC 8 recommends initiating treatment beyond this threshold and aiming for goals of systolic blood pressure (SBP) <140 mm Hg and diastolic blood pressure (DBP)

<90 mm Hg. Although the recommendations of JNC 8 are largely based on consensus expert opinions, high-quality evidence from several randomized control trial supports their recommendation to initiate treatment for HTN in patients ≥60 years when BP is only ≥150/90 mm Hg. Additional recommendations of JNC 8, in terms of thresholds for initiating treatment and BP goals, include initiating treatment for HTN in patients <60 years with CKD or diabetes mellitus (DM) when BP ≥140/90 mm Hg, aiming for SBP <140 mm Hg and DBP <90 mm Hg. In the diabetic population, the recommendation is based largely on the results of the ACCORD-BP (Action to Control Cardiovascular Risk in Diabetes–Blood Pressure) trial, which found that aiming for lower BP goals did not reduce the risk of nonfatal and fatal major adverse cardiovascular events.[4] The more recent SPRINT (*S*ystolic Blood *PR*essure *INT*ervention) trial suggests that intensive treatment to a lower BP goal may improve cardiovascular outcomes and reduce mortality in elderly patients with increased cardiovascular risk; it may be noted, however, that the trial excluded patients with diabetes and prior strokes, including a large proportion of patients with increased cardiovascular risk.[5]

HTN is a frequent reason for admission to the CCU. More commonly, however, a patient is admitted to the CCU for a condition related secondarily to HTN, with high BP being a critical target of therapy and of future risk reduction. For example, although the patient with acute coronary syndrome (ACS) or heart failure (HF) is not admitted primarily for HTN, HTN is one of the mediators of the ongoing myocardial oxygen supply–demand imbalance in ACS, and of pump failure in HF, and thus is a critical target of therapy.

BP is determined by the product of heart rate, stroke volume, and systemic vascular resistance. Heart rate is determined largely by sympathetic activity. Stroke volume depends on cardiac preload and afterload, which in turn depend on multiple variables affecting vascular tone, as well as on myocardial contractility that is determined, among other things, by sympathetic activity. It follows that BP can be reduced by reducing heart rate, stroke volume, and/or vascular resistance.

HTN can be essential or secondary. Secondary HTN is due to a discernible cause, such as renal or endocrine disease, whereas essential HTN, which is responsible for the majority of cases, is not. HTN can also be thought of as an elevation of BP due to one or more abnormalities in cardiac function, vascular function, renal function, and/or neuroendocrine function.

Cardiac: A hyperkinetic circulation due to excessive sympathoadrenal activity

or increased sensitivity of the heart to baseline neurohormonal regulators increases cardiac output and causes HTN with normal systemic vascular resistance, often in younger patients.

Vascular: Elevated vascular resistance, more common in the elderly, due to abnormal blood vessel responsiveness to sympathetic outflow, endothelial damage that disrupts vasodilatory/vasoconstrictor balance, and ion channel defects will raise BP.

Renal: Renovascular disease leads to increased production of angiotensin II and aldosterone, which increase vasomotor tone and sodium/water retention leading to increased cardiac output and systemic vascular resistance.

Neuroendocrine: Neuroendocrine dysfunction as in pheochromocytoma and primary hyperaldosteronism can alter cardiac, vascular, and renal function to cause HTN via a number of mechanisms.

GENERAL PRINCIPLES ABOUT THE PHARMACOLOGIC MANAGEMENT OF HYPERTENSION

The fundamental concept of HTN treatment is that BP can be decreased by reducing heart rate, stroke volume, and/or systemic vascular resistance. These factors are interrelated, and many pharmacologic agents affect more than one of these determinants of BP. The drugs used to treat HTN are many, but when grouped into classes they are surprisingly few. It is important to remember that it is degree of BP reduction and control that is the major determinant of prevention of major adverse cardiovascular outcomes, and not class of antihypertensive drug; this fact has been accepted by major societies such as the ESH and ESC.[3] The armamentarium of drugs used to treat systemic HTN includes those that reduce intravascular volume (diuretics), downregulate sympathetic tone (β-blockers, α-blockers, and central sympatholytics), modulate vascular smooth muscle tone (calcium channel blockers [CCBs] and potassium channel openers), and inhibit the neurohormonal regulators of the circulatory system (angiotensin-converting enzyme inhibitors [ACEIs] and angiotensin receptor blockers [ARBs]). These drug classes make up the bulk of medications used to treat not only HTN but also the most common disease processes that warrant a CCU admission. β-Blockers, for example, are antihypertensives fundamentally important for reasons that go beyond their antihypertensive effects, in the treatment of HF, ACS, acute neurologic syndrome, and acute aortic syndrome. It

is useful to organize drugs in classes and by mechanism of action because an understanding of how the drug class works helps one understand why it is effective for a disease process.

DIURETICS

Diuretics, which function to reduce intravascular volume and vasodilate, increase renal excretion of sodium and water. Diuretics include thiazide (thiazide-type and thiazide-like) diuretics and loop diuretics. Thiazide diuretics (thiazide-like—chlorthalidone, indapamide; thiazide-type diuretics—hydrochlorthiazide) have a long duration of action and moderate intensity of diuresis, making them more suitable for chronic HTN treatment than for short-term aggressive diuresis. After the publication of the ALLHAT (Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack) trial in 2002, thiazides became the initial antihypertensive monotherapy of choice.[6] However, recent evidence has challenged that notion; the ACCOMPLISH (*A*voiding *C*ardiovascular Events in *COM*bination Therapy in *P*atients *LI*ving with *S*ystolic *H*ypertension) trial in 2008 showed that the combination of benazepril and amlodipine was superior to the combination of benazepril and hydrochlorthiazide in reducing cardiovascular outcomes in hypertensive patients with increased cardiovascular risk.[7] Despite this, thiazides are still among the four main classes of antihypertensive drugs recommended for initial monotherapy (in addition to ACEI, ARBs, and dihydropyridine CCBs), as recommended by the expert panel of JNC 8.[2] If a thiazide is to be used, it is always preferable to use chlorthalidone, which is more potent and longer acting than hydrochlorthiazide (despite increased risk of glucose intolerance, hyperuricemia, and hypokalemia).

Loop diuretics (eg, furosemide) have a relatively short duration of action (4 to 6 hours) and are useful more for brisk diuresis than antihypertensive efficacy, making them critical in the treatment of HF exacerbations. However, in patients with CKD and glomerular filtration rate (GFR) of less than 30 mL/min, thiazides are less effective. In such patients, loop diuretics are much more effective as antihypertensives. In patients with a low GFR, their volume status is a major determinant of BP; as such, loop diuretics play a major role in BP management by rapidly modulating volume status. Interestingly, when HTN persists even at high doses of loop diuretic, a thiazide (such as chlorthalidone, hydrochrothiazide, or metolazone) can enhance diuresis. Although ACEI forms

the most important therapy for patients with CKD with proteinuria, in the absence of proteinuria or in the presence of edema, loop diuretics form an initial component of initial therapy for BP management in such patients.

Another diuretic, spironolactone, has recently gained attention after the publication of the PATHWAY-2 (*P*revention *A*nd *T*reatment of *H*ypertension *W*ith *A*lgorithm-based therap*Y*) trial.[8] Spironolactone has been shown to be the most effective add-on drug for the treatment of resistant HTN, defined as suboptimal BP control despite treatment with at least three blood-lowering drugs. This effectiveness of spironolactone in the treatment of HTN supports sodium retention as an underlying pathophysiologic cause of resistant HTN. It is important to monitor electrolytes and renal function during initiation of spironolactone.

ADRENERGIC BLOCKADE: α- AND β-BLOCKERS

β_1 Receptors found on myocardial cells, when activated, increase heart rate (chronotropy) and contractility (inotropy). α_1 Receptors found on vascular smooth muscle promote contraction and thus vasoconstriction.

β-Adrenergic antagonists or β-blockers (eg, metoprolol) have negative chronotropic and negative inotropic effects as well as effects on resistance vessels. In addition, they protect against the cardiac remodeling imposed by adrenergic stimulation and have shown long-term benefit in coronary artery disease (CAD) and HF. α-Blockers (eg, doxazosin), on the other hand, promote peripheral vasodilation, leading to a decrease in peripheral vascular resistance. Some β-blockers (labetalol, carvedilol) block α- and β-receptors, thus mediating vasodilatation (α-blockade) and decreased reflex tachycardia, along with decreased heart rate and decreased cardiac contractility. However, decades ago, the MRC (Medical Research Council) Study in the United Kingdom showed that β-blockers were less effective than other agents as antihypertensives.[9] This has been shown again by several systematic reviews and meta-analyses,[10–12] and none of the major professional societies support the use of β-blockers as initial monotherapy for HTN. Further, in the ALLHAT trial, the doxazosin arm had to be stopped early because of adverse cardiovascular outcomes.[6] α-Blockers are never used for HTN monotherapy, except to concomitantly treat an enlarged prostate.

CALCIUM CHANNEL BLOCKERS

Calcium ions are major mediators of vascular smooth muscle cell contraction as well as inotropic and chronotropic function of the heart. Calcium enters vascular smooth muscle cells, cardiomyocytes, and pacemaker cells via voltage-dependent calcium channels. CCBs, by inhibiting calcium entry into the vascular myocytes, promote myocyte relaxation, thus leading to vasodilation. In a similar way, by inhibiting calcium entry into the cardiac myocyte, they have negative chronotropic and negative dromotropic effects.

CCBs are recommended by the expert panel of JNC 8 as agents that can be used as initial monotherapy for HTN.[2] In general, dihydropyridine CCBs (eg, amlodipine, nifedipine, felodopine, isradipine) are the preferred agents; they are highly selective for arterial tissues, including the coronary arteries, where they cause vasodilation. Intravenous (IV) nicardipine has strong antihypertensive activity; intra-arterially, it decreases vasospasm in subarachnoid hemorrhage, and it is a recommended agent for HTN after acute ischemic stroke and intracerebral hemorrhage (ICH).[13] Clevidipine, a new third-generation IV dihydropyridine CCB, has a high vascular selectivity with a fast onset and offset of BP-lowering effect, thus making it easily and rapidly titratable and an especially attractive drug for acute HTN. In perioperative patients requiring HTN treatment, clevidipine compared favorably to nitroglycerin (NTG), nitroprusside, and nicardipine in terms of BP-reducing efficacy and 30-day outcomes (death, myocardial infarction [MI], stroke, renal failure).[14]

The non-dihydropyridine CCBs (diltiazem, verapamil) bind to different sites and are less selective for vascular smooth muscle; they have negative chronotropic and dromotropic effects on sinoatrial (SA) and atrioventricular (AV) nodal conducting tissue and negative inotropic effects on cardiomyocytes, making them useful heart-rate–controlling agents as in atrial fibrillation with rapid ventricular rate. Non-dihydropyridine CCBs should be used with caution in patients with impaired systolic function or conduction system disease because these agents can exacerbate HF and SA or AV node dysfunction, especially in patients already on β-blocker therapy. As such, dihydropyridine CCBs are preferred agents for HTN monotherapy. Still, diltiazem and verapamil may be useful for HTN, when used concomitantly for some other indication, such as atrial fibrillation. Further more, they are preferred second-line agents in patients with CKD, because they help in reducing proteinuria.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

ACEIs prevent the ACE-mediated conversion of angiotensin I to angiotensin II, leading to decreased circulating angiotensin II and aldosterone (angiotensin II stimulates the release of aldosterone from the adrenal glands). Angiotensin II elevates BP by causing peripheral vasoconstriction and also through sodium and water reabsorption in the distal tubules. In the long term, it promotes HTN by promoting atherosclerosis; this occurs through various mechanisms such as direct effects of angiotensin II on constriction and remodeling of resistance vessels, aldosterone synthesis and release, enhancement of sympathetic outflow from the brain, and facilitation of catecholamine release from the adrenals and peripheral sympathetic nerve terminals. In the heart, angiotensin can cause adverse tissue remodeling. It is an important trigger of several genomic and non-genomic pathways that play a role in pathogenesis of myocardial hypertrophy and fibrosis. Angiotensin II is an upregulator of intracellular genomic pathways that lead to the activation of a hypertrophic gene transcription program and the development of myocardial hypertrophy.[15] It is also one of the stimulators of fibroblasts to myofibroblast transformation, a crucial step in pathogenesis of cardiac fibrosis. Angiotensin also stimulates release of chymase from the cardiac mast cells, which additionally upregulates fibrosis by stimulating collagen production within the fibroblasts.[16]

ACEIs decrease levels of vasoconstricting angiotensin II. By reducing aldosterone production, they also promote natriuresis and reduction of intravascular volume. By decreasing bradykinin breakdown, ACEIs promote vasodilatation. They may be nephroprotective because reducing angtiotensin II levels reduces renal efferent arteriole constriction, thus reducing intraglomerular pressures and limiting glomerular damage over time. For all these reasons, these drugs are particularly useful in patients with hypertensive diabetes and HF. ARBs, by blocking angiotensin receptors, promote vasodilation and reduction in aldosterone levels, thus aiding natriuresis. However, they do not affect the levels of bradykinin.

For HTN, ACEIs are recommended as initial monotherapy by JNC 8 for the general nonblack population. For the black population, irrespective of their diabetic status, thiazides and CCBs are preferred as initial monotherapy.[2] This is based on the findings of the ALLHAT trial, which found these classes of drugs to be superior to ACEIs in the black patient population. However, for patients with CKD having proteinuria, irrespective of their race or their diabetic status, ACEIs form the first-line monotherapy. In the absence of proteinuria, ACEIs still can be used as initial monotherapy in the patient with CKD, although diuretics should

be favored when there is edema. The recommendations for ARBs are similar.

NITRATES

Organic nitrates are chemically reduced to release nitric oxide (NO), an endogenous signaling molecule that causes vascular smooth muscle relaxation. Although NO can dilate both arteries and veins, venous dilation predominates at therapeutic doses. NO-induced venodilation increases venous capacitance, leading to a decrease in the return of blood to the right side of the heart, and subsequently decreased right ventricular and left ventricular (LV) end-diastolic pressure and volume. This decrease in preload reduces myocardial oxygen demand. At higher concentrations, nitrates may cause arterial vasodilation. In the coronary circulation, NTG preferentially dilates large epicardial arteries rather than smaller coronary arterioles, thus preventing coronary steal phenomenon, encountered with such agents as dipyridamole. It is unclear to what extent nitrates' effects on coronary vasodilation benefit the patient with angina because the chronic oxygen deficit in patients with CAD causes maximal dilation of coronary arteries and because atherosclerotic coronary arteries may remain noncompliant even in the face of coronary artery vasodilators. Furthermore, doses of nitrates sufficient to vasodilate epicardial arteries can induce peripheral vasodilation, hypotension, and reflex tachycardia, which harm the delicate supply-demand balance. In patients with HF, however, reflex tachycardia is rare; the venodilation and decreased end-diastolic pressure effects of nitrates make them acceptable at certain doses for decreasing pulmonary congestion in the patient with hypertensive emergency and congestive HF. Side effects related to hypotension include dizziness and syncope; nitrates are contraindicated in hypotension, and not advised in diastolic dysfunction and hypertrophic obstructive cardiomyopathy, two disease states for which adequate preload are critical to sustain cardiac output. Also, nitrates should not be taken by patients taking phosphodiesterase inhibitors (ie, sildenafil [Viagra]).

Sodium nitroprusside is a nitrate that, like NTG, liberates NO but does so nonenzymatically; as a result, nitroprusside does not target specific vessels and consequently dilates both arteries and veins. With rapid onset of action and high efficacy, nitroprusside is useful in hypertensive emergencies, but must be infused with continuous BP monitoring. Sodium nitroprusside is metabolized to products that are potentially toxic if they accumulate excessively: cyanide (acid–base disturbance, cardiac arrythmia) is converted to thiocyanate (psychosis, spasms, convulsions).

HYPERTENSION AND THE CCU

HTN is a risk factor and target of therapy (both short term and long term) for virtually every condition that warrants a CCU admission. We review the most common CCU disease states in terms of pathophysiology, diagnosis, and management in relation to HTN. **Figure 53.2** outlines the initial assessment of a patient with HTN in the hospital who may require care in the CCU. **Figure 53.3** outlines our working group's assessment of a hypertensive emergency.

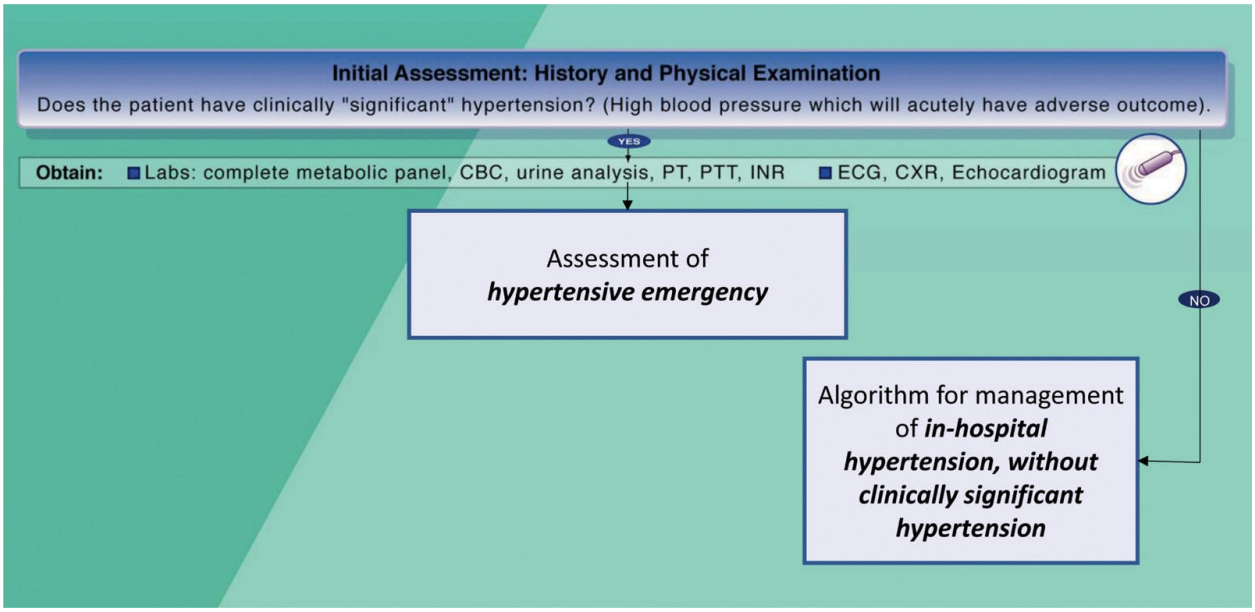

FIGURE 53.2 Initial assessment of a patient with in-hospital hypertension, which might require cardiac care unit (CCU) level of care. CBC, complete blood count; CXR, chest X-ray; ECG, electrocardiogram; INR, international normalized ratio; PT, prothrombin time; PTT, partial thromboplastin time.

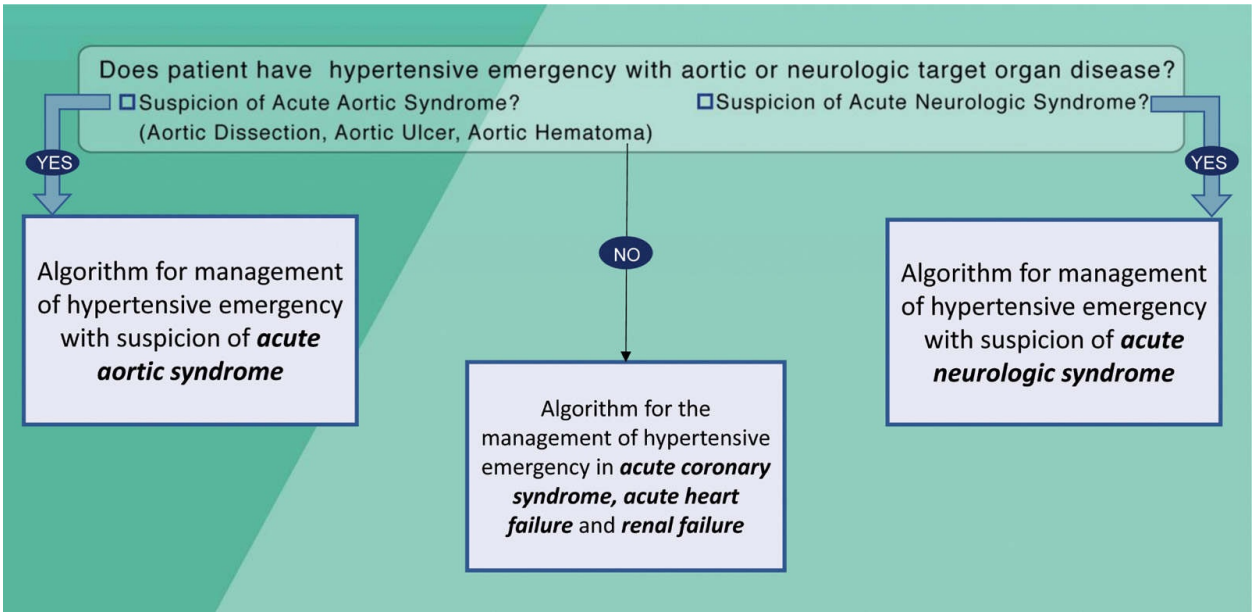

FIGURE 53.3 Assessment of hypertensive emergency.

HYPERTENSION AND DISEASES OF THE AORTA

Diseases of the aorta include aortic atheroma, aneurysm, arteritis, and acute aortic syndromes (aortic dissection, intramural hematoma, penetrating ulcer). These diseases tend to follow an indolent asymptomatic progressive course until they culminate in an acute life-threatening clinical presentation. The most common of these processes is aortic dissection.

Aortic dissection is characterized by an intimal tear and formation of a false lumen within the media of the artery. Repetitive hemodynamic forces produced by the blood ejected into the aorta with each cardiac cycle contribute to the weakening of the aortic intima and to medial degeneration. Sustained HTN intensifies these forces. Acute elevations in heart rate and BP can lead to catastrophic acute worsening of the disease process. The false lumen, as it extends, can obstruct the true lumen, leading to such complications as acute MI, acute renal failure, and stroke. Many patients with aortic dissection have undermining of the elastic or muscular components of the media, which is quantitatively and qualitatively more severe than expected from aging, as seen in Marfan and Ehlers–Danlos syndromes, and congenital bicuspid aortic valve.

Patients with aortic syndrome present with acute onset of severe chest pain that typically radiates through to the back. The pain is at its most severe at onset, unlike the typically crescendo pain of ACS. Although clearly not diagnostic, terms such as “tearing,” “ripping,” and “stabbed me in the chest and back”

should alert the caregiver to the possibility of dissection. Presentations can vary, and thus aortic disease must be considered in any patient presenting with chest pain, especially because some treatments for ACS (thrombolysis and antithrombotic therapy) can worsen acute aortic syndrome.

Therapy for aortic dissection aims to halt progression; lethal complications arise not due to the tear itself but due to the extension of the tear such that occlusion or rupture occurs. Untreated, aortic dissection will result in death in 25% of patients in 24 hours, 50% in 1 week, and over 90% in 1 year. As the major etiologic component of the development and progression of aortic dissection, BP is the major target of treatment. Heart rate is also a major target of treatment because BP and heart rate together create a hemodynamic force that favors extension of the dissection.

Pathway Management

Figure 53.4 outlines the management of a hypertensive emergency with suspicion for an acute aortic syndrome.

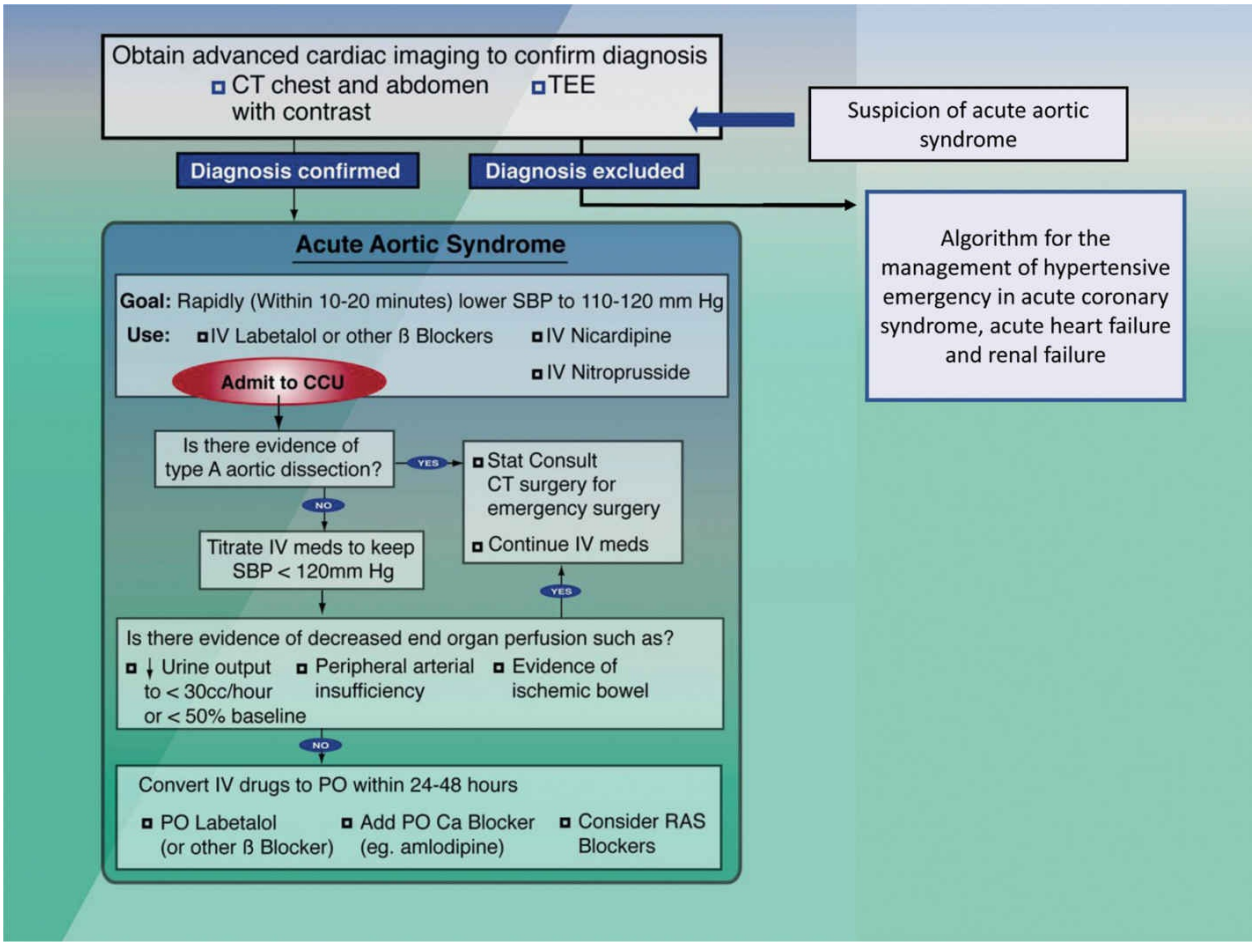

FIGURE 53.4 Management of a hypertensive emergency with suspicion of an acute aortic syndrome. CT, computed tomography; IV, intravenous; RAS, renin–angiotensin system; SBP, systolic blood pressure; TEE, transesophageal echocardiogram.

The modalities available for the diagnosis of aortic dissection include computed tomography (CT), magnetic resonance imaging (MRI), transthoracic echocardiogram (TTE) or transesophageal echocardiogram (TEE), and aortography. The goals of imaging are to establish the diagnosis, determine location of the dissection (ascending, type A dissections are considered surgical emergencies), and determine extent of disease (eg, coronary or cerebral artery involvement). The choice of modality may be influenced by clinical presentation. The patient with suspected aortic dissection who also presents with physical examination findings suspicious for pericardial effusion or aortic regurgitation may benefit more from a TEE than CT, for example.

When the dissection involves the ascending aorta, the focus is surgical management. However, whether the dissection is ascending or descending, medical management to reduce BP and heart rate are critical and urgent.

Labetalol, which has α_1 and β_1 and β_2 adrenergic receptor inhibitory action, is an ideal drug because it reduces BP and heart rate, and can be given intravenously for immediate onset of action and titration. We recommend lowering BP within 10 to 20 minutes to an SBP level of 110 to 120 mm Hg. Esmolol, with its short half-life and β_1 receptor selectivity, may be a good alternative for those with reactive airway disease. The CCB nicardipine is an alternative as well. Once the patient is stabilized, whether surgically for ascending or medically for descending dissection, oral forms of the same medications (β-blocker, CCB, ACEI) are used for long-term BP control, which is crucial for secondary risk reduction.

HYPERTENSION AND ACUTE NEUROLOGIC SYNDROME

Stroke results from either ischemic or hemorrhagic causes. Ischemic stroke can be categorized by presumed mechanism of ischemia into coagulopathies (protein C deficiency, antiphospholipid antibody), small vessel-lacunar (vasculitis, embolic), large vessel-intracranial (dissection, atherosclerosis), large vessel-extracranial (Takayasu, atherosclerotic), and cardioembolic (atrial fibrillation, ventricular thrombus, infectious endocarditis). Some strokes are cryptogenic, or of undetermined cause. Hemorrhagic stroke can be categorized as intracerebral (bleeding into brain parenchyma, further classified as primary and unrelated to a brain lesion, or secondary and related to a congenital or acquired brain lesion or abnormality), subarachnoid, or intraventricular. HTN is a major risk factor for both ischemic (especially small vessel-lacunar) and hemorrhagic stroke, and thus there is little doubt that treating BP for stroke prevention (both primary and secondary prevention) is justified and very important. However, it is in the treatment of HTN for the patient in the acute phase of a stroke that there has been much controversy and ambiguity; recent data are shedding more light on this important issue.

Stroke is a major cause of morbidity and mortality; in 2014, it was the fifth leading cause of death in the United States, behind heart disease, cancer, chronic lower respiratory illnesses, and unintentional injuries.[17] Perhaps more devastating is the morbidity in survivors; stroke is the leading cause of long-term disability in adults. A total of 15% to 30% of stroke survivors are permanently disabled, and 20% require institutional care by 3 months.

Timely diagnosis of stroke, greatly dependent on history and physical examination, is critical because early implementation of treatment can improve

prognosis; some treatments for ischemic stroke, for example, are only implementable within 3 (IV recombinant tissue plasminogen activator [rtPA]) to 6 hours (intra-arterial thrombolysis) from onset of event. For this reason, the most important piece of history is time of symptom onset. Findings such as focal neurologic deficit, persistent neurologic deficit, acute onset of symptoms, and no history of head trauma favor the diagnosis of stroke; the presence of all four of these findings makes a stroke likely. Symptoms also enable the experienced clinician to determine the vascular distribution (eg, anterior or posterior) of a stroke. Once stroke is suspected, severity can be assessed with the NIH (National Institutes of Health) Stroke Scale, the diagnosis can be further pursued with imaging studies, and tests can be obtained to exclude conditions that mimic strokes (tumor, hypertensive encephalopathy, seizure, migraine variant).

The first imaging test to obtain in the acute stroke patient is a noncontrast CT scan of the brain, because this will identify most intracranial hemorrhage (ICH) and help exclude stroke mimickers such as neoplasms. Importantly, CT will not reliably diagnose ischemic stroke when early in its evolution; MRI, on the other hand, will. MRI with diffusion-weighted and perfusion-weighted imaging has a high sensitivity and specificity for ischemic lesions, even within minutes of symptom onset, and can identify brain tissue that is ischemic but not yet infarcted and therefore amenable to being rescued if successfully revascularized. CT angiogram provides maps of cerebral blood flow, thus possibly revealing occlusion or stenosis.

An elevated BP is often detected in the first few hours after stroke. BP is usually higher for acute stroke patients with a history of HTN than in those without premorbid HTN. For ischemic strokes, the elevated BP may be a protective response of the body to maintain perfusion of partially ischemic areas. Still, for every 10 mm Hg increase above 180 mm Hg, the risk of neurologic deterioration increases by 40%, and the risk of poor outcome increases by 23% in the case of ischemic strokes. Despite this association between elevated BP and poor outcomes, the management of arterial HTN in ischemic stroke has been controversial. Investigators found a U-shaped relationship between death and admission BP; both elevated and low admission levels were associated with high rates of early and late death from stroke.[18] Elevations in mean BP during the first few days after stroke had an unfavorable effect on outcomes; death due to brain injury and brain edema correlated with high initial BP. Theoretical reasons for lowering BP include reducing brain edema, reducing risk of hemorrhagic transformation, and preventing further vascular damage. Conversely, it has been

theorized that overly aggressive BP reduction may lead to neurologic worsening.[19] Furthermore, the majority of patients experience a drop in BP within the first hour of stroke without any medical treatment. Recommendations for BP control vary depending on whether it is the acute post-stroke phase or the chronic phase, and whether thrombolysis is being pursued or not; this has been discussed subsequently. In the case of hemorrhagic strokes, the issue is complex as well. Although elevated BP maintains perfusion of jeopardized brain tissues, it serves as a continued driving force for bleeding. However, rapid decrease in BP can impair perfusion and cause ischemia. Recommendations for management are discussed here.

Pathway Management

Figure 53.5 outlines the management of a hypertensive emergency with suspicion for an acute neurologic syndrome.

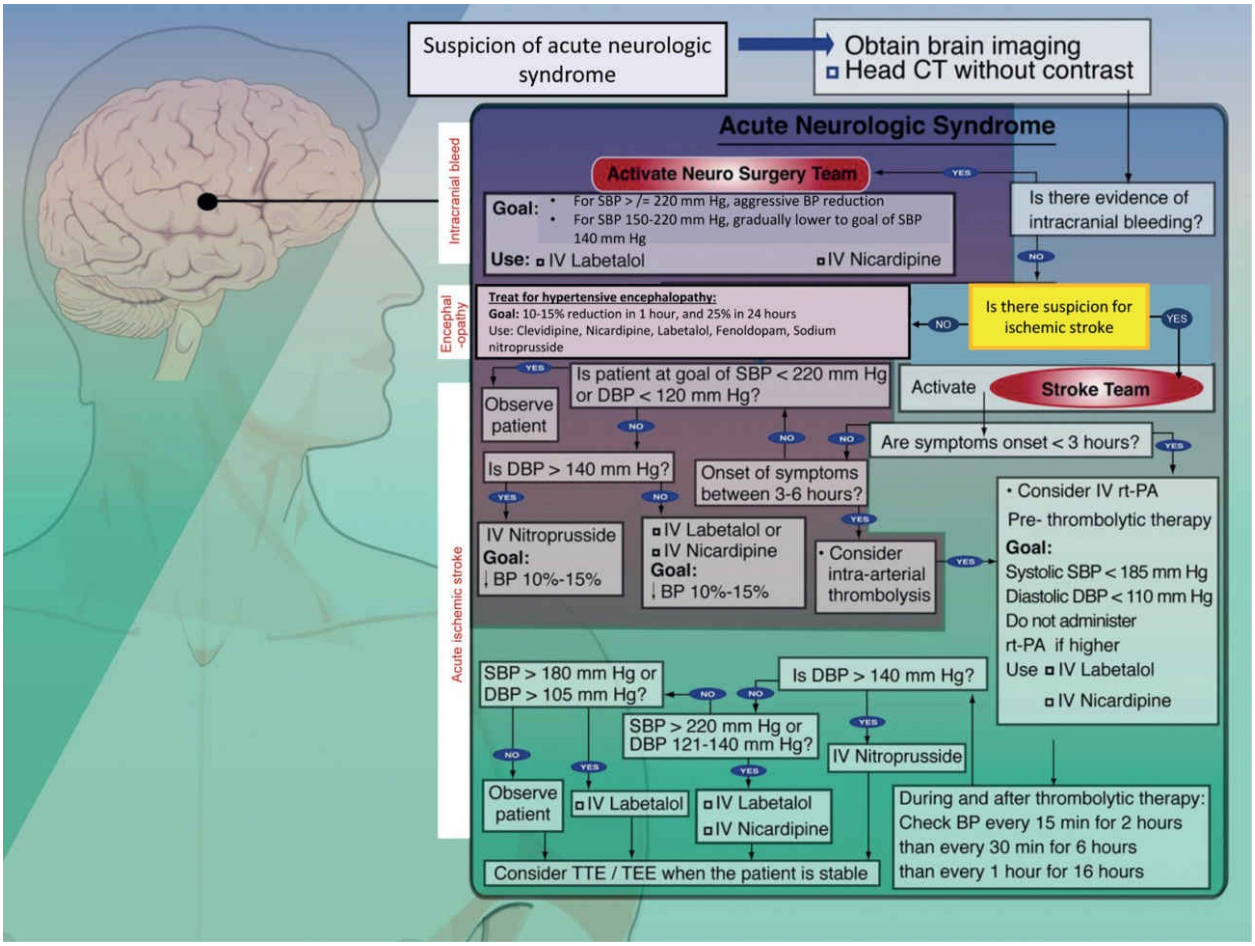

FIGURE 53.5 Management of a hypertensive emergency with suspicion of an acute neurologic syndrome. BP, blood pressure; CT, computed tomography; DBP, diastolic blood pressure; IV, intravenous; rtPA, recombinant tissue plasminogen activator; SBP, systolic blood pressure; TEE, transesophageal echocardiogram; TTE, transthoracic echocardiogram.

Our group subdivides the management of a hypertensive emergency with the suspicion of an acute neurologic syndrome into the management of three distinct clinical scenarios:

a. ICH: With respect to patients with ICH, controversy persists regarding the appropriate goal for BP management. Some studies have shown no benefit in terms of mortality and disability for aggressive BP management,[20,21] whereas others have shown reduction in hematoma size with aggressive BP control.[22] At the moment, guidelines recommend that for SBP > 220 mm Hg, rapid reduction of BP with IV agents is necessary, whereas for SBP between 150 and 220 mm Hg, targeting an SBP of 140 mm Hg should be pursued.[23]

b. Ischemic stroke: For ischemic strokes, the management and guidelines for BP

control are somewhat different. For symptoms less than 3 hours old, IV rtPA is recommended for selected patients without contraindications (eg, history of previous ICH); for symptoms 3 to 6 hours old, intra-arterial thrombolysis may be used. However, BP over 185/110 mm Hg is a contraindication to IV rtPA. In this setting, labetalol and nicardipine may be used to rapidly lower BP. During and after thrombolytic therapy, nitroprusside, labetalol, or nicardipine should be used, depending on how high the BP is, to maintain BP below 180/105 mm Hg.[24]

c. Hypertensive encephalopathy: For hypertensive encephalopathy, on the other hand, the baseline BP must be considered to avoid excessive BP lowering and prevent cerebral ischemia. Lowering the mean arterial pressure by 10% to 15% in the first hour and by 25% in the first 24 hours usually is a safe maneuver because of the pressure autoregulatory cerebral blood flow range.

Patients who were taking antihypertensive medications before their stroke or are found to have sustained HTN after their stroke will need long-term antihypertensive treatment. Historically, there was a belief in the medical community that permissive HTN in the long term was protective for patients after an ischemic stroke. In fact, in patients followed up from the time of a first ischemic stroke to the time of a second stroke in the same territory, risk was increased rather than decreased with higher BP, a finding driven mainly by SBP elevations above 160 mm Hg.[25] The same facts are valid for ICH. Control of the SBP is the cornerstone of secondary prevention of recurrent ICH.[26] The timing of the reinstitution of treatment and the selection of medications will depend on the patient's neurologic status, the underlying stroke mechanism, the patient's ability to swallow medications, and the presence of concomitant disease. Presumably, most patients with mild-to-moderate stroke who are not at high risk for increased intracranial pressure may have their prestroke antihypertensive medications restarted 24 hours after their vascular event.[24]

Figure 53.6 outlines the management of a hypertensive emergency with acute HF, ACS, or renal failure.

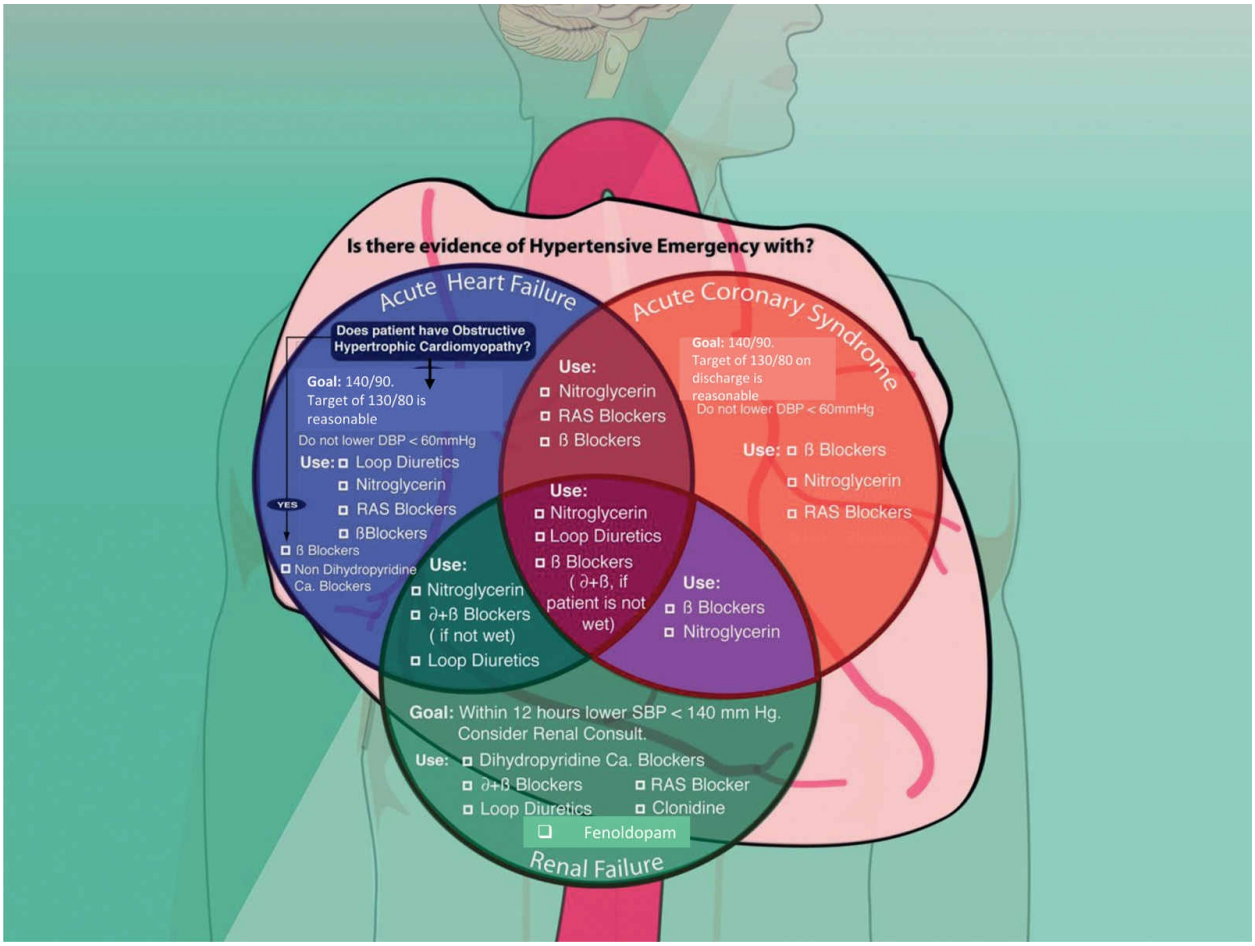

FIGURE 53.6 Management of a hypertensive emergency in acute coronary syndrome, acute heart failure, or renal failure. BP, blood pressure; DBP, diastolic blood pressure; RAA, renin–angiotensin system; SBP, systolic blood pressure.

HYPERTENSION AND ACUTE CORONARY SYNDROME

ACS refers to a spectrum of diseases that range from unstable angina and non–ST-elevation myocardial infarction (NSTEMI) to ST-elevation myocardial infarction (STEMI).

ACS is perhaps best explained in terms of the delicate balance between myocardial oxygen supply and demand. When this balance is disrupted by a disease process that affects coronary blood flow, myocardial ischemia may induce contractile dysfunction, precipitating a vicious cycle that includes tachycardia and hypotension, which may further worsen the supply–demand imbalance.

Myocardial oxygen demand is largely dependent on heart rate, myocardial wall stress (systolic pressure), and LV contractility. Myocardial oxygen supply

depends on the coronary circulation. In contrast to most other vascular beds, myocardial oxygen extraction is near maximal (75% of arterial oxygen content) at rest.[27] Consequently, demand for increased myocardial oxygen consumption must be met primarily by increased oxygen delivery. A 2-fold increase in any of the determinants of oxygen consumption requires an approximately 50% increase in coronary flow.

HTN increases demand: it increases myocardial wall stress and thus requirements of coronary flow. HTN may also limit supply: it is a risk factor for vascular remodeling and atherosclerosis, the disease process that limits coronary blood flow. Even at an early age, increased vascular wall tension in people with high BP leads to thinning, fragmentation, and fracture of elastin fibers, as well as increased collagen deposition in arteries, which results in decreased compliance of these vessels. In addition to these structural abnormalities, the HTN-mediated functional abnormality of increased arterial rigidity due to endothelial dysfunction develops over time because of aging and HTN and contributes to systolic HTN.[28]

Many of the mechanisms that initiate and maintain HTN (increased sympathetic nervous system and renin–angiotensin–aldosterone system [RAAS] activity; deficiencies in release and/or activity of vasodilators, structural and functional abnormalities in conductance and resistance arteries) are also those that mediate damage to target organs, including the coronary vessels and the myocardium.[29] This may be why antihypertensive drugs exert at least some of their beneficial effects on the vasculature by actions that are independent of BP lowering alone.

The medications used to treat ACS can be understood within the framework of the supply/demand balance. β-Blockers work to decrease BP and heart rate, two major determinants of myocardial oxygen demand. Nitrates decrease preload, and thus ventricular filling pressures and wall stress (demand). Nitrates also cause coronary vessel dilatation (supply). Morphine decreases pain and thereby heart rate, while also decreasing venous return and filling pressures (demand). Often, the patient with ACS will need a cardiac catheterization whether for diagnostic or treatment purposes. Cardiac catheterization is the gold standard for diagnosis of coronary vessel disease, and angioplasty and coronary stenting can relieve the stenosis or occlusion (supply) in a way no medication can.

Pathway Management

Detailed guidelines exist for HTN in ACS.[30] In an ACS, β-blockers are the first line of treatment based on their ability to reduce both heart rate and BP and thus myocardial oxygen demand **(Figure 53.6)**. In the case of hypertensive emergences, an IV β-blocker may be needed. NTG has been a cornerstone of therapy for decades in ACS, and in the hypertensive patient, IV NTG is effective in the reduction of BP and symptoms. Patients need to be monitored for potential adverse effects, particularly profound hypotension, which can exacerbate ischemia. Caution should be used if there is right heart dysfunction. If β-blockers are contraindicated, a non-dihydropyridine CCB (diltiazem or verapamil) may be used, assuming there is no LV dysfunction. An ACEI or an ARB can also be considered for the management of HTN in patients with ACS, and must be added when there is LV dysfunction, anterior wall MI, diabetes, and if HTN persists. In persistent HTN even after optimization with β-blockers and ACEI/ARB, a long-acting dihydropyridine CCB (especially if there is persistent angina) or a thiazide may be used. In patients with MI and LV dysfunction, in whom HTN persists despite β-blocker and ACEI, an aldosterone antagonist may be considered. When there is symptomatic HF or CKD with GFR <30 mL/min, a loop diuretic can be used. In patients with ACS, guidelines recommend lowering BP to <140/90 mm Hg in patients who are hemodynamically stable. Targeting BP of <130/80 mm Hg at discharge is reasonable, lowering diastolic pressure <60 mm Hg should be avoided.

HYPERTENSION AND HEART FAILURE

HF can be due to a decrease in cardiac output such that end-organ perfusion is compromised (systolic dysfunction), or due to maintenance of cardiac output at the expense of increased left atrial filling pressures (diastolic dysfunction), or due to both. Both systolic and diastolic dysfunction can be understood in terms of the determinants of cardiac performance.

The determinants of cardiac performance are preload, afterload, contractility, and heart rate. As the ability of the myocardium to maintain normal forward output fails, compensatory mechanisms are activated to preserve circulatory function. Preload increases to increase stroke volume (Frank–Starling mechanism). Hemodynamic stress that cannot be compensated initiates structural changes at the cellular levels, referred to as myocardial remodeling. If the Frank–Starling and remodeling mechanisms are unable to reestablish cardiac output, neurohormonal systems are also activated. Although each of these mechanisms may contribute to maintenance of circulatory function, each may

also contribute to development and progression of pump dysfunction.

HTN is intricately linked to both systolic and diastolic dysfunction by affecting each of these mechanisms. The renin–angiotensin system (RAS) that is so fundamentally linked to HTN and that recruits intravascular volume to sustain end-diastolic filling pressures may elevate preload to the point of putting a patient on the flat or descending portion of the Frank–Starling curve. HTN induces cardiac remodeling and LV hypertrophy; to decrease LV wall stress, contractile proteins are added to myocytes in parallel, thus increasing wall thickness and decreasing cavity size. Increasing thickness and decreasing cavity size relieves the increase in wall stress, but at the expense of LV remodeling and hypertrophy. Finally, the sympathetic activation that increases vascular tone also increases myocardial oxygen demand and eventually results in downregulation of β-adrenergic receptors, further impairing the ability of the system to maintain forward output.

The staples of HF treatment are diuretics, β-blockers, and ACEIs. Diuretics, specifically loop diuretics, combat the increased total body volume that is central to the pathophysiology of HF. β-Blockers and ACEIs/ARBs combat the cardiac remodeling and neurohormonal activation. Aldosterone antagonists are particularly important when there is LV dysfunction, by countering neurohormonal-mediated remodeling. The CCB amlodipine, although not first line, appears to be safe if needed for the treatment of HTN (or angina) in the patient with LV dysfunction.[31]

Pathway Management

Careful guidelines exist for the management of HTN in HF, both systolic and diastolic HF **(Figure 53.6)**.[30,32] β-Blockers and ACEIs, which show benefit in systolic HF, should form first-line therapy. Diuretics are important for volume control and BP; although thiazides can be used, loop diuretics are key in severe HF (New York Heart Association [NYHA] Class III and IV) and in CKD when GFR is <30 mL/min. In persistent HTN in patients with LV dysfunction, aldosterone antagonists may be used. In African Americans, with LV systolic dysfunction, hydralazine and isosorbide dinitrate should be added to standard therapy. In hypertensive emergencies or in patients with severe pulmonary edema, parenteral nitrates play an important role. Although few guidelines exist for management of diastolic dysfunction, BP management—both SBP and DBP—is paramount. In addition, therapy may be directed toward management of pulmonary edema and toward rate control in atrial fibrillation. One caveat in the

management of HTN in the setting of acute HF is the exclusion of hypertrophic cardiomyopathy. In patients with hypertrophic cardiomyopathy, guidelines recommend the exclusive use of a β-blocker or a non-dihydropyridine CCB (in patients with a contraindication to β-blockers) and avoidance of diuretics or NTG.

HYPERTENSION AND RENAL FAILURE

Renal failure tends not to be the primary reason for CCU admission but rather a complication or comorbidity of some other disease process requiring CCU care, such as hypertensive emergency or acute decompensated heart failure (ADHF). Nonetheless, because renal failure is associated with poor outcomes, preserving or improving the CCU patient's renal function must be a primary objective.

Severe and/or long-standing HTN induces renal microvascular damage. Mechanical stress and endothelial injury lead to increased vascular permeability, activation of the coagulation cascade and platelets, and deposition of fibrin. This fibrinoid necrosis narrows the vessel lumen, which causes renal hypoperfusion and triggers massive renin release, generating a vicious cycle of ongoing injury. RAS activation involves production of angiotensin II and release of aldosterone; this in turn leads to further vasoconstriction and sodium reabsorption, worsening HTN. Angiotensin II, acting on the efferent arteriole of the nephron, leads to pressure natriuresis, which can lead to end-organ hypoperfusion, ischemia, and dysfunction. HTN begets renal damage that begets more HTN, which if severe enough causes acute end-organ damage (hypertensive emergency).

Renal failure in the setting of acute HF is a complex issue, and an understanding of the concept of cardiorenal syndrome is essential. HF decreases renal perfusion and predisposes to renal failure. Further more, vascular congestion and increased intra-abdominal pressure in acute HF may also be implicated.[33] With worsening renal failure, there is increased fluid retention and volume overload that can worsen HF. Further more, renal failure makes diuretic dose requirements for HF higher; if HF is hemodynamically significant such that renal perfusion is compromised, inotropes or dialysis may be the only effective options. Diuretics increase solute delivery to distal segments of the nephron, resulting in epithelial cell hypertrophy and hyperplasia, which increases the solute resorptive capacity of the kidney. Reduction in renal extracellular fluid volume also leads to an increase in solute and fluid reabsorption, specifically in the proximal tubule. These mechanisms result in a state in which HF and renal failure worsen each other and make difficult the treatment of both. Although

these patients may be hypotensive initially, they often eventually become hypertensive. The elevated BP may augment renal perfusion, whereas the continued venous congestion causes renal failure to persist, and the rising BP worsens HF. As such, BP management and efficient diuresis is key.

Pathway Management

For the hypertensive emergency patient in acute renal failure, the recommendation is a goal of lowering SBP to 140 mm Hg within 12 hours and considering consultation by a nephrologist (**Figure 53.6**). A recommended strategy is for a 10% to 20% reduction in mean arterial pressure during the first 1 to 2 hours, and then a further 10% to 15% reduction during the next 6 to 12 hours.

Early on, parenteral agents may be needed. Some physicians advocate the use of fenoldopam, which is unique among the parenteral BP agents because it mediates peripheral vasodilation by acting on peripheral dopamine-1 receptors, and thus, despite lowering systemic BP, by acting on these receptors in the renal vessels, it promotes renal perfusion. Thus, fenoldopam improves creatinine clearance, urine flow rates, and sodium excretion in severely hypertensive patients with both normal and impaired renal function.[34] Fenoldopam has onset of action within 5 minutes, peak action by 15 minutes, and duration of action from 30 to 60 minutes. No adverse effects have been reported.

The recommended sequence of add-on parenteral drugs is dihydropyridine CCB (nicardipine: onset 5 to 15 minutes, duration 4 to 6 hours, and increases stroke volume and reduces both cardiac and cerebral ischemia; clevidipine may also be used) and then α- + β-blocker (labetalol: liver metabolism, onset in 2 to 5 minutes, peak at 5 to 15 minutes, duration 2 to 4 hours, maintains cardiac output because of α-blocking effect). In addition, the ultimate therapy includes loop diuretics, RAS blocker, and clonidine. Loop diuretics are essential, especially in acute glomerular diseases, to reduce volume and pressure. ACEIs improve renal blood flow and reduce ischemia; they are essential in acute vascular forms of renal failure, such as scleroderma renal crisis.

Regarding long-term management, it is important to note that patients with CKD die from heart disease more than anything else. CKD is a risk factor for CAD, valvular heart disease, and other causes of heart disease. HTN control is critical to reduce the rate of development of these cardiovascular processes. If HTN is controlled, CKD progresses more slowly. Because the mechanism of HTN in the patient with CKD is RAAS activation, ACE inhibitors and ARBs are

particularly valuable agents. The choice of agents often is dictated by the presence or absence of proteinuria (for which an ACEI or ARB is essential) or if edema is present (for which a diuretic is needed). In patients with proteinuric CKD, ACEI and ARB are first-line agents, irrespective of race.[2] Second-line agents include diuretics and non-dihydropyridine CCB (as they reduce proteinuria), although a diuretic is preferred in the setting of edema. In the absence of proteinuria, diuretics are preferred first-line agents, and these can be followed by dihydropyridine CCB and angiotensin blockers in patients with edema; in the absence of edema, ACEI/ARB or CCB can be used first.[7]

PLAN FOR DISCHARGE THERAPY

Once discharged from the CCU, the patient must take seriously the importance of secondary prevention, of which BP control is an important component.

Lifestyle modifications that have been associated with favorable results in hypertensive patients include weight loss, increased physical activity, smoking cessation, and a low-fat, low-sodium diet. Tightly controlled dietary modification, as in the Dietary Approaches to Stop Hypertension (DASH) study, for example, can reduce mean SBP by 3.0, 6.2, and 6.8 mm Hg in subjects on a low-, intermediate-, and high-sodium-intake diet, respectively. Weight loss, reduced sodium intake, moderation of alcohol consumption, exercise, and an overall healthy dietary pattern are entirely appropriate for patients aiming to control HTN.

Oftentimes, pharmacologic treatment is necessary to control BP, especially for patients discharged from the CCU. The most important question to ask when selecting the initial drug treatment is, which class of drug will deliver the most effective BP lowering for this patient? As mentioned, certain medications have beneficial effects for certain disease states that go beyond the medication's BP-lowering effects (β-blockers for HF). However, it must be emphasized that BP lowering is in itself a driver of benefit. In other words, regardless of the drug used, the goal should be to, lower BP. The response to different classes of drugs is similar when compared head-to-head in heterogeneous populations. However, individual responses can differ strikingly.

Patient and Family Information for: HYPERTENSION IN THE CARDIAC CARE UNIT

CARDIOVASCULAR SYSTEM AND HYPERTENSION

The cardiovascular system serves to propel and transport blood, which carries the elements necessary for healthy functioning of all the organs of the body. Oxygen, glucose, electrolytes, immune cells, clotting cells, and a variety of other blood components must travel to every part of the body.

The cardiovascular system is sometimes compared to a water system with a pump and water pipes. It is a closed system, in that the system is self-contained; there are no openings to the outside. All the blood that starts in the heart returns to the heart (unless, of course, there is damage to the system, as in a tear to a vessel that results in internal or external bleeding). The pipes that leave the pump are largest because they must bear the greatest volumes and pressures. The pipes let off more and more branches as they get farther from the source and therefore get smaller and thinner. The vessels that leave the heart are arteries that feed capillaries before the blood makes its way back to the heart in veins.

BP is an index of the force per unit area inside the arteries. Factors that influence BP are the rate of blood flow through the vessel and the flexibility of the blood vessel wall. The rate of blood flow ejected from the heart through the arteries and veins per minute (cardiac output) depends on the number of heart beats per minute (heart rate) and the amount of blood ejected per beat (stroke volume). The flexibility or resistance of blood vessel walls depends on many factors including age, the nervous system, and hormones. In summary, the heart pump and its cardiac output along with the blood vessels and their resistance are what determine a person’s BP. This is important because it serves as the basis for

understanding how such factors as age, medications, and lifestyle influence our BP.

The medical term for high BP is HTN. HTN is defined as a BP of 140/90 mm Hg or above. The first number represents the SBP; the second is the DBP. As mentioned, the heart beats to propel blood, and does so, on average, between 60 and 80 times/min. When the heart ejects blood, the pressure in the arteries goes up because the pressure generated in the heart's largest chamber is transmitted throughout the closed cardiovascular system and there is a surge in the rate of blood flow through the arteries; this yields the SBP. After the heart muscle contracts, it must relax to prepare for the next contraction and in so doing allows for blood, which returns through veins, to refill the chambers of the heart. This yields the DBP: the pressure in the arteries during the heart muscle's relaxation phase.

CCU AND HYPERTENSION

The CCU is where patients go when they are too sick to be adequately managed on a general hospital floor. The patient in the CCU needs more specialized care and to this end is managed by nurses and doctors with specialized training in critical care and cardiovascular medicine. The nurses are responsible for fewer patients than on a general floor, and thus are able to dedicate a greater level of attention to each patient. The team of doctors assigned to the CCU remains in that unit throughout the day, rather than moving throughout the hospital.

Patients can be admitted to the CCU for a variety of conditions, such as heart attack, HF, tears in the aorta (the major artery that leaves the heart), and very high BP. BP is an important component of every disease condition that warrants a CCU admission. In some cases, BP can be dangerously high; in others dangerously low. In some cases, aberration in BP (too high or too low) is the source of the problem (hypertensive emergency causing HF), whereas in others it is the result of the problem (heart attack causing dangerously low BP). Regardless, BP is something the CCU doctor must manage for every patient, and something the patient must be educated about and take seriously, both for the short term and for the long term.

DRUGS

Surely, patients and their families have heard doctors use an overwhelming number of names of drugs. Not only are there a seemingly endless number of medications but also every medication has at least two names, a generic name and a brand name (ie, metoprolol is also Lopressor and Toprol). It makes things simpler to think of drugs in terms of drug classes. This is how doctors think, and for good reason. Drugs that make up a drug class perform a similar function via a similar mechanism. β-Blockers, for example, help block activity of the β-receptor, found on the surface of many cells, including those of the heart and blood vessels. β-Blockers are very important in the treatment of HF and HTN (among other things). Furthermore, most drugs in a class have a similar-sounding generic name. β-Blockers, for example, end in "lol" (ie, metoprolol, carvedilol, atenolol). So, for example, one remembers the β-blockers as the "-lol" drugs, which are used to treat HF. ACEIs are the "-pril" drugs (ie, lisinopril, captopril, enalapril) most commonly used to treat HTN, HF, and kidney disease. A drug class that is similar to the ACEIs is the ARB family, or "-artan" drugs (ie, irbesartan, candesartan, losartan). These drugs have clinical indications similar to those of the ACE inhibitors, and have the benefit of a lesser likelihood of causing cough as an adverse effect. The CCBs can be subdivided into the dihydropyridne and non-dihydropyridines. The dihydropyridine CCBs are commonly used BP medicines, and can be remembered as the "-dipine" drugs (ie, amlodipine, nicardipine, nifedipine). The α-blocker medicines mediate their BP-reducing effects by blocking a receptor on blood vessels responsible for vessel constriction (as the vessel diameter gets smaller, the pressure within the vessel increases). These "-osin" (ie, tamsulosin, terazosin, doxazosin) medicines have a second use in relieving the symptoms of urinary frequency, hesitancy, and urgency associated with benign prostatic hyperplasia, or BPH. Thinking in terms of classes of medicines, which conveniently tend to have similar-sounding and thus easier-to-remember names, is much easier and more intuitive than remembering individual drugs.

HYPERTENSION AND ITS ROLE IN THE COMMON CCU DISEASE PROCESSES

As mentioned, patients are admitted to the CCU for a variety of conditions, most, if not all, of which have HTN as a significant consideration, either as cause, effect, or important comorbidity.

HYPERTENSION AND DISEASES OF THE AORTA

The aorta is the largest artery of the body. Because it is the first vessel that blood travels through once it leaves the heart, within it travels all of the blood that leaves the heart. All other vessels are branches of a larger vessel and therefore will only receive a fraction of the cardiac output (blood leaving the heart per minute), whereas the aorta must withstand the volume and pressure of the entire cardiac output. It is no surprise, then, that the aorta is the largest, thickest-walled blood vessel in the body. One can imagine that diseases of the aorta are potentially catastrophic; for example, a ruptured vessel in the finger will cause that vessel to spill its fraction of cardiac output, whereas a rupture of the aorta will lead to rapid loss of a huge proportion of the body's blood. Motor vehicle accidents, for example, in which the passenger is propelled forward, and then held back by a seat belt, can cause the aorta to tear, leading to immediate death.

Patients admitted to the CCU for disease of the aorta often have an acute aortic syndrome, subdivided into three conditions: aortic dissection, intramural hematoma, and aortic ulcer. An aortic dissection is a tear in the innermost lining of the aorta; an intramural hematoma is a pooling of blood in the wall of the aorta without any tear in the lining of the vessel; an aortic ulcer occurs when a plaque in the inner lining of the vessel leads to erosion of the inner part of the vessel wall and swelling of the vessel contained by the outermost lining of the wall. Patients with any of the acute aortic syndromes will usually feel sudden onset, severe, "ripping" or "tearing" pain that often feels like it goes through the chest and into the back.

Aortic dissection is a tear in the innermost lining of the aorta such that blood begins infiltrating the wall of the vessel. The problem is that this infiltrating blood pushes the inner lining into the pathway of oncoming blood, leading to obstruction to flow and an expansion of the tear. If the tear is in the first "ascending" part of the aorta, the patient needs surgery; if the tear is in the "descending" aorta, the management is medical and not surgical. Aortic dissection may be a consideration for a patient who presents with chest pain, especially patients who smoke and/or have HTN. Aortic dissection can easily be confused with heart attack; this is important because not only are the treatments different but certain treatments for heart attack, for example, clot breaking medication, can be harmful for a patient with aortic dissection.

High BP is the major risk factor for both types of aortic dissection, and BP is also the major target of medical treatment. Precipitous reductions in BP can sometimes be dangerous in other conditions such as ischemic stroke, but in the

case of acute aortic dissection, the physician can and should be aggressive in lowering BP. BP reduction helps prevent extension of the tear, which could lead to stroke, cardiac tamponade, or other major complications. Every time the heart beats, a surge of blood exerts a force against the vessel wall, forcing blood into the tear and potentially causing the tear to enlarge and extend. β-Blockers, the "-lol" drugs, are often used because they lower not only BP but also the heart rate. IV β-Blockers such as labetalol are used for rapid BP and heart rate reduction to a target of under 120 mm Hg BP and under 60 beats/min heart rate, or as low as tolerated by the patient (lowering heart rate or BP too much can lead to such symptoms as dizziness). The patient is sent to the CCU to continuously monitor heart rate and BP in response to IV medication and also to monitor electrocardiogram readings in case the dissection leads to complications. Once BP is controlled, the patient can be switched to oral medications. The patient must understand the importance of compliance with medical and lifestyle recommendations to prevent future complications of aortic dissection.

HYPERTENSION AND ACUTE NEUROLOGIC SYNDROME

Patients may often be admitted to the CCU for stroke or hypertensive encephalopathy. Stroke, or cerebrovascular accident, is due to decreased oxygenated blood supply to the brain. A heart attack is death of heart muscle due to decreased blood flow to the heart, whereas stroke is death of brain cells due to impaired blood flow to the brain. If blood flow is restored before cell death occurs, brain function may recover completely; this condition is referred to as a TIA or transient ischemic attack. Stroke can be thought of as coming in two forms: stroke due to a blockage (ischemic stroke) versus bleeding (hemorrhagic stroke) of an artery supplying the brain. The end result, brain cell death, is similar for both. In addition, stroke may increase pressure in the skull and thus cause compression of surrounding healthy brain tissue because of edema or swelling in ischemic stroke and accumulation of blood in hemorrhagic stroke. In hypertensive encephalopathy, on the other hand, severe HTN causes not localized brain ischemia but rather global brain dysfunction with its associated symptoms. As a result, patients suffering from stroke often have focal neurologic deficits (weakness in a limb, slurring of speech, facial drooping), whereas patients with hypertensive encephalopathy lack focal symptoms and present instead with nausea, blurry vision, headache, and/or altered consciousness.

The first step in the assessment of a patient with suspected neurologic syndrome is a head CT scan to evaluate for bleeding in the skull. CT scans are

effective for detecting blood, and although not necessarily helpful in the diagnosis of hypertensive encephalopathy or early ischemic stroke, a CT scan is the first test because an intracranial bleed, if found, might require immediate neurosurgery.

HTN is a major risk factor for acute neurologic syndrome, and a major target of therapy. For hemorrhagic stroke, BP must be lowered promptly but not to such an extent that arterial pressure becomes inadequate to sufficiently overcome intracranial pressure; cerebral perfusion pressure, or the net BP gradient responsible for blood flow to healthy brain tissue, depends on adequate arterial pressure. Generally, the BP goal is 140 mm Hg for SBP. For ischemic stroke, it has been commonly accepted in the medical community that aggressive lowering of BP may do more harm than good. On the other hand, high BP increases the risk of expansion of edema and/or conversion of an ischemic stroke into a hemorrhagic one. Many patients have spontaneous declines in BP during the first 24 hours of stroke onset. In general, the BP goals for patients with ischemic strokes are different depending on whether interventions involving “clot busters” called “thrombolytics” are undertaken to reestablish blood flow in the blocked artery. When thrombolytic therapy is undertaken, lower BP targets are aimed for during and after the procedure (around 180/105 mm Hg). When thrombolytics are not used, no treatment is required when BP is less than 220/120 mm Hg. In 2013, an expert panel reiterated these recommendations.

For hypertensive encephalopathy, the baseline BP must be taken into consideration to avoid excessive BP lowering and to prevent cerebral ischemia. Lowering the mean pressure by 10% to 15% in the first hour and by 25% over 1 day is usually safe.

HYPERTENSION AND ACUTE CORONARY SYNDROME

An ACS is a decreased blood supply to the heart (myocardial cell ischemia) that may or may not result in myocardial cell injury or death and that is due to CAD. The three forms of ACS are unstable angina, non-STEMI, and STEMI. These three entities are manifestations of the same disease process and were extensively discussed in Section A of this book.

The heart is thought of as the organ that supplies blood to the rest of the body; in fact, the heart supplies blood to the rest of the body and to itself. It does so through vessels known as coronary arteries, which come off the aorta immediately after the blood leaves the heart. There are three large coronary arteries that travel along the surface of the heart before diving deep to feed all

the cells of the heart muscle. A blockage to flow in any of the coronary arteries can cut off supply enough to starve cells and lead to their death. If cells of a certain portion of the heart fail to beat adequately, the heart may not generate enough force to sustain cardiac output. A heart attack, or MI, may cause the heart to stop beating effectively (HF), or stop beating altogether (sudden cardiac death). HTN is considered a major risk factor for CAD, and thus for MI and HF.

The key concept to understand regarding coronary blood supply is that of supply and demand. The heart is unique in that it is responsible for both its supply and demand. As the heart beats harder, it supplies more blood flow, but it also demands more blood flow. HTN affects demand: higher BP forces the heart to beat harder, thus increasing the heart's demand for blood. A 70% blockage may still allow the necessary blood supply to the normotensive patient's heart, but for the hypertensive patient's more demanding heart, a 70% blockage may result in chest pain or, worse, myocardial cell damage. HTN also affects supply: higher BP leads to the development of the blockages themselves. Through mechanisms, many still to be completely understood, HTN promotes atherogenesis, or the development of plaques within the inner lining of arteries such as the coronary arteries. Not only do plaques make passageways for blood flow narrower over time but they can also rupture, releasing contents that can immediately clot and completely block blood flow. This plaque rupture is what usually causes devastating MIs.

Initial therapy of HTN in patients presenting to the CCU with an ACS should use medications that improve myocardial supply, lessen demand, or both. β-Blockers, for example, not only lower BP but they also lower the heart rate, and thus lessen the amount of energy the heart expends and the amount of blood flow it demands. Nitrates lower BP, but they also lessen the amount of blood returning to the heart, thus lessening the volume of blood the heart must pump per beat, which also lessens demand. Nitrates and β-blockers are often first-line BP medications in patients with ACS. One exception is in the patient whose heart is so damaged that lowering the heart rate may further lessen cardiac output; in this situation, β-blockers should not be used. ACEIs and ARBs can also be used to lower BP.

Target BP is 140/90 mm Hg. DBP should not be lowered too significantly because it is the diastolic pressure that provides the force to send blood through the coronary arteries; too low a DBP may be harmful.

Upon discharge, the patient who has suffered a heart attack should be on a β-blocker and ACEI if possible. These medications lower BP and help the heart

preserve or even regain function.

HYPERTENSION AND HEART FAILURE

The heart, as described, is a pump that allows for blood to be propelled throughout the cardiovascular system of blood vessels. To effectively perform this task, the heart must fill with an adequate volume of blood, pass this blood between each of its four chambers, and have sufficient muscle strength to eject blood against a significant resistance in the aorta to the entire body.

Chambers divide the heart into a right (right atrium and right ventricle) and left (left atrium and left ventricle) side. When blood returns to the heart through veins, it passes through the right atrium and ventricle before passing through the lungs to pick up oxygen and then passes to the left atrium and ventricle, where sufficient pressure is generated to propel blood to the entire body. The left ventricle is the heart's strongest and largest chamber.

HF is failure of the heart to propel blood, whether because the muscle is weak or because the heart does not fill adequately, such that either cardiac output is insufficient to meet the demands of the body's tissues or these demands are met at the expense of blood "backing up" in the direction of the lungs. In other words, HF can be due to poor forward flow or adequate forward flow but with concomitant inappropriate backward flow.

HF can be due to a multitude of abnormalities: ischemia such as in the form of a heart attack; damaged valves; drugs such as alcohol or certain chemotherapies; and, of course, HTN are among the many possible causes of HF.

HTN forces the heart to pump harder to overcome the greater resistance to forward flow, and over time the heart muscle starts to fail; it may become stiff or weak or both, resulting in forward and/or backward flow failure.

Acute HF is one of the most common reasons for admission to the CCU. A patient may have already been diagnosed with HF, and for some reason (not taking medications, not adhering to a dietary regimen, an irregular heart rhythm, a heart attack, uncontrolled BP) suffer an insult that disrupts the delicate balance and throws the patient into acutely symptomatic HF. It is also possible that a patient admitted to the CCU with HF never had any symptoms of HF. A previously adequately functioning heart may go into failure because of a heart attack, or severe damage to a heart valve, or severe HTN. A heart that is accustomed to beating against a BP of 120/80 mm Hg may fail to overcome a sudden burden of 220/120 mm Hg, or a heart that is forced to beat against a pressure of 150/100 mm Hg for years and years may do well in the beginning

but with time, stretch and thicken and eventually decompensate. Regardless of the scenario, to treat HTN is to relieve the burden against which the failing heart is struggling to pump.

HTN is a common cause of HF; about 75% of patients admitted with HF have HTN. HTN is also a major target of therapy for HF. In fact, the medications that treat HF—β-blockers ("-lol" meds), ACEIs ("pril" meds), ARBs ("-artan" meds), and diuretics or water pills—also have effects on BP.

The initial urgent step is to stabilize the patient. A doctor will aim to reduce BP, ultimately to 140/90 mm Hg or lower, although not too quickly as to potentially starve certain tissues of adequate blood supply. Once the patient is stabilized, tight BP control becomes a fundamental component of long-term care. The patient with HF can easily decompensate again if he or she has a drinking binge, or salty-food binge, or skips a couple of days' doses of medicines. Managing HTN must be emphasized as crucial for preventing future decompensations and giving the heart the best chance of recovering over time.

HYPERTENSION AND RENAL FAILURE

The kidneys filter blood; they excrete much of what is not needed and retain much of what is needed. They also help maintain total body water and electrolyte (sodium, potassium, calcium, etc.) concentrations within a rather narrow healthy range. When a person becomes dehydrated, the kidneys are able to retain fluid and reduce urine output dramatically; if a person were to drink excessively, the kidneys could excrete liters and liters of free water daily. The elegant and delicate mechanism that allows such regulation involves an intricate series of blood vessels and kidney tubules and electrolyte channels; this delicate structure can be disrupted when forced to withstand the forces of high BP over many years.

Renal failure can be acute or chronic; in other words, it can develop over hours to days often with obvious symptoms, or it can develop slowly often without symptoms for several years after kidney damage first begins. HTN can cause both acute and chronic kidney damage. In fact, HTN is the second leading cause of CKD, after diabetes. Renal failure can be a reason for admission to the CCU (when due to hypertensive emergency), but more likely, it is a common complication of another disease process that warrants admission to the CCU.

Hypertensive emergency is defined as BP high enough (often DBP above 120 mm Hg) to cause end-organ damage. "End organs" most commonly affected by extremely high BP are the brain, heart, and kidneys. The high BP damages the

delicate system of arteries feeding the kidney and disrupts the filtering mechanism, leading to such symptoms as decreased urine output, nausea, swelling in the legs, and generalized malaise. The goal in management of acute renal failure due to severe HTN is to limit further renal damage through BP control. The choice of optimal drug therapy is controversial. Although nitroprusside is the drug with the longest track record, it does have potential cyanide and thiocyanate toxicity, especially with prolonged infusions of high doses of nitroprusside. Fenoldopam is another useful IV agent. Other antihypertensive drugs that preserve renal blood flow are CCBs and adrenergic blocking agents.

It is worth mentioning that kidney damage is not only a consequence of HTN but also a cause of HTN. Patients with CKD, especially those on dialysis, are at very high risk for having HTN.

As mentioned, although kidney disease due to hypertensive emergency is a cause for CCU admission, more commonly a patient in the CCU for some other reason (heart attack, HF) develops renal failure concomitantly because the heart attack or HF, for example, led to decreased blood supply to the kidneys. The renal failure makes more complicated the treatment of heart disease and becomes in itself an important target of treatment. For example, diuretics, often referred to as “water pills,” are critical for HF treatment. A patient in the CCU with HF is often “volume-overloaded,” sometimes as much as 20 or 30 pounds heavier than usual because of water retention. The goal is to remove this water, but (1) this fluid removal can damage the kidneys, and (2) kidney damage coupled with the low output state of HF can make the fluid removal difficult. The kidney damage, at least partly brought on by the HF and/or its treatment, has made treatment of the HF more difficult. In recent years, some doctors have used the term “cardiorenal syndrome” precisely to emphasize how strongly linked are the kidney and the heart, in that function and treatment of one very often affects function and treatment of the other.

In summary, kidney damage can be a reason for CCU admission, as in the case of hypertensive emergency, but more often, kidney damage is related secondarily to, and complicates treatment of, the primary disease process that necessitated CCU admission. Good management of HTN can help preserve both kidney and cardiovascular health. When the patient with kidney damage recovers and leaves the hospital, BP control is of paramount importance.

Diabetes Mellitus in the Cardiac Care Unit

INTRODUCTION

Diabetes mellitus (DM) is a complex chronic condition, with heterogeneous clinical presentation and disease progression, depending on the type of diabetes and its underlying pathophysiology. However, the defining feature of diabetes is an inappropriate elevation of blood glucose (BG), known as hyperglycemia, regardless of the underlying pathophysiologic disorder. Persistent chronic hyperglycemia leads to tissue injury resulting in micro- and macrovascular complications, such as neuropathy, retinopathy, nephropathy, and cardiovascular diseases (CVDs).

In the initial part of this chapter, we discuss the diagnostic and classification criteria of DM and general principles of care in patients with diabetes; in the latter part we focus on diabetes management in the CCU setting and discuss epidemiologic studies of patients admitted to the CCU with diabetes, outcomes in patients with hyperglycemia admitted to the CCU, and an overview of strategies for hyperglycemia management in the CCU.

DIABETES MELLITUS: GENERAL PRINCIPLES

WHAT IS DIABETES MELLITUS? DIAGNOSIS AND CLASSIFICATION

The defining feature of DM is an inappropriate elevation of BG—hyperglycemia. This could be due to excessive glucose production, impaired glucose clearance, or both. Sustained, chronic hyperglycemia, over several years, leads to tissue injury resulting in chronic micro- and macrovascular complications such as diabetic neuropathy, retinopathy, and nephropathy and atherothrombotic vascular diseases. "Inappropriate" hyperglycemia has been defined by experts as the level which, if chronically sustained, will lead to the development of diabetic complications.

The current criteria used to make the diagnosis of DM are listed in **Table 54.1**. According to the American Diabetes Association (ADA) 2011 criteria, either random plasma glucose, fasting plasma glucose, an oral glucose tolerance test, or a hemoglobin A_{1C} (% glycosylated hemoglobin, A_{1C}) can be used to diagnose diabetes.[1]

TABLE 54.1 Diagnosis of Diabetes Mellitus

CRITERIA FOR THE DIAGNOSIS OF DIABETES

1. $A_{1C} \geq 6.5\%$. The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay (http://www.ngsp.org, accessed January 2, 2017)[a]
   OR
2. FPG ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 h[a]
   OR
3. Two-hour plasma glucose ≥ 200 mg/dL (11. 1 mmol/L) during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water[a]
   OR
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥ 200 mg/dL (11. 1 mmol/L)

CATEGORIES OF INCREASED RISK FOR DIABETES (PREDIABETES)[b]

1. FPG 100–125 mg/dL (5.6–6.9 mmol/L) [IFG]
2. Two-hour plasma glucose in the 75-g OGTT 140–199 mg/dL (7.8–11.0 mmol/L) [IGT]
3. A_{1C} 5.7%–6.4%

[a]In the absence of unequivocal hyperglycemia, criteria 1–3 should be confirmed by repeat testing.
[b]For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at higher ends of the range.

NGSP: National Glycohemoglobin Standardization Program, DCCT: Diabetes Control and Complications Trial, FPG:

Fasting plasma glucose, OGTT: Oral glucose tolerance test
IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

DM is currently classified by etiology as type 1, type 2, gestational, or other specified types (**Table 54.2**). Type 1 diabetes is characterized by an absolute or severe insulin deficiency and is immune mediated. Type 2 diabetes is a complex polygenic disease characterized by both insulin resistance and relative insulin deficiency, that is, insulin levels and secretion are inappropriate to the levels of insulin resistance and out of proportion to the glucose stimuli (dual defect).[2] Gestational DM is characterized by onset during pregnancy owing to increased insulin resistance generated by the hormonal milieu. Typically, it resolves at the end of pregnancy; however, women with gestational diabetes are at higher risk for developing type 2 diabetes later in life.[3] Other specific types of diabetes listed by etiology are a result of genetic defects in β-cell function and/or insulin action (monogenic diabetes), exocrine pancreatic disease, some endocrinopathies, drug or chemically induced (exogenous corticosteroid administration, etc.), or other rare forms (infections, immune mediated, etc.). These specific forms could manifest clinically in a manner similar to either type 1 or type 2 diabetes.

TABLE 54.2 Classification of Diabetes Mellitus

Type 1 Diabetes
• Due to autoimmune β-cell destruction, usually leading to absolute insulin deficiency
Type 2 Diabetes
• Due to a progressive loss of β-cell insulin secretion frequently on the background of insulin resistance
Gestational Diabetes
• Diabetes diagnosed in the second or third trimester of pregnancy that was not clearly overt diabetes prior to gestation.
Other Specific Types
• Monogenic diabetes syndromes • Neonatal diabetes • Maturity-onset diabetes of the young (MODY) • Diseases of the exocrine pancreas (cystic fibrosis, etc.) • Drug- or chemical-induced diabetes (treatment of HIV/AIDS, glucocorticoids, treatment after organ transplantation)

Adapted from: American Diabetes Association. Classification and diagnosis of diabetes. Sec. 2. In Standards of Medical Care in Diabetes 2017. Diabetes Care 2017;40(Suppl. 1):S11–S24

Type 1 Diabetes

Certain clinical aspects of diabetes presentation are characteristic of type 1 diabetes: diabetic ketoacidosis (DKA); signs of insulin deficiency such as weight loss and/or BG level above 250 mg/dL accompanied by non–fasting positive urine ketones; acute onset in a child or young adult; triggered by recent infection or viral illness; onset during puberty or association with other autoimmune diseases (thyroiditis, Graves disease, pernicious anemia, celiac, and Addison disease).

Type 2 Diabetes

The pathogenesis of type 2 diabetes is very different from that of type 1 diabetes. As opposed to type 1 diabetes, in type 2, insulin resistance is almost universally present, and the defect in insulin secretion is milder—just secretion is not high enough to overcome the resistance (β-cell dysfunction).

Prediabetes and Screening for Diabetes Mellitus

Type 2 diabetes is often preceded by a condition called prediabetes characterized by either abnormal fasting glucose levels (impaired fasting glucose or IFG) and/or impaired glucose tolerance (IGT, abnormal postprandial glucose), which leads to increased levels of A_{1C} (**Table 54.1**). During the prediabetes stage, there is a gradual increase in insulin resistance as a result of various causes (aging, obesity, physical inactivity, or genetics) which, when not accompanied by an increase in insulin secretion, will eventually result in elevated BG levels in the diabetic range (**Figure 54.1**). Prediabetes can be identified through the same tests used to diagnose diabetes (**Table 54.1**). It is now recommended that individuals at risk be screened for the presence of type 2 diabetes (**Table 54.3**).[1] During this screening, normal glucose tolerance, prediabetes, or full-blown diabetes can be identified. The screening is very important because (a) preventive measures such as weight loss and/or increased physical activity and sometimes pharmacologic measures could prevent or delay the development of type 2 diabetes in the individuals with prediabetes and (b) early diagnosis and treatment of the clinical manifestation of type 2 diabetes could prevent chronic complications and improve chances of survival.

TABLE 54.3 Criteria for Testing for Diabetes in Asymptomatic Adult Individuals

1. Testing should be considered in all adults who are overweight (BMI ≥25 kg/m2 or ≥23 kg/m2 in Asian Americans) adults who have one or more of the following risk factors:
   A1C≥5.7% (39 mmol/mol), IGT, or IFG on previous testing Physical inactivity
   First-degree relative with diabetes mellitus
   Members of a high-risk race/ethnicity (eg, African American, Latino, Native American, Asian American, Pacific Islander)
   Women who delivered a baby weighing >9 lb or were diagnosed with Gestational Diabetes Mellitus (GDM)
   Hypertension (140/90 mm Hg or on therapy for hypertension)
   HDL cholesterol level 250 mg/dL (2.82 mmol/L)
   Women with polycystic ovary syndrome (PCOS)
   Other clinical conditions associated with insulin resistance (eg, severe obesity, acanthosisnigricans)
   History of CVD
2. In the absence of the above mentioned criteria, testing for diabetes should begin at age 45 y
3. If results are normal, testing should be repeated at least at 3-y intervals, with consideration for more frequent testing depending on initial results and risk status

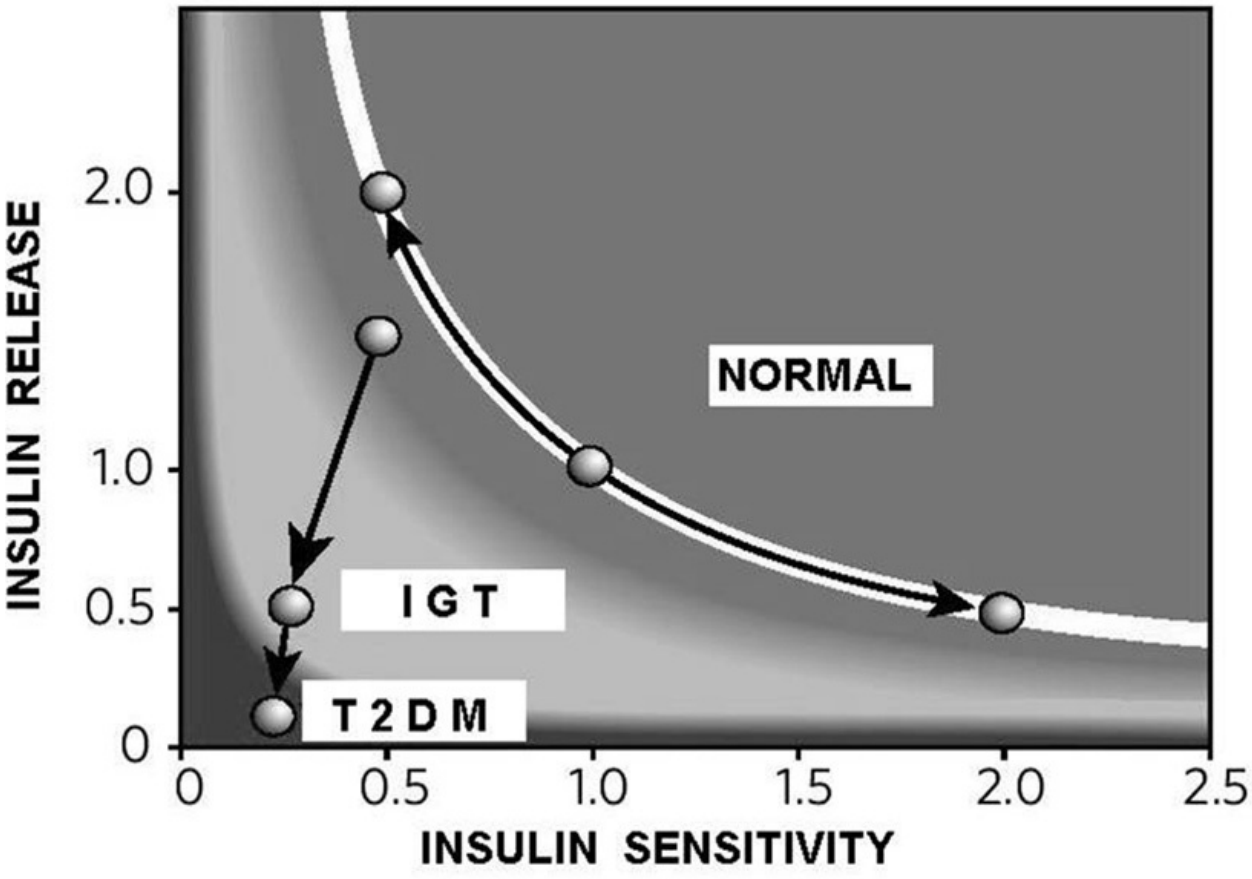

FIGURE 54.1 Relationship between insulin sensitivity and insulin release. DM, diabetes mellitus; IGT, impaired glucose tolerance.

Metabolic Syndrome

Prediabetes and insulin resistance are integral parts of the so-called metabolic syndrome, which is defined as a clustering of risk factors that predict the

development of both type 2 diabetes and CVD. More than 80% of patients with type 2 diabetes have metabolic syndrome and clustering of risk factors for CVD, which include hypertension, dyslipidemia, and associated inflammation and hypercoagulable state.[4] The clustering of these risk factors predicts the development of CVD independent of the degree of hyperglycemia. The treatment of the risk factors and the underlying pathophysiologic causes could prevent both diabetes and CVD. The most prominent underlying modifiable pathophysiologic causes are abdominal obesity and insulin resistance.[5] Inflammation and hypercoagulable states are also important factors to be addressed. The comprehensive treatment of the metabolic syndrome includes smoking cessation, assessment of diabetes risk and implementation of diabetes prevention strategies, control of blood pressure, control of glucose if type 2 diabetes is present, reduction of abdominal obesity, increase in physical activity to at least 30 minutes of activity daily (above usual), decrease in saturated fats to less than 7% of total calories, elimination of trans fat, addressing lipid levels such as low-density lipoprotein, triglycerides, and high-density lipoprotein cholesterol according to the 10-year calculated Framingham risk and eating five servings of fruits and vegetables per day.[6]

CLINICAL MANIFESTATIONS AND COMPLICATIONS OF DIABETES MELLITUS

Clinical manifestations of DM could be acute (DKA or hyperosmolar hyperglycemic state [HHS]) or chronic. The chronic complications manifest as microvascular (retinopathy, neuropathy, nephropathy) or macrovascular (cerebrovascular disease, coronary artery disease [CAD], peripheral vascular disease) disease. Other complications are susceptibility to infections and connective tissue disorders. Positive correlations were found between glycemic control (as measured by the A_{1C} level) and prevalence and incidence of diabetic microvascular complications. Prospective randomized trials have shown that intensive control of BG significantly reduces the risk of microvascular complications in both type 1 and type 2 diabetes. The effect of tight glucose control on macrovascular complications in the absence of intensified control of other risk factors for macrovascular disease is presently controversial. It is known, however, that tight control of other CVD risk factors such as hypertension and elevated lipids does significantly reduce risk of fatal and nonfatal macrovascular events in both type 1 and type 2 diabetes patients. This

reduction in risk was reported to be 20% to 50% with blood pressure control, 25% to 55% with lipid control, but only 10% to 20% with tight glucose control.[7] A comprehensive approach including tight glucose control and control of other CVD risk factors was reported to lower both micro- and macrovascular complications by 35%.[8] Unintended consequences and adverse effects of tight glucose control could be hypoglycemia, weight gain, and possible short-term worsening of proliferative retinopathy, especially and mostly when the patients require insulin, such as patients with type 1 or long-standing type 2 disease. Of particular concern is the effect of hypoglycemia on macrovascular event rates and outcomes.[7]

PHARMACOLOGIC TREATMENT OF HYPERGLYCEMIA: GENERAL PRINCIPLES IN THE OUTPATIENT SETTING

INSULIN: Patients with type 1 diabetes are always treated with insulin. In fact, one of the reasons it is very important to make the differentiation between type 1 and type 2 diabetes is to determine if there is a need for insulin at all times to avoid DKA. Patients with type 2 diabetes may also be requiring insulin for control of BG, although lack of insulin will not produce DKA except in rare cases. Insulin is used in type 2 patients when it is not possible to achieve glucose level goals with oral agents alone. Insulin treatment should be physiologic and anticipatory. That is, it should include long-acting (basal) insulin to suppress glucose production overnight and normalize fasting glucose and rapid-acting (prandial) insulin to cover meal-related glucose excursions. This physiologic concept is called the basal-bolus concept (**Figure 54.2**). Examples of different types of insulin and their peak action time and duration of action are shown in **Table 54.4**. Insulin delivered with a prefilled insulin pen, rather than from a bottle with a syringe and needle, is easier to accurately dose (**Figure 54.3A**). Similar principles, as described earlier, are used for continuous subcutaneous (SQ) insulin delivery systems utilizing an insulin pump (**Figure 54.3B**).

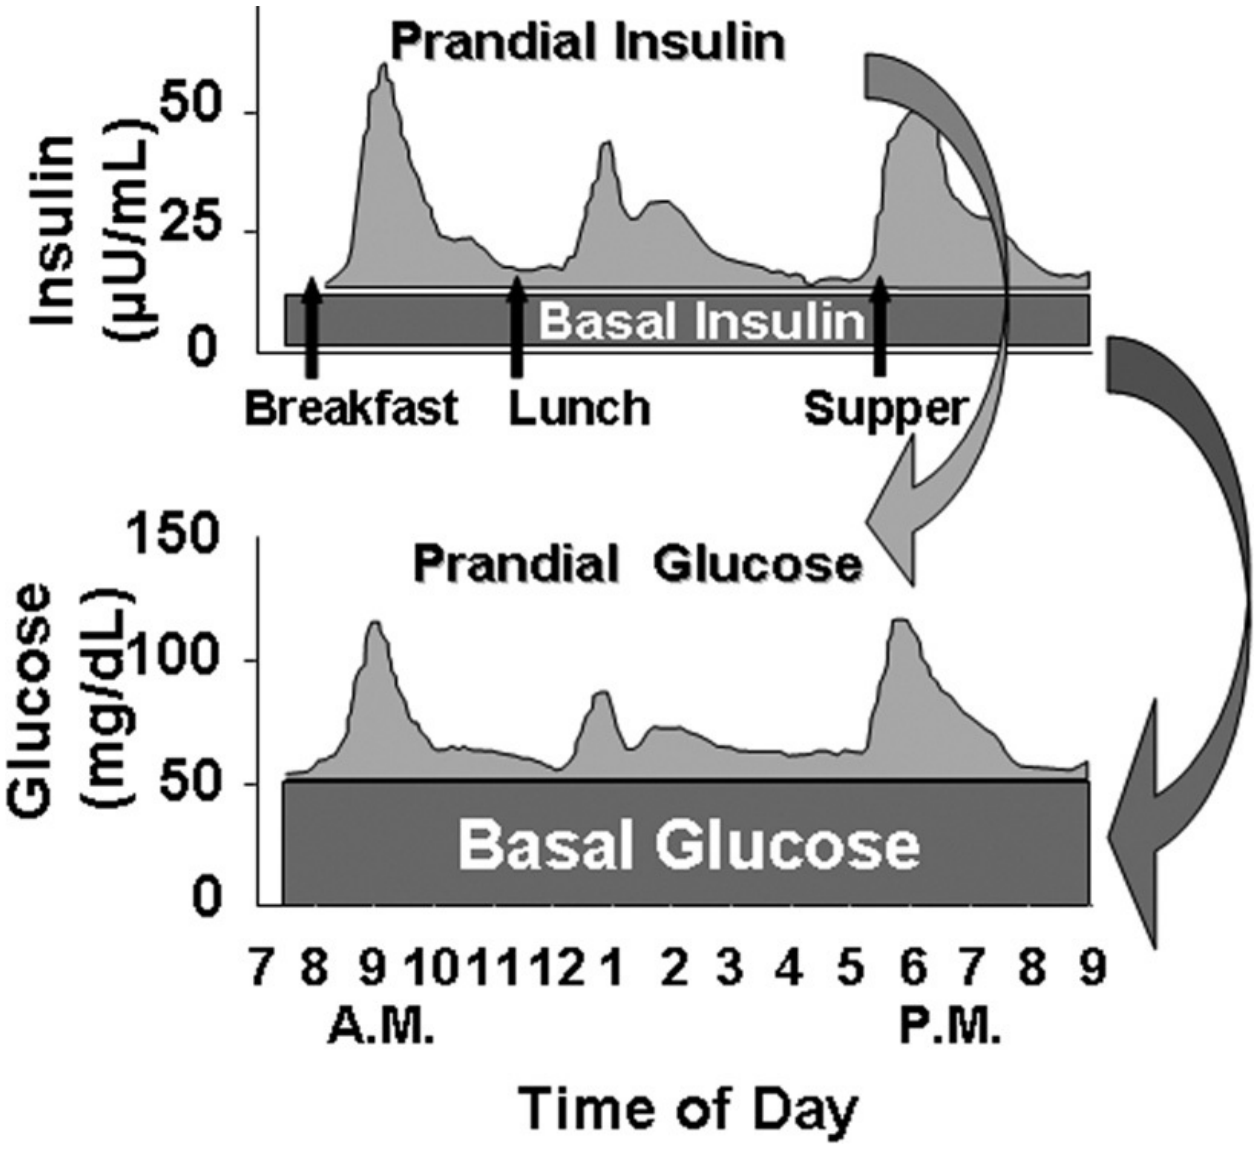

FIGURE 54.2 Physiologic insulin administration: the basal-bolus concept. The prandial insulin is 50% of the total daily dose administered before each meal to cover the prandial glucose excursions. The basal insulin is 50% of the total daily dose and controls fasting glucose by suppressing glucose production between meals and overnight. (Adapted from the Society for Hospital Medicine Glycemic Control Task Force presentation at www.hospitalmedicine.org.)

TABLE 54.4 Insulin Preparations by Subcutaneous Administration: Onset, Peak, and Duration of Action

INSULIN, GENERIC NAME (BRAND)	ONSET	PEAK	EFFECTIVE (h)
Rapid-acting (prandial or correction insulin)			
Aspart (Novolog), lispro (Humalog), glulisine (Apidra)	5–15"	30–90"	<5

Short acting (prandial or correction insulin)			
Insulin regular (Novolin/Humulin)	30–60"	2–3 h	5–8
Intermediate (basal insulin q12h)			
Insulin NPH (Novolin or Humulin) (OK in pregnancy)	2–4 h	4–10 h	10–16
Long-acting (basal insulin q24h or q12h)			
Insulin glargine (Lantus) (avoid in pregnancy)	2–4 h	No peak	20–24
Insulin detemir (Levemir) (avoid in pregnancy)	3–8 h	No peak	6–23
Premixed (basal and prandial mixed)			
75% Lispro prot. susp./25% lispro (Humalog mix 75/25)	5–15"	DUAL	10–16
50% Lispro prot. susp./50% lispro (Humalog mix 50/50)	5–15"	DUAL	10–16
70% Aspart prot. susp./30% aspart (Novolog mix 70/30)	5–15"	DUAL	10–16
70% NPH/30% regular (Novolin or Humulin 70/30)	30–60"	DUAL	10–16

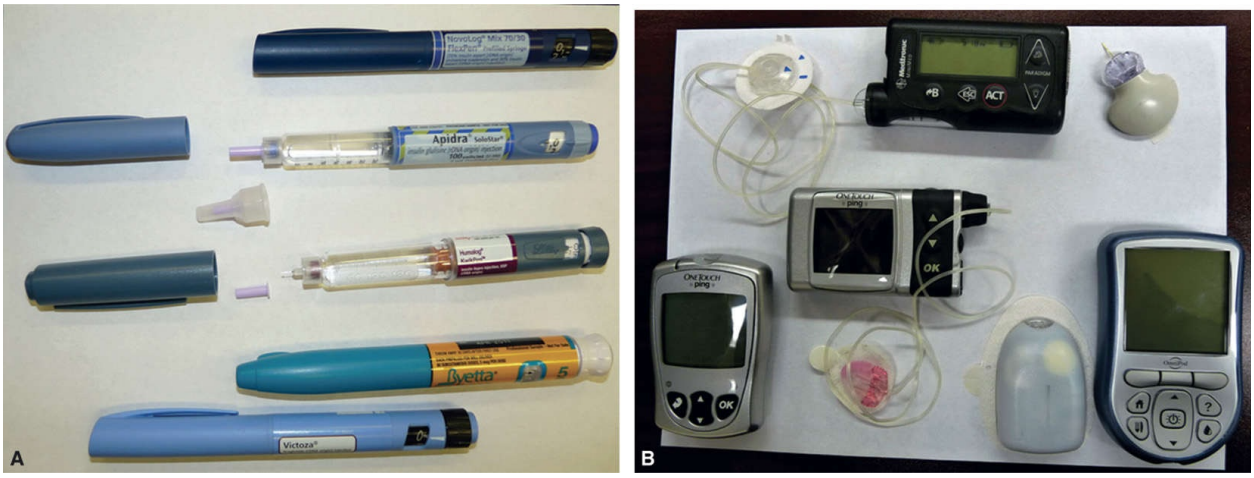

FIGURE 54.3 A, Insulin injection devices: insulin pens (short-acting, long-acting, and mixed insulins) and pens used to deliver GLP-1 analogs (Byetta and Victoza). Insulin pens are easier to use than syringes, improve patients' attitude and adherence towards the injectable treatment, and have accurate dosing mechanisms when used as prescribed. B, Insulin pumps and CGMS devices. Insulin pumps deliver insulin through a plastic catheter inserted subcutaneously; they can communicate wirelessly with a glucometer. CGMS devices measure glucose continuously through a sensor inserted subcutaneously. The hope is that in the near future, CGMS devices and insulin pumps could be combined to form an artificial pancreas. CGMS, continuous glucose monitoring system.

Oral Hypoglycemic Agents

These drugs lower glucose by several mechanisms: improve insulin resistance (sensitizers), improve insulin secretion (secretagogues), improve insulin secretion but also decrease glucagon and gastric emptying through modulation of incretin and gut hormone levels, and those which lower glucose by decreasing absorption in the gut or increase its excretion in the urine. The agents that improve insulin resistance are either biguanides (eg, metformin) or thiazolidinedione. They work through increasing insulin sensitivity in the liver, muscle, and adipose tissue. The secretagogues work directly on the β-cells (sulfonylureas, amino acid derivatives, and meglitinides). α-Glucosidase inhibitors decrease glucose absorption in the gut. Sodium-glucose co-transporter 2 inhibitors, the most recent class of oral hypoglycemic agents, reduce BG levels by increasing urinary glucose excretion. The drugs that work through modulating incretin levels (glucagon-like peptide or GLP-1 and others) are analogs of GLP-1 and dipeptidyl peptidase (DPP-4) inhibitors. DPP-4 inhibitors (eg, sitagliptin) enhance the effects of endogenous incretins by preventing their breakdown by DPP-4 as well as through other mechanisms. All these oral agents have potential side effects and have to be used with caution in hospitalized patients particularly when renal and hepatic failure are present, because they increase the risk of hypoglycemia. Combination treatments of different oral drug classes work well and are often used. Such combinations should be tried before insulin treatment is initiated. Insulin should be initiated early, however, if there is evidence of severe β-cell dysfunction, such as rapid weight loss or very high A_{1C} > 9%, despite sustained efforts at diet and exercise and multiple oral agent combinations.

GLP-1 Analogs and Amylin

Amylin is a hormone that is co-secreted from the pancreas together with insulin. Amylin was shown to play a role in synchronizing the emptying of nutrients from the stomach with the secretion of insulin through acting in the brain to slow gastric emptying, lower gluconeogenesis, and decrease food intake. In type 1 diabetes, amylin levels are low, and its replacement leads to less dramatic fluctuations of BG. GLP-1 analogs, which produce GLP 1 effects, that is, decrease in glucagon and increase in insulin and amylin secretions, have also been developed. These are drugs that need to be administered through an SQ injection, and increase GLP-1 to levels greater than those observed after

administration of DPP-4 inhibitors. GLP-1 analogs promote decrease in food intake and weight loss in a large number of overweight and obese patients who take them and are frequently prescribed to obese patients with type 2 diabetes. Their development in user-friendly pens enhances their excellent results (**Figure 54.3A**). Unfortunately, some patients may not be able to tolerate them because of nausea. More severe but infrequent side effects include acute pancreatitis and renal failure. These drugs are not indicated for use during hospitalizations.

Glycemic Targets in Outpatient Settings

It is currently recommended to aim for tight glucose control as early as possible in the course of diabetes treatment (**Table 54.5**).[1] The target A_{1C} level recommended by the ADA is less than 7% or as close to normal as is safely possible to achieve in most nonpregnant adults.[1] More stringent goals (such as 6.5%) could be sought if achieved without significant hypoglycemia or other adverse effects of treatment. This stringent goal could be recommended in patients with recent-onset diabetes, those treated with lifestyle or metformin only, those with long life expectancy, and/or no significant CVD. Less stringent goals (A_{1C} of 8% or less) are recommended for patients with a history of severe hypoglycemia, limited life expectancy, extensive complications and/or comorbid conditions, or those with long-standing diabetes in whom the goal is difficult to achieve despite appropriate education, monitoring, and appropriate use of multiple glucose-lowering agents including insulin.

TABLE 54.5 Recommendations for Glycemic Control during Chronic Outpatient Management

A_{1C} < 7.0%	
Preprandial capillary plasma glucose	90–130 mg/dL
Peak postprandial capillary plasma glucose[a]	180 mg/dL
Key concepts in setting glycemic goals are as follows: • A_{1C} is the primary target for glycemic control • Goals should be individualized based on	
Duration of diabetes	Known CVD or advanced microvascular complications
Age/life expectancy	Comorbid conditions

Hypoglycemia unawareness	Individual patient considerations
	• Certain populations (children, pregnant women, and elderly) require special considerations • More stringent goals (A_{1C} < 6.5%) if able to achieve without significant hypoglycemia or polypharmacy for individual patients: short diabetes duration, on lifestyle or metformin only, long life expectancy, no significant CVD • Less stringent goals (A_{1C} < 8%) for patients: with history of severe hypoglycemia, advanced diabetes complications, extensive comorbid conditions, limited life expectancy, long-standing diabetes where goal is difficult to achieve despite optimal treatment • Postprandial glucose may be targeted if A_{1C} goals are not met despite reaching preprandial goals

[a]Postprandial glucose measurements should be made 1to 2 hours after the beginning of the meal.
CVD, cardiovascular disease.

The A_{1C} should be tested every 6 months if the value is at target or every 3 months when not at target or when treatment changes. Levels of A_{1C} together with the prevalence of hypoglycemia will dictate the management of glucose control. Correlation of A_{1C} with average glucose level is seen in **Table 54.6**. If A_{1C} is less than 7% and the hypoglycemia is not frequent and/or severe, then the treatment can be maintained at the current level. If A_{1C} is between 7% and 8%, this is likely due to 2-hour postprandial elevations, the following need to be reviewed: meal and activity plans, glucose monitoring techniques and frequency, compliance with medication administration and schedule, and sick day management. If A_{1C} is more than 8%, in addition to previous recommendations, goal setting, assessment of psychosocial issues, DSME (diabetes self-management education workshops) referral and medication adjustments are likely all needed (**Table 54.5**).

TABLE 54.6 Correlation of A_{1C} With Average Glucose

	MEAN PLASMA GLUCOSE	
A_{1C}(%)	***mg/dL***	***mmol/L***
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4

11	269	14.9
12	298	16.5

These estimates are based on ADAG data of approximately 2,700 glucose measurements over 3 months per A_{1C} measurement in 507 adults with type 1, type 2, and no diabetes. The correlation between A_{1C} and average glucose was 0.92. A calculator for converting A_{1C} results into estimated average glucose (eAG), in either mg/dL or mmol/L, is available in http://professional.diabetes.org/eAG.

Hypoglycemia Management

The correct management of hypoglycemia is crucially important in all patients with diabetes who receive insulin or insulin secretagogue medications but especially in those with CVD or advanced complications. The hypoglycemia should be correctly evaluated and treated. It is defined as mild to moderate when levels of BG range from 50 to 70 mg/dL and/or patients can treat it themselves. It can be treated with oral, simple, easily absorbable carbohydrate, such as glucose tablets or gel, orange juice, or soft drinks containing 15 to 20 g of glucose. Glucose levels should be checked again in 15 minutes, and patients must be instructed to carry glucose with them at all times. Severe hypoglycemia is usually when glucose is less than 50 mg/dL, it is accompanied by altered consciousness, and patients need assistance. They need to take 20 to 30 g of simple glucose by mouth (if able), be given glucagon by intramuscular (IM) injection, or be rescued by emergency medical personnel with intravenous (IV) glucose administration. If any severe hypoglycemia episodes occur, then precipitating causes should be assessed, patients should be referred to DSME, use of glucagon IM injections should be taught to family members or care takers, and BG goals should be revised. If patients have frequent severe hypoglycemia or have hypoglycemia unawareness, then support of families and friends is absolutely needed, patients should wear identifying bracelets, and driving is not recommended.

IDENTIFYING AND TREATING COMPLICATIONS OF DIABETES

The treatment of chronic diabetes complications should be conducted according to published standards of care to ensure early diagnosis and prevent progression. These standards of care are published yearly by the ADA.[1] For microvascular disease, retinopathy, nephropathy, and neuropathy are targeted.

Retinopathy

Retinopathy is one of the ophthalmic complications of DM. It could be background or proliferative and could lead to retinal detachment, vitreous bleeding, and blindness if not treated. Early laser treatment could prevent blindness. Diabetes is also a risk factor for development of cataracts and glaucoma. Patients should have annual dilated eye examinations after 3 years from onset of type 1 diabetes and at onset of type 2 diabetes. Prevention of background or proliferative retinopathy occurrence or worsening is not only through continuing tight control of BG but also by smoking cessation and control of blood pressure and lipids.

Nephropathy

Diabetic nephropathy manifests itself as proteinuria, glomerulosclerosis, and renal failure. Nephropathy should be screened for annually with a urinary microalbumin/albumin determination. Goal is <30 mg/g creatinine, which corresponds roughly to 30 mg protein per 24 hours. In addition, glomerular filtration rate (GFR) and creatinine level need to be monitored at least annually. The prevention of nephropathy should be done through tight glucose and blood pressure control and through administration of agents that lower proteinuria, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. Treatment of nephropathy presenting with hematuria and nephrotic-range proteinuria include dietary protein reduction, blood pressure lowering to less than 125/75 mm Hg and revised glucose management for reduced GFR as well as a nephrology consult. If GFR < 30 mL/min, chronic kidney disease (CKD) management principles apply. Oral hypoglycemic agents' safety should be reassessed with worsening GFR.

Neuropathy

Diabetic neuropathy could be peripheral or autonomic and could lead to diabetic foot ulcer, diabetic arthropathy, and deformities with pathologic fractures, cellulitis, osteomyelitis, and amputations. The annual screening of feet for diabetes includes a complete assessment of sensation. Inspection of feet should be done at every visit; feet at high risk should be referred to podiatric care and for orthotics.

OTHER ASPECTS OF DIABETES MANAGEMENT

For all newly diagnosed diabetics, essential care should also address the

following: (a) diabetes self-management education and nutrition education; (b) psychosocial screening; (c) pregnancy, contraception, and osteoporosis in women, and erectile dysfunction in men; and (d) dental care and vaccinations. A minimum amount of diabetes education (survival skills) should be taught in the hospital before discharge, and patients should be referred to an outpatient ADA-certified diabetes self-management education program. In such programs, there is an initial workshop that follows a core curriculum so core knowledge reaches all patients. Usually this is completed in about 6 hours. Self-knowledge assessment tests are given before and after the teaching sessions. Patients should attend a refresher course each year for up to 4 hours/year. Diabetes self-management nutrition education addresses diet and energy balance: weight loss issues if needed, need for carbohydrate counting in insulin-requiring patients, risk of low BG with decreased energy intake, increase in physical activity, increase in dietary fiber (14 g/1,000 kcal) and alcohol intake (maximum one drink per day for women and two drinks per day for men). Physical activity is recommended to be of both aerobic and resistance-type training and should be done in combination. Aerobic activity should be at least 150 min/week and it should be of moderate intensity, 50% to 70% of maximum heart rate (220-age). Resistance exercise should be done 3 times a week if there are no contraindications, such as the presence of proliferative diabetic retinopathy. A screening is needed to assess the literacy level that is essential for diabetes self-management education of glucose monitoring and medication adherence. Mood disorders such as depression and anxiety must be addressed because they can influence diabetes control as well as coping. Social barriers (family and economic issues) and physical barriers (blindness, amputations, etc.) are all likely to affect diabetes management and should be addressed accordingly.

DIABETES MELLITUS IN THE CARDIAC CARE UNIT

HYPERGLYCEMIA AND DIABETES IN THE CCU

Hyperglycemia is a common condition among hospitalized patients with and without diagnosed diabetes. Hyperglycemia on admission can affect up to 50% to 60% of patients admitted with acute coronary syndrome (ACS) and acute decompensated heart failure (HF), which varies based on the definition applied. More importantly, it has been reported that 14% to 50% of those presenting with ACS and hyperglycemia on admission were never diagnosed with diabetes.[9]

Hyperglycemia in patients admitted to the cardiac care unit (CCU) can be seen in three main scenarios: (1) those with previously known diagnosis of DM (of any type), (2) those with undiagnosed DM but meeting criteria for diagnosis during admission, and (3) those with stress hyperglycemia. Patients with previously diagnosed diabetes will commonly have worsening of their glycemic status—partly due to stress hyperglycemia, as explained here. Hyperglycemia in hospitalized patients with ACS has been associated with increased morbidity, mortality, and poor hospital-related outcomes, regardless of their previous status.[10]

INPATIENT HYPERGLYCEMIA AND STRESS HYPERGLYCEMIA—BRIEF DEFINITION

In the general hospitalized population, acute—or inpatient—hyperglycemia was traditionally considered as an admission or random BG ranging from >110 to >200 mg/dL in several studies.[10] Subsequently, the ADA, the AACE and the Endocrine Society defined inpatient hyperglycemia as a BG ≥ 140 mg/dL on admission or at any time during the hospitalization, or an admission HgA_{1C} > 6.5%, in patients with or without diabetes.[11]

In hospitalized patients with ACS, the American Heart Association, in the scientific statement on "Hyperglycemia and Acute Coronary Syndrome" similarly defined inpatient hyperglycemia as an admission BG > 140 mg/dL during an admission, and recommended intensive glucose control in patients with BG > 180 mg/dL, regardless of their prior diabetes status. These recommendations are supported by several observational studies demonstrating that admission, mean 24-hour or mean in-hospital BG > 140 mg/dL is associated with increased mortality in the ACS population, and that lowering glucose to <140 mg/dL is associated with improved survival.[12]

Stress hyperglycemia refers to a transient elevation of BG occurring during acute illnesses, which resolves spontaneously after the acute insult dissipates. This disorder can occur in patients with or without diabetes, and has been associated with higher risk of complications and mortality compared to patients with previously diagnosed DM.[13] Trauma, infection, and surgery result in remarkable metabolic stress on the human body. Stress associated with critical illness is characterized by the activation of inflammatory cellular mediators and the hypothalamic pituitary-adrenal axis. In addition, the level of insulin is decreased, along with associated insulin resistance, at least partially from stress

hormones in acutely ill patients.

In patients with ACS and “isolated” stress hyperglycemia (without previously known diabetes), the risk of mortality increases as the BG levels go above 120 to 140 mg/dL; whereas in patients with known DM and ACS, the risk of mortality starts to increase when the BG is >200 mg/dL.[14] These patients are also at increased risk of developing diabetes in the future. Greci et al. demonstrated that up to 60% of patients with stress hyperglycemia may be diagnosed with DM at 1 year[15]; therefore, screening and follow up after discharge are essential in these patients.

INCIDENCE AND PREVALENCE OF HYPERGLYCEMIA AND DIABETES IN THE CCU

According to the International Diabetes Federation, there were over 415 million people worldwide with DM in 2015 (http://www.diabetesatlas.org, accessed January 1, 2017). From 1980 to 2014 in the United States, the number of people with diabetes has increased by 4-fold, from 5.5 million to 22.0 million (https://www.cdc.gov/diabetes/statistics, accessed January 1, 2017).

There is a direct relationship between the increased prevalence of obesity and DM2 in the United States over the past two to three decades, escalating to epidemic numbers. Patients with metabolic syndrome usually have visceral obesity and insulin resistance, and are at risk for developing DM2 and CVD. Patients with DM2 and those with associated metabolic syndrome, in particular, are at high risk for CAD, cerebrovascular events, nonischemic cardiomyopathy, peripheral vascular disease, and death.[16]

The overall prevalence of hyperglycemia among hospitalized patients ranges from 32% to 42% in critically ill patients to 20% to 35% in non–critically ill patients.[11] Hospitalized patients with CVDs may have a higher burden of diabetes. In the CRUSADE study, up to 36.3% of patients with non-ST segment elevation myocardial infarction had known diabetes.[17]

In patients with ACS, hyperglycemia (with or without previously recognized diabetes) ranges from 25% to >50%, depending on the definition used by the different studies (> 110 vs 140 vs >180 mg/dL).[12] Unfortunately, the higher burden of diabetes may commonly be unrecognized by patients already presenting to the hospital with diabetes-related complications such as CVDs. In several large studies, the scenario of unrecognized diabetes has been reported in 10% to 50% of those presenting with ACS and hyperglycemia.[18]

Hyperglycemia in patients admitted for HF is also common. It has been reported that the prevalence of hyperglycemia in this population is about 42% in patients without diabetes and up to 40% to 50% in patients with diabetes.[19]

HYPERGLYCEMIA AND OUTCOMES IN HOSPITALIZED PATIENTS WITH DIFFERENT CARDIAC DISORDERS

Hyperglycemia in hospitalized patients has been associated with increased mortality and adverse outcomes. Paradoxically, patients admitted with hyperglycemia without a prior diagnosis of DM have been shown to have worse outcomes compared to those with previously diagnosed DM.[10]

Hyperglycemia and Acute Coronary Syndromes

In patients with known diabetes admitted with ACS, several studies have demonstrated that admission hyperglycemia is associated with increased risk of hospital mortality and hospital-related complications. A meta-analysis of patients with diabetes admitted with ACS reported that admission BG ≥ 180 mg/dL was associated with a 70% relative risk increase in hospital mortality, compared with normoglycemic patients on admission.[10]

Whether hyperglycemia on admission predisposes the patient to myocardial injury or is just a marker of disease severity is unclear. Hyperglycemia on admission is well accepted to be an independent predictor for poor outcomes in patients with and without diagnosed diabetes presenting with ACS. However, admission BG only represents a very specific time in the hospitalization. Persistent hyperglycemia during a hospitalization for ACS was found to be a better predictor of mortality than admission BG. Thus, some authors advocate the use of mean hospital glucose as the most accurate and practical glucometric tool in this population.[10]

In patients admitted with ACS and unrecognized DM, a meta-analysis reported that mortality increases as BG increases above 110 mg/dL, compared with normoglycemic patients.[10] Similarly, the HI-5 study showed that the 6-month mortality rate was higher in patients with BG > 144 mg/dL.[20]

Hyperglycemia and Heart Failure

With regard to patients admitted with acute HF, several studies reported an increased risk of in-hospital and overall mortality in patients with hyperglycemia.[21,22] A recent report from the “Swedish National Diabetes

Registry" reported that patients with type 1 diabetes have 4-fold increased risk for HF hospitalizations, whereas poor glycemic control and albuminuria were considered strong risk factors.[22]

Hyperglycemia and Atrial Fibrillation

Atrial fibrillation (AF) is the most common chronic cardiac arrhythmia, and its prevalence is directly related to advancing age. The prevalence of DM2 is about 7% to 16% in patients with AF. A recent meta-analysis of patients with DM2 reported a 40% increased risk of AF, compared to unaffected patients. DM2 has also been found to be an independent risk factor for AF hospitalization.[23]

Hyperglycemia and Outcomes of Coronary Artery Bypass Grafting

Diabetes can affect up to 30% to 40% of patients undergoing coronary artery bypass graft (CABG) surgery. In a retrospective study at the Mayo Clinic, patients with intraoperative hyperglycemia were found to have a higher rate of mortality and complications, such as AF, sternal wound infections, prolonged mechanical ventilation, urinary tract infection, delirium, and strokes, following CABG surgery, regardless of whether they had previously recognized diabetes or not.[24] In the recent GLUCO-CABG trial, Umpierrez et al. randomized patients with inpatient hyperglycemia (BG > 140 mg/dL) to receive an intensive glycemic control; aiming BG targets between 100 and 140 mg/dL, versus a more conservative target of 141 to 180 mg/dL. The authors found similar results regarding a composite of outcomes, including mortality, wound infection, pneumonia, bacteremia, acute kidney injury, and major adverse cardiovascular events (42% vs 52%, $P = 0.08$). However, patients without known diabetes, so-called stress hyperglycemia, had a significantly lower rate of complications (34% vs 55%, $P = 0.008$).[25]

Hyperglycemia and Outcomes of Heart Transplant Surgery

Heart transplant recipients will sometimes be cared for by the CCU staff. Pre-transplant DM is a common comorbidity, presenting in up to 25% of patients undergoing heart or lung transplantation. Lang et al.[26] reported similar rates of acute rejections, graft vasculopathy, and infections in recipients with pre-transplant DM, whereas others reported higher rates of infections and posttransplant CAD/graft vasculopathy.[27]

HYPOGLYCEMIA AND OUTCOMES IN PATIENTS HOSPITALIZED WITH CARDIAC CONDITIONS

Several professional societies recommended glucose control in hospitalized patients admitted to critical settings, including those admitted with ACS. However, hypoglycemia is an inevitable consequence of glycemic management and has been associated with increased morbidity and mortality.[28]

Extensive literature has shown that hypoglycemia is a common event in the hospitalized patient. Patients with acute CVDs are very vulnerable to the deleterious effects of hypoglycemia. Hypoglycemia is associated with increased risk of arrhythmias, ranging from bradycardia to ventricular ectopic beats and QT prolongation, mostly because of sympathetic and adrenal activation.[29] The relationship between mortality and glycemic control in hospitalized patients with ACS follows a U-shape curve.[30]

However, several studies have shown that spontaneous hypoglycemia is associated with worse outcomes and mortality than iatrogenic hypoglycemia in hospitalized patients. These results suggest that spontaneous inpatient hypoglycemia may be a marker of disease severity.

INTRODUCTION TO THE MANAGEMENT OF HYPERGLYCEMIA IN THE CCU

The negative impact of hyperglycemia and hypoglycemia in patients admitted to the CCU merits a comprehensive and multidisciplinary management plan. This plan may include dietary modifications, glucose monitoring, personalized glycemic targets to improve hyperglycemia while preventing hypoglycemia, a safe transitioning plan from the CCU to the regular medicine floors and/or home, and proper outpatient follow-up.

GLUCOSE MONITORING IN THE CCU

Given the negative impact of both inpatient hyperglycemia and hypoglycemia, it is necessary to closely monitor the BG levels in all patients admitted to the CCU. Current guidelines recommend glucose monitoring every 1 to 2 hours in critically ill patients. An international consensus meeting recommended against relying solely on the use of capillary BG for monitoring, given the poor reliability in critically ill patients. In patients with permanent vascular access (arterial and/or venous), all samples should be taken from this site following standard safety precautions. Arterial catheters may be preferred in patients with

shock, severe peripheral edema, and/or on vasopressor therapy. In patients without arterial or venous catheters, capillary BG can be used. The samples should be analyzed in the blood gas analyzer machines within the intensive care unit (ICU) or CCU, because results can be rapidly available compared to hospitals' central laboratory.[31]

Novel technologies, such as the continuous glucose monitoring (CGM) system, have shown promising results in the area of glucose monitoring in the hospital. Previous studies raised concern for inaccurate BG readings in critically ill patients; however, recent prospective randomized trials have demonstrated better accuracy and safety in patients in the CCU.[32] Closed-loop insulin delivering system is a novel technology that could aid in the management of inpatient and peri-operative hyperglycemia. Closed-loop systems are composed of an insulin pump allowing appropriate insulin doses and a glucose sensor for CGM. Landmark studies in ambulatory patients and a few pilot studies in the hospital have shown that these systems may improve glycemic control, decrease hypoglycemia, and the burden of diabetes care. However, these initial pilot studies are awaiting larger multicenter studies for efficacy and safety validation. Their main limitations at this time are high cost, lack of training among providers and patients, time needed for implementation, and lack of outcome data at this time.[33]

GLYCEMIC TARGETS IN CRITICALLY ILL PATIENTS ADMITTED TO THE CCU

The benefits of a proactive management of inpatient hyperglycemia are well known in the general hospitalized population with or without known diabetes. For critically ill patients, the American Association of Clinical Endocrinologists (AACE) and the ADA recommend starting an IV insulin infusion and frequent glucose monitoring for patients with BG ≥ 180 mg/dL, targeting a BG of 140 to 180 mg/dL, with lower targets of 110 to 140 mg/dL only in selected patients.[11] The Society of Critical Care similarly recommends an insulin infusion for BG > 150 mg/dL and to maintain BG below that target, but absolutely <180 mg/dL.[28]

In patients with ACS, a scientific statement from the American Heart Association Diabetes Committee in 2008, recommended starting intensive insulin therapy in patients with hyperglycemia >180 mg/dL, regardless of their prior history of diabetes. They recommended using a validated and efficient IV insulin protocol with close BG monitoring. Similarly, the European Society of

Cardiology in 2012 recommended maintaining BG between 90 and <200 mg/dL in patients with ST segment elevation myocardial infarction, but absolutely avoiding hypoglycemia. Insulin therapy should be decreased and/or adjusted if BG < 70 mg/dL and should be reassessed if BG < 100 mg/dL.[12,34]

For non–critically ill patients, the Endocrine Society and AACE/ADA guidelines recommended a target premeal BG of <140 mg/dL and random BG < 180 mg/dL, with subcutaneous (SQ) basal-bolus regimen preferred.[11]

GLYCEMIC TREATMENT: INSULIN THERAPY IN THE CCU

The LEUVEN study was a landmark study performed by Van den Bergh et al. in Leuven, Belgium in 2001. This study opened an interesting area of investigation in glucose control in surgical critically ill patients and outcomes. Initially, this single-center study showed a mortality benefit in patients treated with insulin to an "intense glycemic target," BG between 80 and 100 mg/dL, compared to a less strict goal of BG between 180 and 200 mg/dL. Notably, there were more severe hypoglycemic episodes in the intervention arm. However, these results were not replicated by several other prospective studies, including the van den Bergh group.[35,36]

The subsequent study by the van der Bergh group in Leuven, including patients in the medical intensive care unit (MICU) this time, showed no difference in mortality. This study also found higher rates of hypoglycemia, presumably because of changes in the nutrition management between the two patient populations, in the intense glycemic group.[37] The largest trial of intense glucose control in the ICU to date is the "Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE-SUGAR)" trial. This trial randomly assigned patients in the MICU and surgical intensive care unit (SICU) to an intensive BG target (BG between 81 and 108 mg/dL) versus a conventional/less strict glucose target (BG < 180 mg/dL). Conversely, this study showed that the intensive glycemic control group had a higher 90-day mortality and incidence of hypoglycemic episodes.[36]

Some small studies have yielded small but significant differences in mortality when goals are less stringent, but comparison is hard and hampered because of the heterogeneity of different studies. The DIGAMI and HI-5 trials are the two landmarks studies of glucose control in the ACS patient population. The first DIGAMI trial studied the effects of intensive in-hospital insulin treatment (insulin-glucose infusion for at least 24 hours followed by multidose SQ insulin

regimen) versus usual care in 620 patients with acute myocardial infarction with or without diabetes and an admission glucose of 200 mg/dL. Patients with myocardial infarction were randomized to receive insulin infusion to maintain BG 126 to 180 mg/dL versus standard of care without an insulin infusion. Better glycemic control was achieved in the intensive insulin therapy arm (mean 24-hour posttreatment BG of 173 vs 210 mg/dL in the control group). A significant 28% mortality reduction benefit was seen in the intervention arm after long-term follow up of 3.4 years.[38] The DIGAMI 2 trial attempted to compare three different treatment regimens (acute insulin-glucose infusion followed by insulin-based long-term glucose control; insulin-glucose infusion followed by standard glucose control on discharge; and routine metabolic management in both inpatient and outpatient settings) and found no difference in outcomes between the three regimens.[39] Moreover, the subsequent HI-5 trial was the first randomized trial that included patients with hyperglycemia without a diagnosis of diabetes. Patients were assigned to an intensive insulin infusion arm (BG goal of 72 to 180) and a conventional arm that was treated with their usual diabetes medication including SQ insulin. There was no difference in mortality rates among the groups during hospitalization or at 3 or 6 months. There were, however, significant reductions in post–myocardial infarction HF during the hospitalization (10% absolute risk reduction) and in reinfarction at 3 months.[20]

This brief description of some of the landmark studies regarding hyperglycemia in critically ill patients with ACS was intended to show the conflicting results of intensive glycemic targets in this population. These controversial results may probably be due to heterogeneity in patient characteristics and study protocols. We advise the readers to exercise some caution with extrapolation of the data from general MICU and SICU patients, or combined trials into the CCU practice. Nevertheless, hyperglycemia management targeting less stringent goals has become part of the standard of care in hospitalized patients, as endorsed by several national organizations.[11,12,28,34]

INSULIN INTRAVENOUS INFUSION THERAPY (“DRIP”) IN THE CCU

The preferred approach to manage medical or surgical critically ill patients is using an insulin infusion protocol with regular human insulin.[28] There are several validated infusion protocols, some nurse-driven or computer-generated algorithms, that have been validated for their safety and efficacy.[40] Oral

hypoglycemic agents are generally not recommended for the critically ill and non–critically ill hospitalized patients, and should be discontinued upon admission to the CCU.[25]

In brief, most insulin infusion protocols include instructions on how much insulin to start infusing based on the initial BG. Then, the insulin rate per hour is adjusted on the basis of the rate of BG change. In addition, the protocol will instruct on how to correct hypoglycemia, and adjust the infusion rate to prevent it again. It has been shown that BG targets are usually achieved within approximately 4 to 8 hours in most patients. The onset of regular insulin after IV administration is within 15 minutes, with a half-life of 9 minutes, a maximal effect within 15 to 30 minutes, and a duration of 30 to 60 minutes. Thus, this safely ensures a rapid up- or down-titration of the doses in anticipated (ie, rapid decline of BG, use of vasopressors) or unanticipated (ie, acute clinical status deteriorations, hypoglycemia) situations.[28]

Several centers use nurse-driven computer-based algorithms, whereas others use paper-based protocols. The Glucommander is an example of a computer-driven insulin infusion software, developed since 1984. After entering a bedside BG into the system, the Glucommander calculated the initial insulin infusion rate (ie, BG − 60 mg/dL × 0.02 = insulin dose/h). The system will notify the nurse or provider when the next bedside BG is needed. The system continues making adjustment recommendations of the insulin infusion until it is stopped by the provider. The pilot studies by Davidson et al. showed that the system can maintain BG within target range, without significant hypoglycemia, and run by nonspecialized staff.[40]

Peri-operative patients may require additional considerations. Oral hypoglycemic agents and non–insulin injectable agents should be held on the day of the surgery. For patients with DM2 who will be fasting (NPO) for at least 8 hours before surgery, basal insulin should be adjusted to 75% to 100% of the regular home dose the night before surgery, depending on the patient’s glycemic curve. Because the patient is fasting, prandial insulin is, by definition, not required. However, correctional sliding-scale insulin every 4 to 6 hours should be used for correction of residual hyperglycemia, while NPO. For patients using neutral protamine Hagedorn (NPH) insulin, because of the increased risk of hypoglycemia compared with basal insulin analogs—glargine or detemir—it is recommended to give about 75% of the usual dose the day before surgery and 50% to 75% on the surgical day. IV insulin infusion protocols can allow for rapid insulin adjustments based on BG in these scenarios of rapid glucose shifts.

Close glucose monitoring every 1 to 2 hours is usually recommended for monitoring. For short-duration (approximately <4 hours) and small or simple surgical procedures, SQ insulin can be used. For longer and more complicated procedures (>4 hours) IV insulin infusion is the recommended approach.[41,42]

In our institution, we have created a pathway for management of hyperglycemia in cardiac patients, which is depicted in **Figure 54.4**.[43]

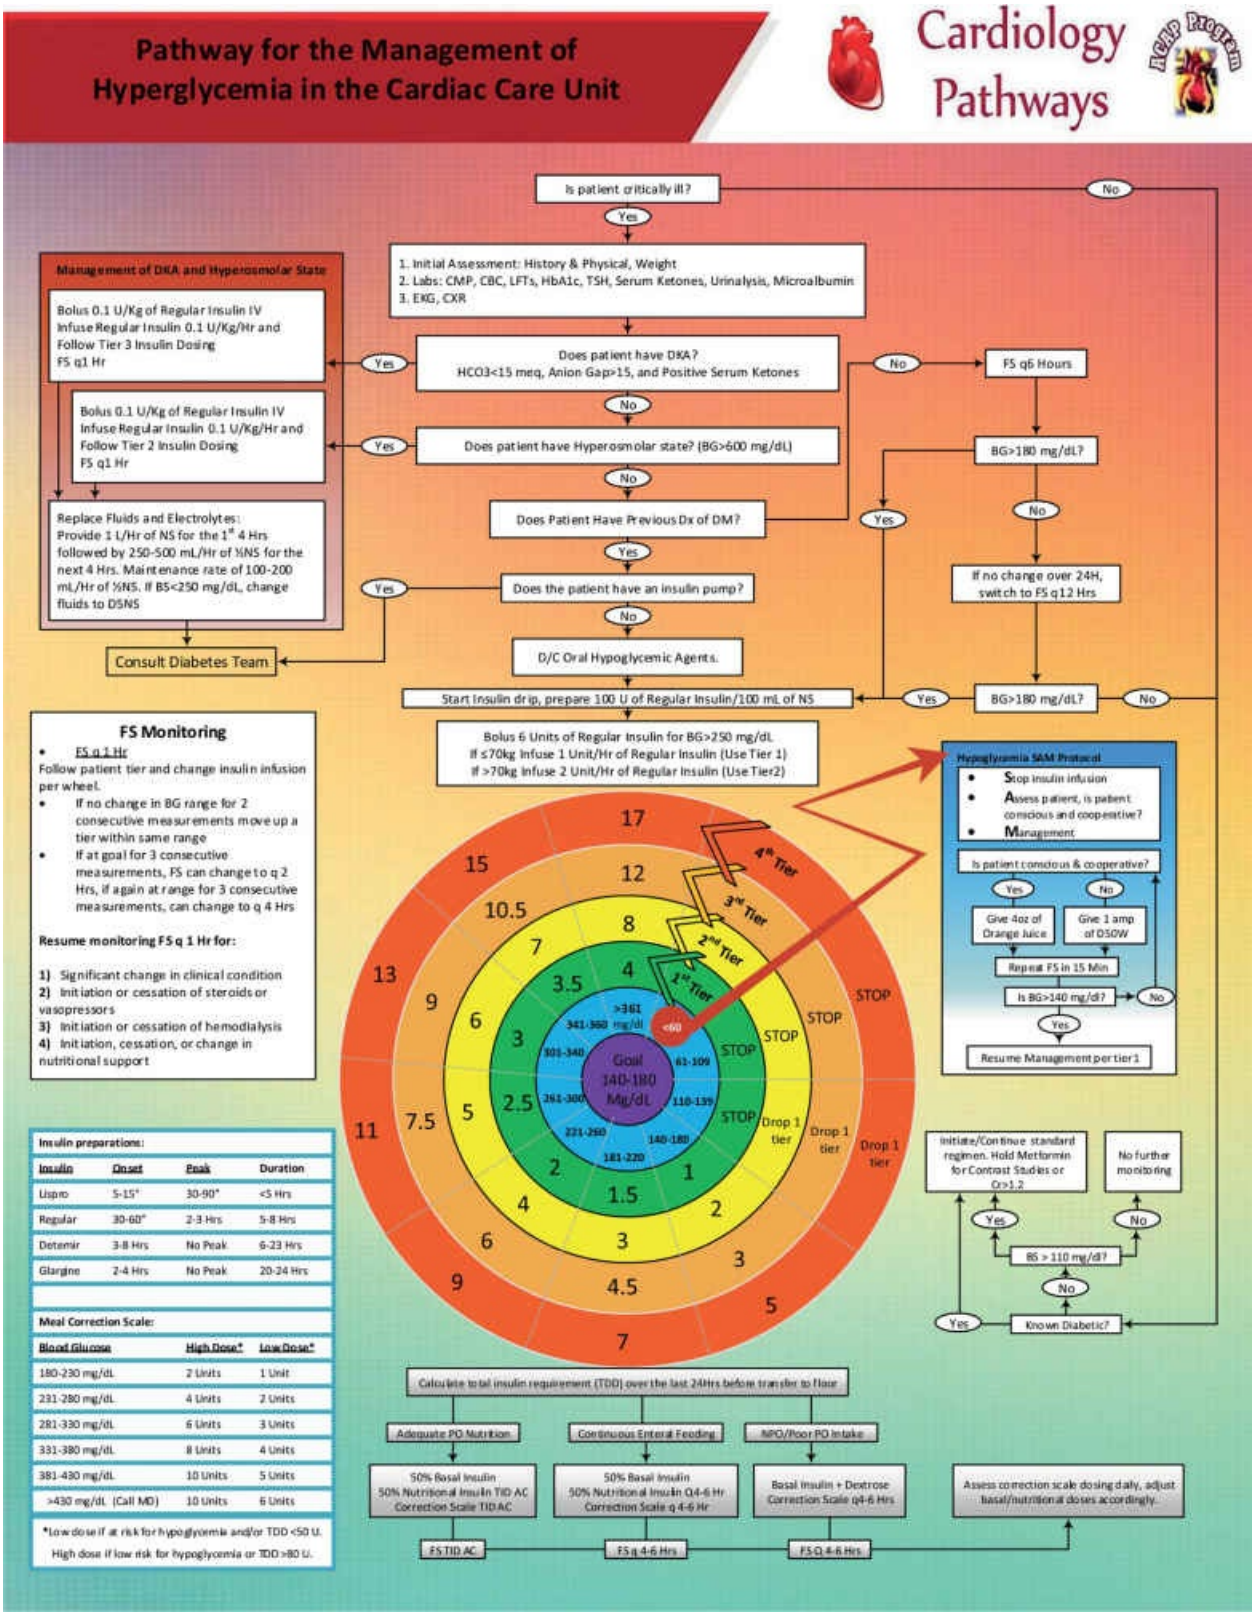

FIGURE 54.4 Pathway for the management of hyperglycemia in the cardiac care unit. BG, blood glucose; CBC, complete blood count; CMP, comprehensive metabolic panel; CXR, chest X-ray; ECG, electrocardio

gram; DKA, diabetic ketoacidosis; FS, fasting sugar; LFT, liver function test; NS, normal saline; TDD, total daily dose; TSH, thyroid-stimulating hormone

Pathway for the Management of Hyperglycemia in the Cardiac Care Unit

The main goal of this pathway is to provide glycemic control for critically ill patients. Initial assessment of the former group of patients should include history, physical examination, and recording of weight. We have also defined a basic laboratory test panel required for all patients (**Figure 54.5**). We included patients with DKA and patients with hyperosmolar state and provided guidelines for their management (**Figure 54.6**). These patients might not necessarily be treated in the cardiac care unit depending on their associated cardiovascular morbidities. Patients managed in this protocol have a diagnosis of DM. If a patient is not known to have DM, capillary BG determinations every 6 hours will be required. A BG of 180 mg/dL qualifies patients for enrollment into our pathway of insulin infusion protocol (**Figure 54.7**).

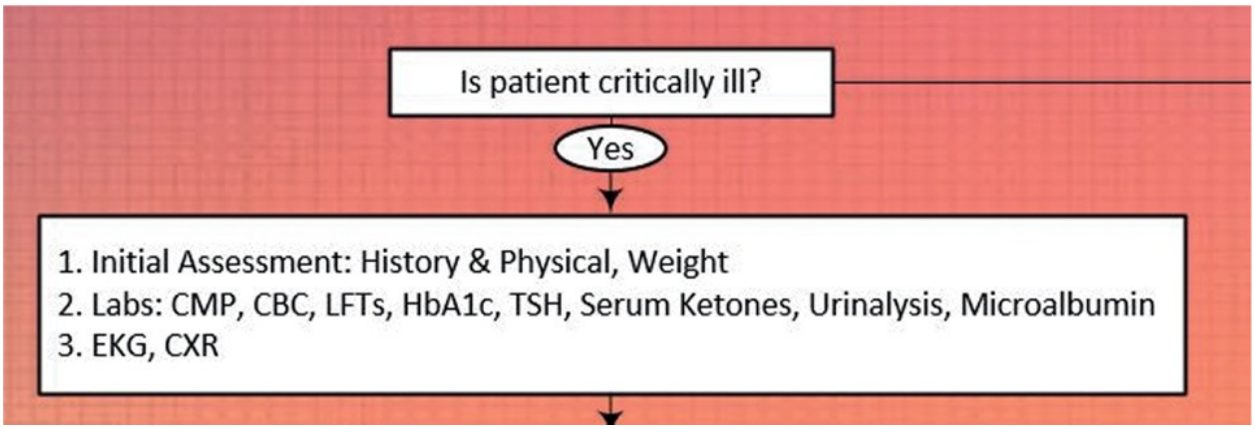

FIGURE 54.5 Initial assessment of patients with hyperglycemia who are screened to a cardiac care unit. CBC, complete blood count; CMP, comprehensive metabolic panel; CXR, chest X-ray; ECG, electrocardiogram; LFT, liver function test; TSH, thyroid-stimulating hormone.

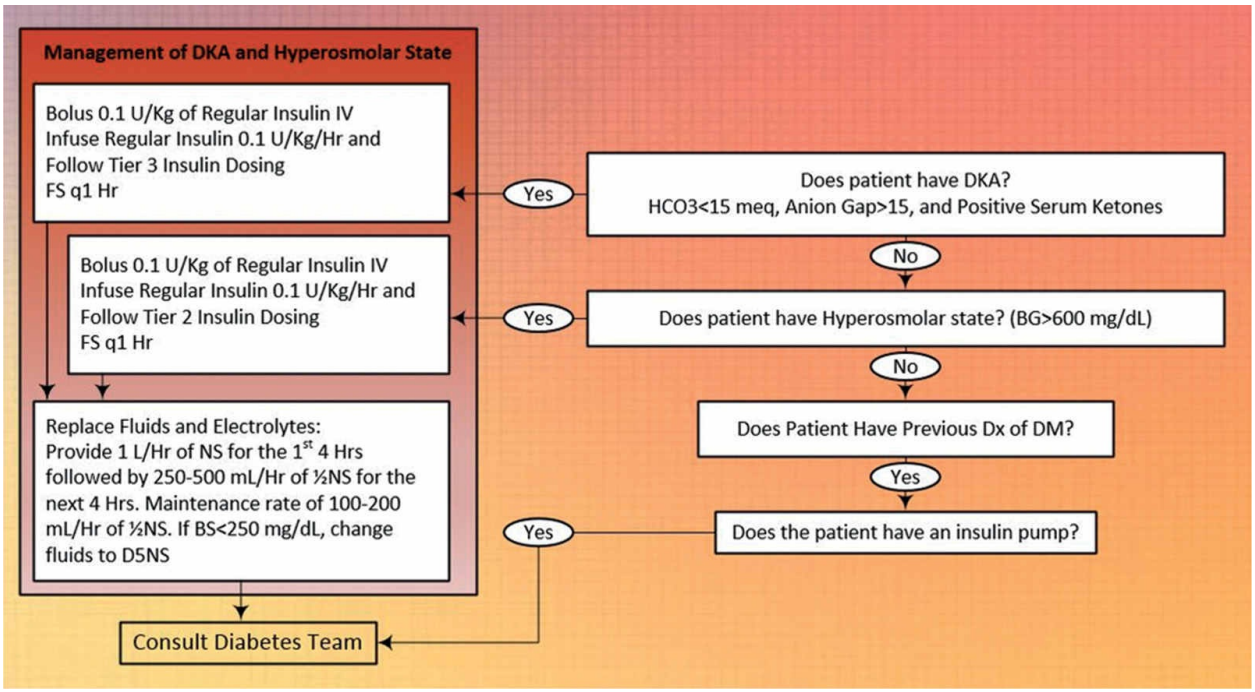

FIGURE 54.6 Management of DKA and hyperosmolar state and activation of diabetes team. DKA, diabetes ketoacidosis; DM, diabetes mellitus; IV, intravenous.

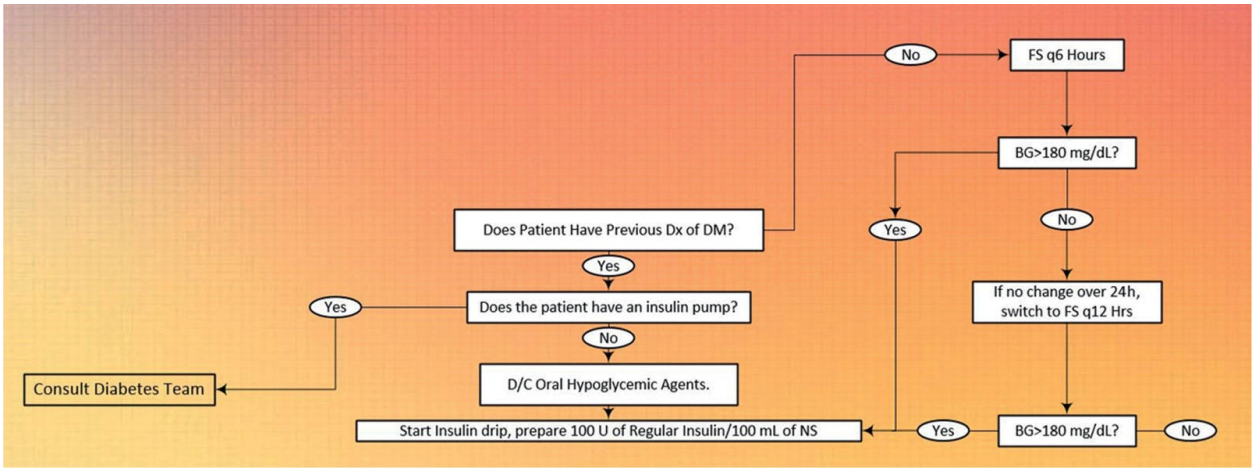

FIGURE 54.7 Blood glucose determination for enrollment into the hyperglycemia pathway. DM, diabetes mellitus; NS, normal saline.

Initiation of the insulin infusion is achieved by providing a bolus of 6 units of regular insulin for patients with a BG of 250 mg/dL or more and starting an infusion protocol that is based on weight. If the initial BG value is above 180 but below 250 mg/dL, the patient will not need the bolus insulin and will be started on weight-based insulin drip only (**Figure 54.8**).

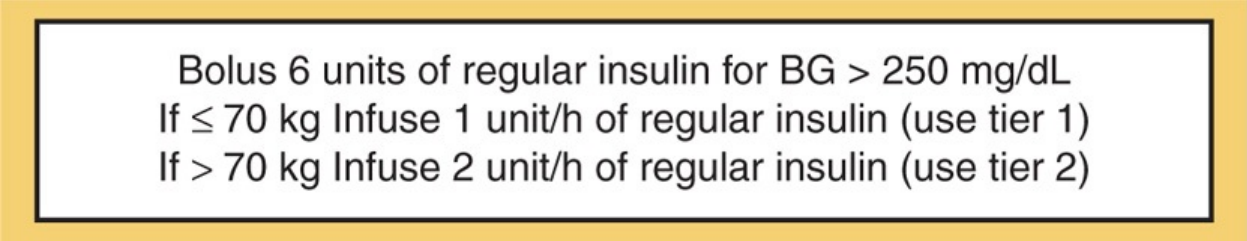

FIGURE 54.8 Initiation of insulin infusion protocol. BG, blood glucose; DM, diabetes mellitus; NS, normal saline.

The key element of this pathway is the "wheel" that provides treatment instruction for insulin administration (**Figure 54.9**). This wheel is made up of six circles. The core circle shows the acceptable glycemic range for all the patients and the inner circle represents the measured BG ranges. The four outer circles represent four different rates of insulin infusion, also known as "tiers." For patients who are less than 70 kg, the insulin infusion rate should be calculated on the basis of tier 1. For patients who weigh more than 70 kg, the infusion rate is based on tier 2. BG monitoring is performed every 1 hour. The infusion rate is then adjusted according to the instructions corresponding to the BG of the same tier: "dialing up and down the wheel within the tier." If there is *no* decrease in BG range for two consecutive measurements, the health care provider moves up a tier at the same glucose range.

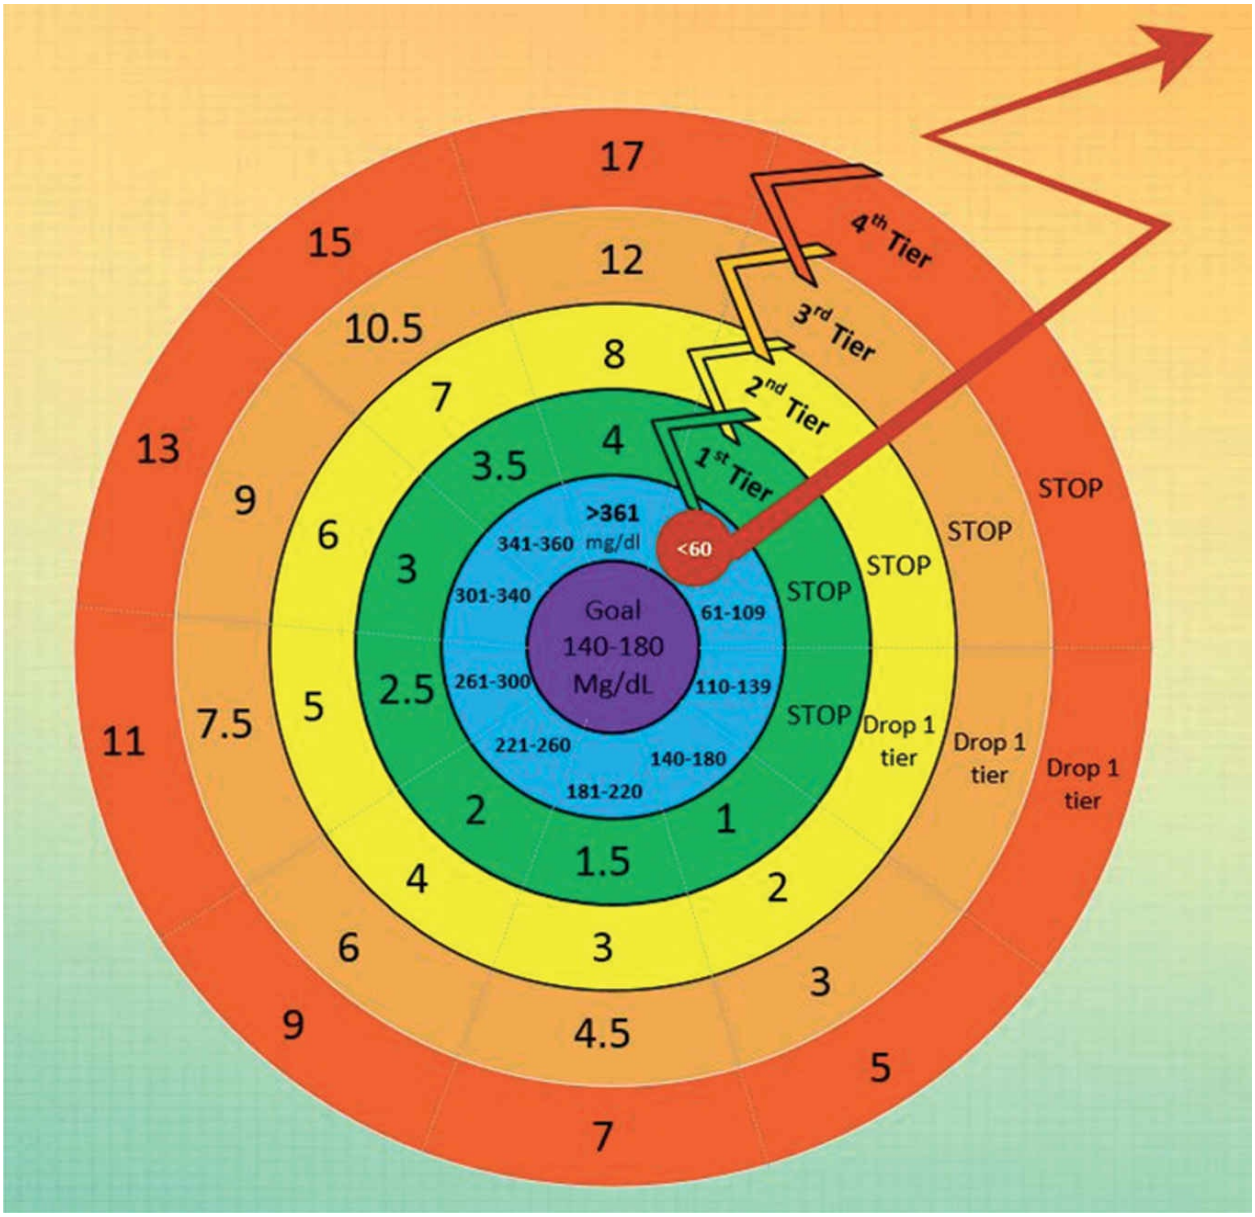

FIGURE 54.9 The "wheel" as a tool for insulin infusion.

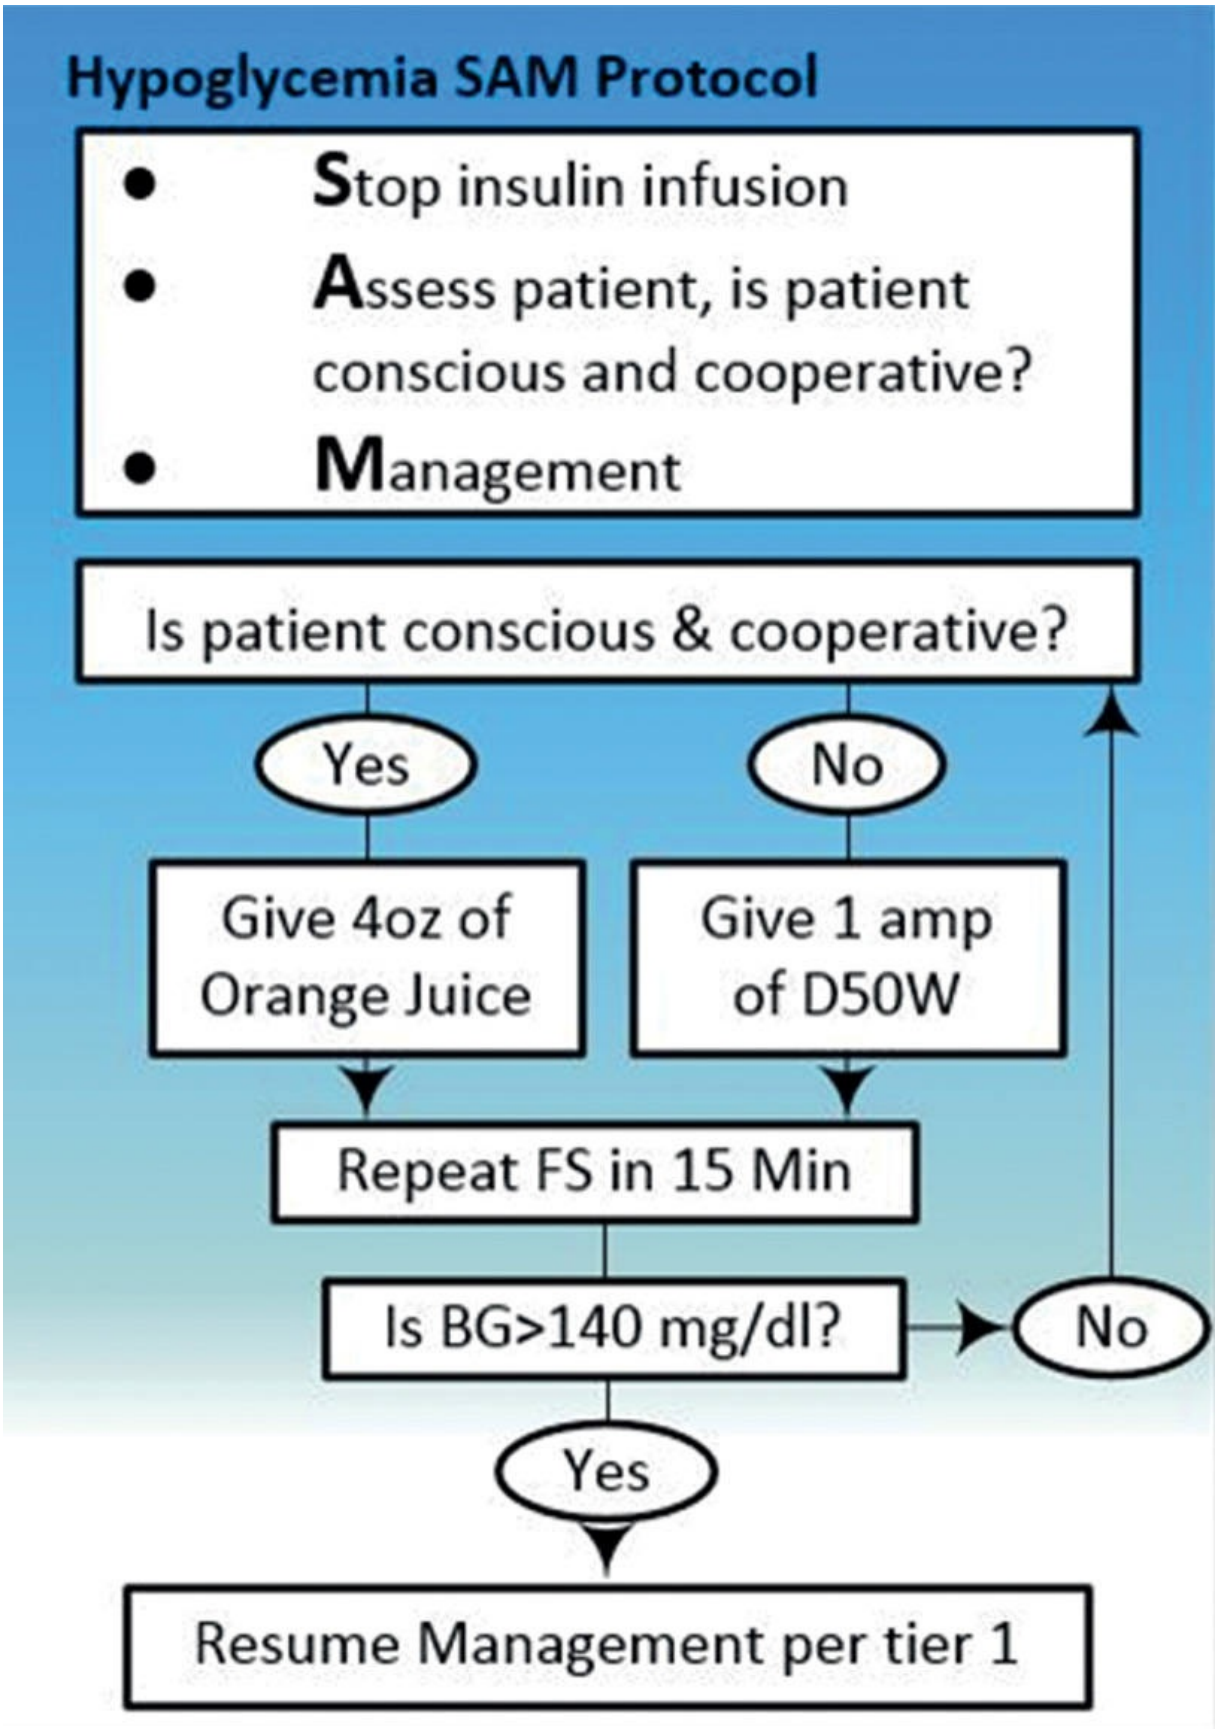
A major goal in the management of hyperglycemia is the prevention of hypoglycemia. If a patient is found to be hypoglycemic (defined as BG of 60 mg/dL or less), a protocol for management is provided, as seen in **Figure 54.10**. We named this protocol SAM to reflect the key components of treatment: *S*top insulin infusion, *A*ssess the patient for consciousness and cooperation, and *M*anage the patient (with orange juice or D50%W infusion). If a patient's BG exceeds 140 mg/dL, the management using the "wheel" is resumed with the initial insulin infusion rate based on tier 1 and the corresponding BG.



Hypoglycemia SAM Protocol
Stop insulin infusion
Assess patient, is patient conscious and cooperative?
Management
Is patient conscious & cooperative?
Yes
No
Give 4oz of Orange Juice
Give 1 amp of D50W
Repeat FS in 15 Min
Is BG>140 mg/dl?
No
Yes
Resume Management per tier 1

FIGURE 54.10 Management of hypoglycemia. BG, blood glucose; FS, fasting sugar.

Instructions for frequency of BG monitoring are provided to the health care provider. Initially, all monitoring is performed every 1 hour. If BG results are at goal for three consecutive readings, then the frequency of monitoring is decreased to every 2 hours and, again, if there is no change for three consecutive readings, it is decreased to every 4 hours. Return to frequent monitoring (BG every 1 hour) is required for the following conditions: significant change in clinical condition; initiation or cessation of corticosteroids or vasopressors; initiation or cessation of hemodialysis and/or initiation, cessation, or change in nutritional support (**Figure 54.11**).

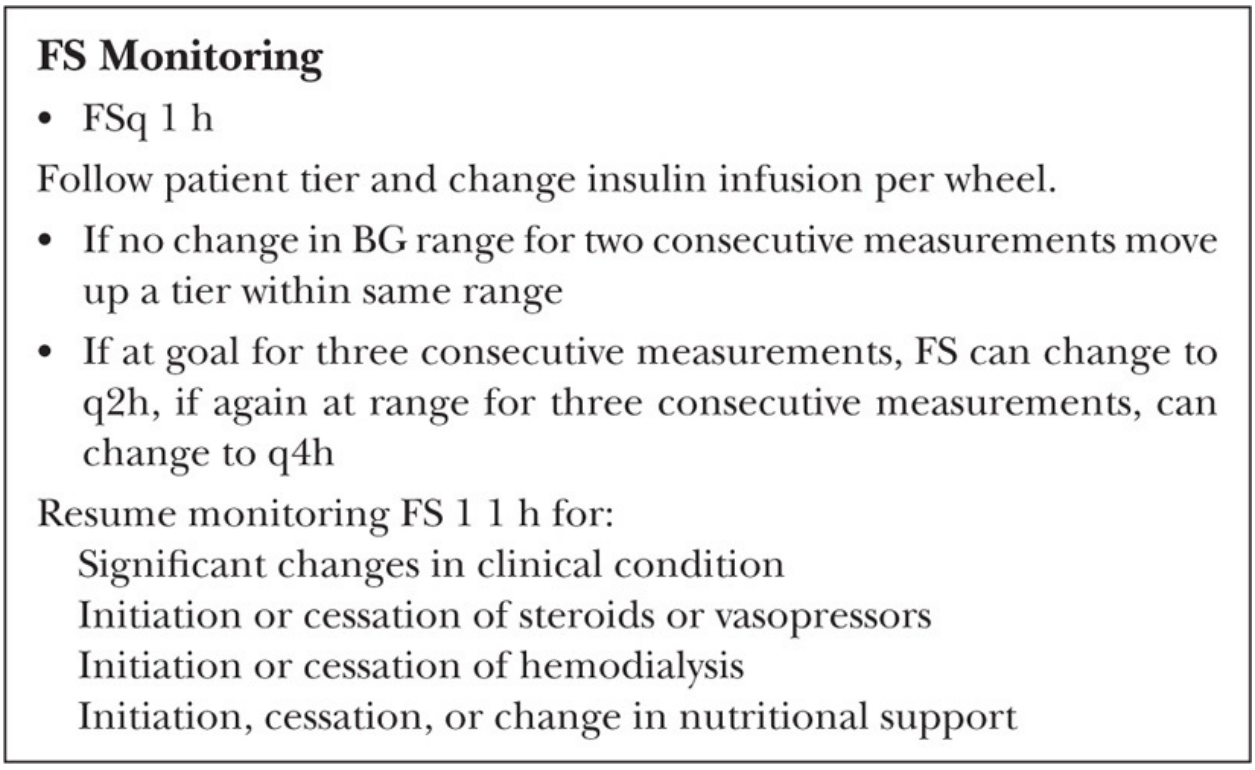


FIGURE 54.11 Guidelines for finger stick monitoring for patients with hyperglycemia. BG, blood glucose; FS, fasting sugar.

A protocol was developed to convert from the insulin infusion to SQ insulin injection without sacrificing diabetes control. First, the health care provider calculates the total insulin requirement (total daily dose [TDD]) over the last 24-hour period in the cardiac care unit. The patients are then divided into the following three groups based on their nutritional status.

Group I: Patients With Adequate PO Intake

This group of patients receives a combination of long-acting insulin (50% of the TDD)—usually glargine—at bedtime and the rapid-acting insulin lispro in three equal doses before every meal. They will also receive correctional scale insulin before every meal (to be added to the standing nutritional insulin dose) based on glucose monitoring before each meal (**Figure 54.12**).

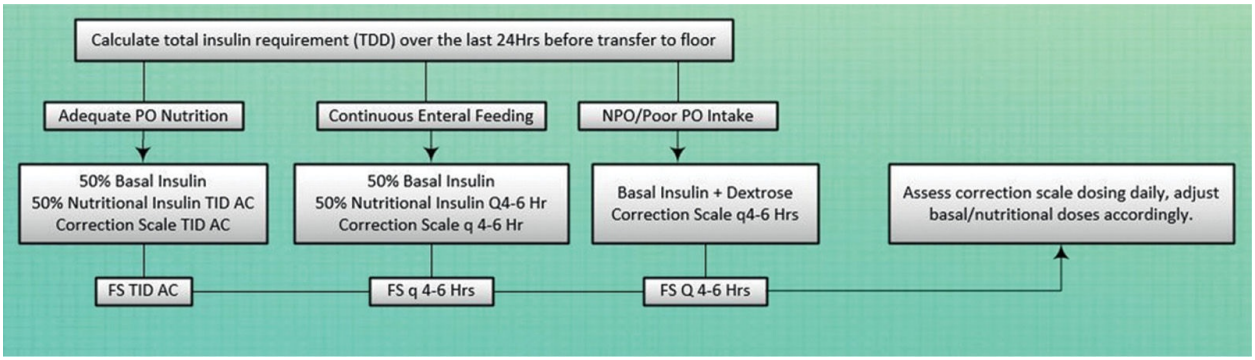

FIGURE 54.12 A protocol for conversion from insulin infusion to subcutaneous insulin injection. FS, fasting sugar; TDD, total daily dose.

Group II: Patients on Continuous Enteral Feeding

Patients on continuous enteral feeding, just like those with adequate PO intake, will receive 50% of their TDD as long-acting insulin at bedtime and will also receive the rest of the TDD in three divided doses of nutritional insulin. The only difference will be in the timing of this nutritional and correctional insulin. Because these patients are receiving continuous enteral feeding, there is no specific meal time during the day to be the base of measurements and administration of insulin. In these patients, both BG measurements and insulin administration will happen every 4 to 6 hours to give them a smoother glycemic range during the day (**Figure 54.12**).

Group III: Patients Who Are NPO or Those With Inadequate PO Intake

Because these patients do not have any reliable source of nutrition, they will not receive nutritional insulin. They will still need basal insulin (specifically if they are type 1 diabetic). To receive basal insulin without hypoglycemia, these patients need to be on dextrose infusion. They will also benefit from BG measurements every 4 to 6 hours and will need correctional scale insulin if these values are high.

In all of these patients, the 24-hour insulin requirements should be checked frequently and the basal and nutritional doses should be adjusted accordingly to minimize the amount of correctional insulin needed (**Figure 54.12**).

Correctional Insulin Scale

We provide two doses for meal correctional insulin in our pathway, the high-dose and the low-dose scale (**Figure 54.13**). The health care provider can also pick the value in between that will represent the medium dose scale of correctional insulin. Use of either of the dosing values is mainly based on clinically estimated risk of hyper- or hypoglycemia.

Insulin preparations:			
Insulin	**Onset**	**Peak**	**Duration (h)**
Lispro	5–15”	30–90”	<5
Regular	30–60”	2–3 h	5–8
Detemir	3–8 h	No Peak	6–23
Glargine	2–4 h	No Peak	20–24
Meal Correction Scale:			
Blood Glucose		**High Dose* (units)**	**Low Dose* (units)**
180–230 mg/dL		2	1 Unit
231–280 mg/dL		4	2
281–330 mg/dL		6	3
331–380 mg/dL		8	4
381–430 mg/dL		10	5
>430 mg/dL (Call MD)		10	6
*Low dose if at risk for hypoglycemia and/or TDD < 50 U. High dose if low risk for hypoglycemia or TDD> 80 U.			

FIGURE 54.13 Correctional sliding scale and characteristics of different insulin preparations. TDD, total daily dose.

Medium- or high-dose scale is used mostly in patients who are obese, or have acute, severe illness or infection or those on some medications including steroids, vasopressors, certain antipsychotics, or any other medication that causes a rise in BG level. Low-dose scale is used in patients who are NPO or those who suffer from malnutrition, low body weight, lean type 1 DM, or poor PO intake. This scale is also appropriate to use in those with renal insufficiency, hepatic disease, HF, shock, adrenal failure, burns, alcoholism, malignancy, or those with a history of severe or recurrent hypoglycemia.

Another approach to decide regarding the dosage of the correctional scale is based on patients’ total daily insulin intake with low dose used in those with TDD < 50 units, medium dose in those with TDD 51 to 80 units, and high dose in those with TDD > 81 units.

We also provide pharmacologic characteristics of different types of insulin

preparation that are used most commonly in the cardiac care unit (**Figure 54.13**).

Non–Critically Ill Patients in the Cardiac Care Unit

Non–critically ill patients will not benefit from aggressive control of their BG using insulin infusion. These patients will need a standard regimen for management of their DM while they are in the hospital. Those with known diabetes who are on established and effective diabetic regimen should be kept on their respective regimens while in the hospital. The only exception will be to hold the metformin if they are about to undergo contrast studies. Other patients without a history of diabetes who fulfill the criteria for DM diagnosis should be assessed and started on a guideline-based regimen to control their DM. The remainder of the patients who do not fulfill diagnostic criteria of DM will not benefit from frequent BG measurements (**Figure 54.14**).

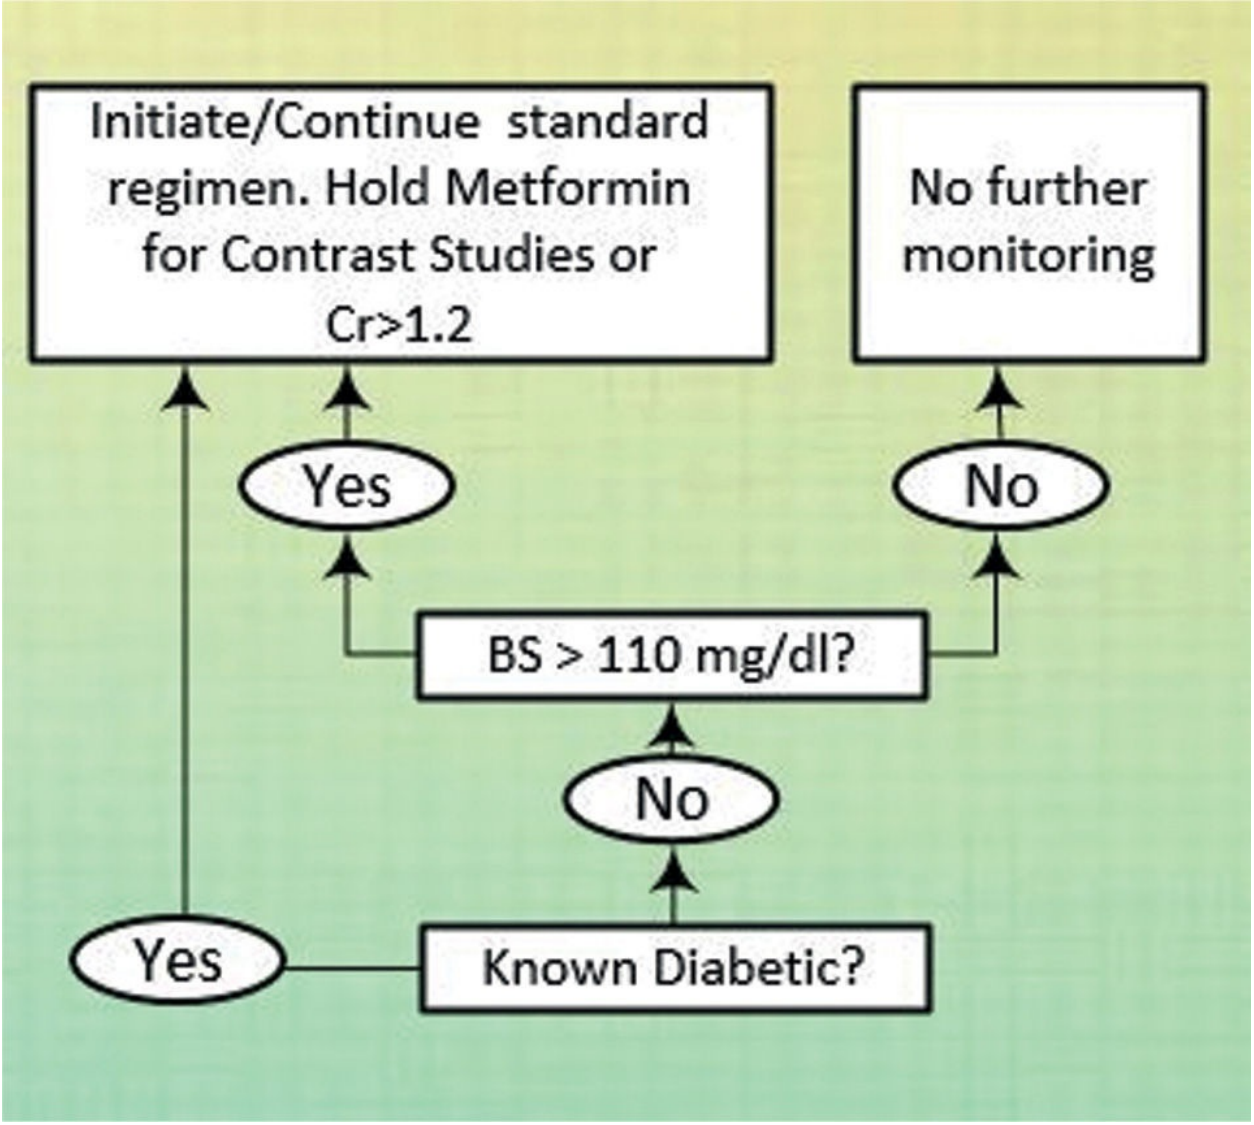

FIGURE 54.14 Management of hyperglycemia in non–critically ill patients. BS, Blood sugar..

This comprehensive pathway provides a detailed algorithm for management of hyperglycemia in cardiac care units. It introduces the novel concepts of the "wheel," which is the primary tool permitting rapid restoration of euglycemia and is the focus of this pathway.

TRANSITION OF CARE—FROM THE CCU TO MEDICINE WARD, FROM HOSPITAL WARDS TO HOME

Patients may be transitioned to a SQ insulin regimen once clinically stable, when restarted on oral diet, and/or when transferred out of the CCU. Several factors should be considered during the "transition period," including insulin

requirements while on the insulin infusion, current or planned nutrition, and/or concurrent infections or medications, such as steroids. Several randomized controlled trials using SQ basal-bolus insulin regimens have reported better glycemic control and reduction of complications compared to sliding-scale insulin in patients with type 2 diabetes.[44] Insulin sliding scales as a sole management approach is strongly discouraged in patients transitioned from the CCU to the general wards. Sliding-scale insulin regimens treat hyperglycemia after it has already occurred, instead of "proactively" preventing the occurrence of hyperglycemia with scheduled insulin doses. This "reactive" approach can lead to rapid changes in BG levels, exacerbating both hyperglycemia and hypoglycemia. The recent Basal-Plus study, a randomized controlled trial consisting of basal insulin plus correctional premeal doses of rapid-acting insulin per sliding scale, showed that this approach may be an alternative in some situations, such as in patients not eating full meals, or with nausea, or with very mild hyperglycemia.[45]

Communication between the multidisciplinary team members, including CCU nurses, diabetes team members, and primary medicine team, is key for a safe transition. The involvement of several members will ensure appropriate glucose monitoring, insulin dose adjustments, and close communication. Before transitioning the patient to the SQ basal-bolus insulin regimen, some clinical characteristics should be evaluated. The patient should have reached clinical stability, have stable glycemic control for several hours, and not continue to require critical medical or nursing care. Some authors suggest a period ranging from 6 to 24 hours of glycemic control with minimal variability in IV insulin rates. Patients should ideally be without vasopressors or inotropic agents and have a stable nutrition plan or should be tolerating PO diet. In patients admitted with DKA, the anion gap and acidosis should have normalized before considering transitioning to SQ insulin. Postoperative stress, pain, variable oral intake, infection, and underlying insulin resistance are all factors that affect insulin requirements. Given the short half-life of IV regular insulin, SQ insulin should be given before stopping the infusion, to avoid rebound hyperglycemia or acidosis. Consideration should also be given to the time to onset of each type of SQ insulin. For instance, glargine should be given at least 2 hours in advance before stopping the IV insulin.[46]

The insulin infusion requirements are usually high during the first few hours of treatment of patients with DKA or HHS, progressing into a highly variable infusion rate, before finally settling down to a more stable pattern. Similarly,

patients with stress hyperglycemia have markedly increased insulin infusion utilization within the first 48 to 72 hours post surgery. Using these variable insulin rates (ie, change greater than two units per hour), especially the initial extremely high rates, in the 24-hour SQ total insulin calculation will yield a result that potentially overestimates the patient's requirements once clinically stable and off the insulin infusion.[46] For this reason, it is recommended to use the hourly insulin rate from a previous period when BG was stable and within target range; in other words, the rate was reasonable and stable for some time. One can then look at the infusion rates during this stable period of time, ideally 6 to 8 hours in duration, to calculate the average insulin rate per hour required. This hourly insulin rate is multiplied by 24 to extrapolate these data to a 24-hour time period and the total 24-hour insulin requirements is calculated. Some authors suggest utilizing 50% to 60% of this 24-hour insulin dose in patients with stress hyperglycemia and no previous diagnosis of diabetes, whereas up to 60% to 80% can be used in patients with DM2 and high insulin requirements. The total insulin dose is then divided into 50% basal and 50% bolus insulin.[46]

In hospital settings, basal insulin analogs, such as glargine or detemir, are generally preferred over NPH or mixed insulin because they have been associated with less glycemic variability and less severe hypoglycemia.[47] Renal dysfunction is common in hospitalized patients, increasing the risk of insulin and non–insulin-related hypoglycemia. Baldwin et al. studied two basal-bolus (glargine-glulisine) insulin-dosing regimens in patients hospitalized with DM and CKD (eGFR < 45 mL/min). The authors found that a weight-based insulin regimen of 0.25 units/kg/d was associated with 50% less hypoglycemia (15.8% vs 30%, $P = 0.08$).[48]

It is important to establish institutional protocol for transition from the inpatient to the outpatient settings. In general, length of stay for patients with diabetes, although longer than for those without, has been gradually decreasing just as for all inpatient stays being on average 5 to 6 days. Therefore, the discharge plan for patients with diabetes has to be set from the admission. In established diabetes, it is important to determine the goals for the patient's level of glycemic control. A recent prospective study recommended using the admission HbA_{1C} to determine the diabetes plan.[49] In patients with stress hyperglycemia, it is important to coordinate appropriate follow-up to assess for the development of diabetes later.

Patient and Family Information for: DIABETES MELLITUS IN THE CARDIAC CARE UNIT

DIABETES MELLITUS: GENERAL PRINCIPLES

WHAT IS DIABETES MELLITUS AND HOW IS IT DIAGNOSED?

Diabetes Mellitus (DM) is a condition in which the level of glucose or sugar in the blood is higher than normal (also called hyperglycemia). A higher level of glucose in the system over a long period of time leads to injury to different organs in the body, generally affecting the nerves, eyes, and possibly the arteries as well. According to the American Diabetes Association (ADA) criteria, a number of measurements can be used to make the diagnosis of DM, such as the following:

1. Randomly measured levels of glucose in the blood
2. The measurement of glucose while fasting
3. The measurement of blood sugar after a standardized glucose intake is given to the patient orally
4. By measuring the amount of glucose particles attached to blood hemoglobin (A_{1C}), which represents average blood glucose (BG) level over a 3-month period and is a very consistent indicator of risk for diabetes complications

Some of these measurements need to be repeated to confirm the final diagnosis of diabetes.

WHAT CAUSES DIABETES?

DM has various types including type 1, type 2, gestational (associated with pregnancy), or other specified and less common types. Insulin is the hormone mainly responsible for titration of blood sugar level and is secreted from pancreas (an organ in the abdomen that is closely associated with intestinal tract). Type 1 diabetes means that the pancreas is not producing enough, or any, insulin to maintain the blood sugar in the normal range. Type 2 diabetes is not only characterized by resistance to the action of insulin for multiple reasons but also by a relative decrease in the body's ability to secrete insulin (insulin is produced but not in sufficient quantities or in an appropriate pattern to overcome the insulin resistance). Increased resistance to insulin, owing to greater quantities of different hormones in the blood that occur during pregnancy, is the basis for gestational diabetes. The resistance to insulin usually resolves after the patient gives birth but the presence of gestational diabetes constitutes a high-risk factor of developing type 2 diabetes later in the patient's life and therefore these patient's require close follow-up. Other less common types of diabetes could be because of genetic defects affecting insulin's action, pancreatic disease with decreased insulin production, various endocrine dysfunctions, various drugs, rare infections, immune-mediated reactions, and so on. The overall clinical manifestation of these other types are similar to either type 1 or type 2 diabetes.

Type 1 diabetes: Insulin therapy is essential in patients with type 1 diabetes because they do not produce any. DKA is a known complication of type 1 diabetes in patients not receiving insulin injections. This is a very dangerous condition characterized by dehydration, nausea, and vomiting and is so severe that it can lead to coma and even death if left untreated. It is completely reversible with the appropriate administration of insulin and glucose.

Type 2 diabetes: Basically it means a resistance to insulin and the body's inability to compensate by producing more from the pancreas. Type 2 diabetes is always preceded by a condition called prediabetes. Prediabetes is defined by high levels of fasting glucose, unusual rise in blood sugar in response to the higher amounts of glucose intake, and higher levels of A_{1C} but not to the degree seen in full-blown diabetes. A gradual increase in resistance to insulin's action (insulin resistance) occurs with aging, obesity, physical inactivity, and genetic factors. If the insulin resistance is not overcome by producing more insulin then, this will lead to increased glucose in the blood and finally frank DM. It is important to understand that obesity, especially "male-type" abdominal obesity is the central component in developing prediabetes and type 2 diabetes.

Prediabetes can be detected through the same tests as full-blown diabetes.

Individuals considered “at risk” should be screened for both prediabetes and type 2 diabetes. Early detection not only allows an early implementation of preventive measures aimed at reducing insulin resistance (weight loss, increased physical activity, etc.) but can also prevent chronic complications and can improve longevity and chances of complication-free survival.

ELEVATED BLOOD GLUCOSE WHILE HOSPITALIZED (INPATIENT HYPERGLYCEMIA)

Sometimes acutely ill patients who are not known to have had diabetes or prediabetes of any kind may develop high BG while admitted to the hospital because the stress on the body from illness causes a state of insulin resistance. This can also happen in patients who have latent diabetes, prediabetes, or just are at risk for diabetes development but are normally glucose tolerant when not sick. It is unclear how frequently this leads to persistent diabetes after hospitalization, but inpatient elevations of BG have been linked to worse outcomes in the critical care units. If the patient survives the critical event but shows signs of impaired glucose tolerance (IGT) (prediabetes), this can be an indication for the future development of diabetes, and it should be addressed by the physician caring for the patient in the outpatient setting.

CLINICAL MANIFESTATION OF DIABETES MELLITUS

Clinical manifestations of DM could be acute (such as diabetic ketoacidosis (DKA) or chronic. The chronic complications may affect the small blood vessels (microvascular) or large blood vessels (macrovascular) in the body. Microvascular complications include worsening vision, nerve dysfunction (neuropathy), and damage to the kidneys. Macrovascular complications include effects on the brain, heart, and other peripheral blood vessels (atherosclerosis and clotting). Other complications include an increased risk of infections and disorders of the skin, joints, and muscles.

TREATING ELEVATED BLOOD GLUCOSE TO ACHIEVE TARGET (OUTPATIENT MANAGEMENT)

Currently it is recommended to aim for tight glucose control early in the course of diabetes. There are several ways to assess glucose control in DM. One can frequently test BG throughout the day with a glucometer (a handheld machine for bedside or home BG measurements), measure A_{1C}, or measure BG

continuously through a subcutaneous catheter (inserted under the skin), which is called continuous glucose monitoring. Glucose monitoring is essential for the patients to achieve the glucose targets. A_{1C} reflects mean glucose over a 2- to 3-month period. Beyond the desirable range, it is a marker for risk of complications. The target level of A_{1C} recommended by the ADA is <7% or as close to normal as safely possible to achieve. It should be tested every 6 months if the value is at target or every 3 months when not on target, or when treatment changes. Other glucose targets for tight control have been defined for fasting BG and for glucose checked 2 hours after consumption of a meal (postprandial). The fasting glucose target has been defined by the ADA as 90 to 130 mg/dL, whereas 2-hour postprandial glucose target has been defined as <180 mg/dL peak value. Glucose monitoring is best demonstrated by a diabetes educator, who can also best determine the devices that should be used and how often to test. The glucose should be monitored at least 3 times/day, before each of the main meals, for patients on insulin injections to guide dosing. Those not on insulin could use self-monitoring as a guide to success.

MANAGEMENT OF LOW BLOOD GLUCOSE (HYPOGLYCEMIA)

The correct management of low levels of BG is crucial in all diabetics but especially in those with cardiac disease, vascular disease, or advanced complications. The low BG levels should be correctly evaluated and treated immediately. The severity of low glucose levels is considered mild to moderate when levels of BG range from 50 to 70 mg/dL and/or patients can treat it themselves. It can be treated with simple, and easily absorbable oral sources of carbohydrate such as glucose tablets/gel, orange juice, or soft drinks containing 15 to 20 g glucose. Glucose levels should be checked again in 15 minutes and patients must be educated to carry a source of glucose with them at all times. Extremely low BG levels of <50 mg/dL, when accompanied by altered consciousness and requiring the patients to need assistance, is considered to be very severe. The patient needs to take 20 to 30 g of simple glucose orally if able to or be given glucagon (a hormone produced by the pancreas, which counteracts insulin) by intramuscular injection. If the patient is not responsive to the previous methods, then 911 should be called for IV glucose to be administered. If severe hypoglycemia is consistently present, patients should be referred for a diabetes self-management education workshop, where the use of glucagon injection should be taught to family members or caretakers. In addition, BG

goals have to be revised. If patients have frequent episodes of low BG or are unaware of the symptoms that usually accompany these low levels, they need support from family members or friends to prevent them from harm. These at-risk patients should wear identifying bracelets and it is not recommended that they drive.

IDENTIFYING AND TREATING COMPLICATIONS OF DIABETES

The treatment of chronic complications of diabetes should be conducted according to published standards of care to ensure early diagnosis and to prevent progression. These standards of care are published yearly by the ADA. Retinopathy, nephropathy, and neuropathy are the targeted complications. Retinopathy is one of the eye complications of DM. It can lead to blindness if not treated early with laser or other methods. Diabetes is also a risk factor for the development of cataracts and glaucoma. Patients should have annual dilated eye examinations after 3 years from the onset of type 1 diabetes and immediately at the time of diagnosis for type 2 diabetes. Prevention of retinopathy is through tight control of BG and also by smoking cessation along with control of blood pressure and blood lipids (cholesterol and triglycerides). Diabetic nephropathy (kidney injury) manifests itself as protein leaking into the urine, which eventually can lead to kidney failure requiring dialysis. The amount of protein leaking into the urine should be checked annually with a random spot urine test. Also, the kidney function needs to be monitored at least annually. The prevention of kidney failure should be done through tight glucose and blood pressure control and through administration of agents that lower leakage of protein in the urine. When severe protein leakage is present, there may be swelling of the legs, and the treatment should include dietary protein reduction, blood pressure lowering to <125/75 mm Hg, and revised glucose management goals. Diabetic neuropathy or nerve damage can affect the “peripheral” nerves (those going to the feet and legs, hands, etc.) or the nerves that go to the internal organs. The former can lead to diabetic foot ulcers, damage to the joints, and deformities of the feet with fractures and infections and, ultimately, even amputations. Inspection of the feet should be done at every visit; feet identified to be at high risk should be referred for podiatric care and for orthotics. Patients should have diabetes self-management education including foot care training.

DIABETES MELLITUS IN THE CARDIAC CARE UNIT

HIGH PREVALENCE OF DIABETES MELLITUS AND HYPERGLYCEMIA IN THE ACUTE CORONARY SYNDROME

Patients with type 2 diabetes have a very high incidence of obesity and the so-called metabolic syndrome. Obesity, particularly abdominal obesity, predisposes the body to become more resistant to the effects of insulin. Metabolic syndrome is a constellation of insulin resistance with resultant metabolic derangements that puts the patient at particularly high risk for DM as well as CVD. Other associated metabolic abnormalities of this syndrome that include inflammation, abnormal lipid levels in the blood and a tendency to have blood clots in the vascular system are also associated with acute complications of CVD such as CAD which can lead to coronary syndrome (ACS). or heart attack. Numerous studies have shown that there is a very high prevalence of diabetes in patients admitted to the CCU with acute coronary syndrome (ACS). In addition to being frequently present in ACS, diabetes also predicts unfavorable outcomes in those who have ACS. Patients afflicted with both conditions (diabetes and ACS) have more frequent high blood pressure, high cholesterol, and kidney failure. This is regardless of whether the diabetes is new onset or established. High blood sugar affects ACS outcomes even if diabetes was not present before the event and is diagnosed in the hospital.

STRATEGIES FOR IMPROVING OUTCOMES IN ACUTE CORONARY SYMPTOM COMPLICATED BY DIABETES AND/OR HIGH BLOOD GLUCOSE

To counteract complications from cardiac events in type 2 diabetes, various blood-thinning medications and early strategies to unblock blood vessels are done as early as possible. In addition to these important lifesaving therapies that are similar to those utilized in non–diabetic patients, glucose-lowering therapies and aggressive use of secondary prevention therapies for control of high blood pressure, cholesterol, and inflammation are also utilized. Currently, the consensus is that high BG should be lowered in patients with diabetes and ACS, but the level to be obtained will be dependent on how safe it is to get there without causing hypoglycemia. Both hyperglycemia and hypoglycemia are harmful and should be avoided in the CCU. Many patients with diabetes might need round-the-clock infusions of insulin intravenously to keep their BG level in the appropriate range. The rate at which this infusion enters the body is calculated and adjusted by frequent monitoring of BG levels via glucometers.

TRANSITION TO OUTPATIENT CARE

As soon as the patient's condition is stable and he/she is able to eat, the IV infusion of insulin can be safely switched to SQ (under the skin) injections in preparation for transfer to a general medical floor outside the CCU and eventually home. While in critical conditions, the body's insulin requirements are usually higher and as the acute critical condition improves, the insulin requirements usually go back to their baseline.

OTHER ASPECTS OF DIABETES MANAGEMENT

It is important to assess the goals of diabetes management before the hospital discharge and to follow up with primary care providers outside the hospital to make sure these goals are reached successfully. For anyone with a newly diagnosed DM, essential care also includes diabetes self-management education and nutrition education. If diabetes is diagnosed for the first time while the patient is in hospital, a minimum amount of diabetes education (survival skills) will be taught in the hospital before discharge and patients will be referred to an outpatient, ADA-certified, diabetes self-management education program. Diabetes self-management nutrition education addresses diet and energy balance, weight loss issues if needed, need for carbohydrate (sugar intake) counting in insulin-requiring patients, risk of low BG with decreased calorie intake, increase in physical activity, increase in dietary fiber (14 g/1,000 kcal), and alcohol intake (maximum one drink per day for women and two drinks per day for men).

Physical activity is recommended to be of both aerobic and resistance-type training and should be done in combination. Aerobic activity should be at least 150 minutes per week and it should be of moderate intensity, 50% to 70% of maximum heart rate (220-age). Resistance exercise should be done 3 times a week if there are no contraindications, such as the presence of advanced diabetic retinopathy. Blood pressure targets are lower for diabetics compared to general population (130/80 mm Hg in diabetics and125/75 mm Hg in diabetics with advanced kidney disease). Cholesterol levels also need particular attention in diabetics. Compliance with dietary recommendations and also regular physical activity not only improves the BG but will also significantly improve the cholesterol and triglyceride levels. The doctor might also prescribe cholesterol-lowering medications to help decrease risk of heart and vascular disease. Mood disorders such as depression and anxiety as well as social (family and economic issues) or physical (blindness, amputations, etc.) barriers can affect diabetes

management. Inform the doctor about any possible barrier to an optimum diabetes management plan.

In those with inpatient hyperglycemia but without prior history of diabetes, it is important to arrange for regular follow-up after discharge to determine whether the hyperglycemia persists, and if not whether the patient is at risk of developing diabetes.

For more information about diabetes and treatments, visit the ADA website at http://www.diabetes.org/.

Lipid Management in the Cardiac Care Unit

LIPIDS, ATHEROSCLEROSIS, AND CARDIOVASCULAR RISK

Elevated plasma lipoproteins are among the most important risk factors for coronary heart disease and are the driving force of atherogenesis. This strong link has been consistently demonstrated over the past decades in pathologic, epidemiologic, genetic, and interventional clinical studies, establishing causality between low-density lipoprotein cholesterol (LDL-C) and atherosclerosis.

Lipoprotein particles accumulate in the intima of arteries in hypercholesterolemic states and undergo oxidative and other modifications that are accelerated during endothelial dysfunction, leading to the uptake of LDL-C by macrophages and generation of foam cells evolving into fatty streaks.[1] This process initiates smooth muscle proliferation and the formation of a fibrous cap, covering the lipid core filled with macrophages. The concept of “response to retention” provides a mechanistic link between accumulation of lipoprotein particles, proinflammatory effects, and the initiation and progression of the atherosclerotic plaque.[2]

Epidemiologic studies have firmly established a direct relationship between serum cholesterol levels and the prevalence of atherosclerotic cardiovascular

disease (CVD). Many large randomized controlled trials in the statin era have documented that lowering total cholesterol and LDL-C reduces the risk for both coronary heart disease and stroke, largely irrespective of the initial lipid profile, in a wide range of individuals, including those at relatively low risk for vascular events, and in direct relationship to the intensity of the statin regimen.[3–5] Epidemiologic data have also shown that the concentration of high-density lipoprotein cholesterol (HDL-C) is an independent, inverse predictor for CVD and is important in global risk assessment. However, there is a lack of convincing evidence that raising HDL-C by pharmacologic interventions reduces the risk for CVD, and therefore currently low HDL-C concentration is not a primary target of drug therapy. A renewed interest driven by epidemiologic and genetic data supports triglyceride-rich lipoproteins and their cholesterol content (remnant cholesterol) as an additional contributor to CVD and cardiovascular mortality. However, conclusive evidence as to whether lowering high triglycerides levels reduces the risk of CVD is lacking.

Interindividual variability in blood lipids concentration is derived from both lifestyle and inherited factors. Single-gene mutations in LDL receptor pathway are strongly associated with high cholesterol levels and predispose to familial hypercholesterolemia and premature CVD.[6] In contrast, low cholesterol levels from birth caused by proprotein convertase subtilisin/kexin type 9 (PCSK9) loss-of-function gene mutations confer protection from atherosclerotic disease.[7] Genetic studies further show that genetic variants causing lifetime low LDL-C levels are associated with very low rates of coronary heart disease.[8] Polymorphisms (SNPs) from several genes that are associated with modulation of cholesterol levels were also demonstrated to be an independent risk factor for CVD. In contrast to the causal relationship between LDL-C and CVD, genetic mechanisms that raise plasma HDL-C were not reported to be related to lower risk of myocardial infarction. This challenges the concept that raising plasma HDL-C will uniformly translate into reduction in the risk of coronary heart disease.[9] Research now focuses on assessment of HDL functionality as a marker for atherosclerotic risk and a better target for therapeutic intervention than HDL-C.

PLASMA LIPID PROFILE

Routine lipid profile in most clinical biochemistry laboratories includes direct

measurement of total cholesterol, HDL-C, and triglycerides. LDL-C is usually measured indirectly, calculated by the Friedewald equation: LDL-C = Total cholesterol minus HDL-C minus triglycerides/5 (with values in mg/dL). Friedewald equation underestimates LDL-C levels when triglycerides are elevated, and therefore LDL-C is not calculated indirectly when triglycerides are above 300–400 mg/dL, depending on specific institute laboratory. Direct measurement of LDL-C when triglyceride concentrations are high is feasible, but not available routinely at all institutions. Accordingly, calculation of non–HDL-C from standard lipid panel as total cholesterol minus HDL-C is recommended in hypertriglyceridemic states, and expresses the cholesterol content of all atherogenic apolipoprotein B (apoB)–containing particles. Non–HDL-C does not require additional charge, appears to be a more accurate marker of cardiovascular risk than LDL-C, and should be considered an alternative risk marker and a secondary treatment target, especially in hypertriglyceridemic states such as in metabolic syndrome, diabetes, and chronic kidney disease. The specific target for non–HDL-C should be about 30 mg/dL higher than the corresponding LDL-C target. To improve patient compliance with lipid testing, a recent consensus panel advocated the routine use of nonfasting lipid profiles, whereas fasting sampling should be considered when nonfasting triglycerides are signifcantly elevated.[10]

Early studies indicated that cholesterol levels (both LDL-C and HDL-C) start to decline 24 hours after acute myocardial infarction because of an acute-phase response, reach the nadir on approximately day 7, and normalize within 2 months after acute coronary syndrome (ACS). These changes in lipid levels should be taken into account when making clinical decisions in treating hyperlipidemia after ACS, and efforts should be made to take blood samples for lipid profile early in the course of ACS.

LIPOPROTEIN *(a)*

Lipoprotein(a) [Lp(a)] is a genetic, causal risk factor for CVD, showing an independent and continuous association with cardiovascular risk, including myocardial infarction, stroke, peripheral arterial disease, and calcific aortic valve stenosis.[11,12] Lp(a) is composed of a single molecule of apoB100 covalently linked to apo(a), which contains a unique region that is structurally homologous to plasminogen. It is suggested that Lp(a) induces both prothrombotic activity because of competitively antagonizing plasminogen binding and potential atherogenic effect secondary to arterial deposition of oxidized phospholipids by

apoB. Candidates for Lp(a) screening include patients with a strong family history of premature CVD, patients with hypercholesterolemia in which Lp(a) has synergistic effects with elevated LDL-C levels, and patients with ACS and recurrent cardiovascular events despite maximal statin therapy. Niacin is the only medication that has consistently shown a dose-dependent lowering effect on Lp(a), reducing levels up to 30% in clinical trials. Lipoprotein apheresis is an effective therapeutic option reserved for severe cases of progressive coronary disease despite optimal drug therapy.[12] Although Lp(a) is a major causal cardiovascular risk factor in both genetic and population studies, there are no controlled trials that have shown that lowering Lp(a) through pharmacotherapy significantly reduces risk. Novel therapies such as PCSK9 inhibitors reduce 25% to 30% of Lp(a) concentration, and recent promising phase I studies in humans demonstrated a more significant reduction of Lp(a) levels by antisense oligonucleotides (ASOs) that inhibit apo(a) mRNA translation.

ADVANCED LIPOPROTEIN TESTING

Advanced lipoprotein analysis, including testing of lipoprotein subfractions, LDL particle number, and apoB concentration, has been proposed as a more accurate measure to assess the risk attributable to atherogenic lipoproteins and as a potential means to reduce residual cardiovascular risk. The cholesterol content of LDL particles varies substantially between individuals, and subjects with the same LDL-C level may have discordant numbers of LDL particles. Many patients with high cardiometabolic risk or diabetes have relatively normal levels of LDL-C that poorly characterize the excess concentration and risk of small dense LDL particles. The discordance between LDL-C and LDL particle number was shown to impact cardiovascular risk in the Framingham and Multi-Ethnic Study of Atherosclerosis (MESA)studies.[13,14] Therefore, measurements of LDL particle number or apoB rather than the cholesterol content of LDL may be more adequate to assess the residual risk for coronary disease in high cardiometabolic risk subjects who achieve “optimal” LDL-C levels. However, the clinical utility of advanced lipoprotein analysis is still debated, and this test is not routinely in use in clinical medicine.

FAMILIAL HYPERCHOLESTEROLEMIA

Familial hypercholesterolemia (FH) is a common monogenic disorder of lipoprotein metabolism, associated with high concentrations of LDL-C,

predisposing affected individuals and their families to premature coronary heart disease.[6] FH is prevalent globally, reaching 1:300 in the general population in its heterozygous form because of principally autosomal dominant inheritance. Nevertheless, FH is vastly underdiagnosed and undertreated in most countries. Patients with FH are often unrecognized despite typical presentation with premature coronary heart disease and severely elevated LDL-C levels. Cardiovascular risk is driven by the presence of concomitant risk factors and the cumulative LDL-C burden throughout life, which is a function of age of initiation of drug therapy and compliance with treatment. LDL-C ≥ 190 mg/dL in adults and ≥ 160 mg/dL in children raises the likelihood of the presence of monogenic disorder. However, in the setting of the general population, customary LDL-C cutoffs of 190 mg/dL in children, 220 mg/dL between ages 20 and 29 years, and 240 mg/dL in adults ≥ 30 years are associated with an 80% probability of FH (MEDPED criteria). Secondary causes of severe hypercholesterolemia should be excluded (**Table 55.1**). Family history of hypercholesterolemia and coronary disease at young age in relatives, as well as physical stigmata such as tendon xanthomas and arcus cornea, which are seen in about 30% to 40% of patients and are correlated with severity and duration of hypercholesterolemia, are aditional diagnostic criteria.

TABLE 55.1 Secondary Causes of Hyperlipidemia

DISORDERS AFFECTING LIPIDS	MEDICATIONS AFFECTING LIPIDS

[a]PCOS, polycystic ovary syndrome; SSRI, selective serotonin reuptake inhibitors.

Identification of FH patients is important, because early intensive treatment and cascade screening of families may further reduce cardiovascular event rates. Although direct detection of causative gene mutations is available and molecular genetics for screening family relatives is carried out successfully in several countries, genetic testing is still costly and is not systematically feasible in most places. Cardiovascular divisions such as the cardiac care unit may provide ideal locations to promote identification and treatment of high-risk patients with FH.

LIPID MANAGEMENT IN ACS

STATINS

Statins are the cornerstone of pharmacologic therapy in the prevention of atherosclerotic CVD. Statins inhibit HMG-CoA reductase, the rate-limiting step of cholesterol synthesis, subsequently upregulating LDL receptors on the surface of hepatocytes. Statins are targeted mainly for significant reduction of LDL-C levels, up to 55%, but improve, to some extent, all components of the lipid profile. Large-scale, randomized, controlled statin trials of both primary and secondary prevention in humans have shown repeatedly that LDL-C reduction by statins correlates linearly with CVD, reducing myocardial infarction, stroke, and cardiovascular death.[4,5] These trials have demonstrated that the beneficial effects of statins are preserved also in subjects with low baseline LDL-C< 100 mg/dL and in patients with diabetes. Furthermore, intensive lipid lowering with a more potent or higher dose statin resulted in further reduction of both LDL-C levels and major cardiovascular events compared with a less intensive regimen, in both stable and acute coronary artery disease populations. Patients with a history of atherosclerotic vascular disease, including ischemic stroke or peripheral artery disease, are considered coronary heart disease risk equivalents, and, as such, are targeted for high-intensity statin therapy to reduce cardiovascular events.

EFFECTS OF EARLY STATIN TREATMENT ON CLINICAL OUTCOMES AFTER ACS

Early initiation of statin treatment has become a guideline-directed standard of care after ACS because of several landmark randomized prospective trials

presented during the years 2001 to 2004. The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) study was the first large study investigating the potential clinical benefit of the early use of statins in ACS.[15] Initiation of high-dose atorvastatin (80 mg/d) early (24–96 hours) after ACS reduced cardiovascular adverse events during the first 4 months after starting therapy, especially new hospitalizations for recurrent ischemia. In the A-to -Z trial, patients admitted for ACS and treated with an early intensive statin therapy (simvastatin 40 mg/d for 1 month followed by 80 mg/d) had lower mortality risk compared to less intensive treatment (placebo for 4 months followed by simvastatin 20 mg/d) that was started later.[16] However, the study failed to show an improvement in overall cardiovascular outcomes. The Pravastatin or Atorvastatin Evaluation and Infection Therapy–Thrombolysis in Myocardial Infarction 22 (PROVE IT–TIMI 22) trial compared a standard statin regime (pravastatin 40 mg/d) to intensive treatment (atorvastatin 80 mg/d), within 10 days of hospital admission for ACS, confirming that high-intensity statin therapy provided greater protection, reducing the rate of cardiovascular adverse events in 16% during a mean follow-up of 24 months, as well as 30-day clinical outcomes.[17] Additional substudy later confirmed the results in the subset of patients who performed percutaneous coronary intervention (PCI) for the acute coronary event, and showed reduced target vessel revascularization in the patients randomized for high-intensity statin.

Although the results of these studies seem to support the protective role of high-intensity statin therapy in the early period after ACS, it should be noted that several meta-analyses summarizing the evidence on early statin therapy for ACS showed favorable but nonsignificant reduction in death or myocardial infarction in the short term, but significant reduction in the occurrence of unstable angina at 4 months following ACS.[18,19] Past ACC/AHA guidelines recommended (Level of Evidence 1A) the use of statin therapy before hospital discharge for all patients with ACS regardless of the baseline LDL-C. The most recent ACC/AHA 2013 guidelines on the treatment of blood cholesterol state that high-intensity statin therapy (atorvastatin 40 to 80 mg or rosuvastatin 20 to 40 mg) should be initiated or continued as first-line therapy in all patients ≤75 years of age that have clinical atherosclerotic CVD but do not relate specifically to the early phase post-ACS.[20]

STATIN-ASSOCIATED BENEFITS IN PATIENTS UNDERGOING PCI

Several studies have reported that short-term preprocedural administration of

statins might reduce the incidence of adverse effects after PCI. The Atorvastatin for Reduction of Myocardial Damage during Angioplasty—Acute Coronary Syndromes (ARMYDA-ACS) trial evaluated the loading dose of high-intensity atorvastatin before PCI in NSTEMI ACS, showing a reduced incidence of cardiovascular events in the first month after PCI.[21] A meta-analysis addressing the impact of timing of statin administration given before or after PCI on clinical outcomes reported that administration of statins before PCI reduces the odds of myocardial infarction at 30 days to a greater extent compared with a post-PCI administration, and that the earlier the statin administration, the lower the risk of early major adverse cardiovascular events.[22]

BENEFICIAL MECHANISMS OF EARLY STATIN INITIATION

The mechanisms underlying the protective actions of early statin administration may be independent of LDL-C reduction. Statins have been shown to modulate several mechanisms involved in the pathogenesis of ACS, including inflammation, oxidative stress, and vascular smooth muscle proliferation. Beneficial effects on platelet aggregation and endothelial function were also reported. Intravascular ultrasound (IVUS) studies have shown that statins significantly decrease plaque volume after ACS,[23] and cumulative data support the effectiveness of statin treatment in promoting plaque stabilization and regression, especially after ACS and with the use of high-intensity statins.[24]

STATINS AND THE PREVENTION OF CONTRAST-INDUCED ACUTE KIDNEY INJURY

Patients with ACS have a 3-fold higher risk of developing contrast-induced acute kidney injury, which is associated with prolonged hospitalization and increased morbidity and mortality. The Atorvastatin for Reduction of Myocardial Damage during Angioplasty—Contrast-Induced Nephropathy (ARMYDA-CIN) trial has shown that short-term pretreatment with high-dose atorvastatin decreases the incidence of contrast-induced nephropathy in statin-naïve patients with ACS undergoing early PCI.[25] More recently, the Protective Effect of Rosuvastatin and Antiplatelet Therapy On contrast-induced acute kidney injury and myocardial damage in patients with Acute Coronary Syndrome (PRATO-ACS) study has similarly demonstrated that preprocedural high-dose rosuvastatin given on admission to statin-naïve patients with ACS, who were scheduled for an early invasive procedure, can prevent contrast-induced acute

kidney injury and improve short-term clinical outcomes.[26] More effective kidney protection was demonstrated in ACS subjects with higher baseline high-sensitivity C-reactive protein (hs-CRP) levels.

STATIN INTOLERANCE AND ADVERSE EFFECTS

Statin therapy is generally considered to be safe. However, muscular symptoms are common in clinical practice, may reduce patients' adherence to therapy, and can be a barrier in maximizing cardiovascular risk reduction, especially in secondary prevention of CVD, of which high-intensity statins are now indicated. The clinical spectrum of statin-induced myotoxicity includes myalgia (reaching 1%–3% in randomized-controlled trials, but 10%–20% in observational and epidemiologic studies), less commonly myositis with significant elevated creatine kinase levels, and, very rarely, rhabdomyolysis. Asymptomatic rise in creatine kinase concentration is also observed. Factors that increase the risk of statin-induced myopathy include patient-related factors such as advanced-age, female gender, lower weight, excess of alcohol and strenuous exercise, as well as hypothyroidism, vitamin D deficiency, statin–drugs interactions, high statin dose, Asian ancestry, and genetic predisposition. In addition to ruling out possible conditions that may increase the risk of muscle symptoms, the management options include reduction in statin dose, alternate day regimens of statins with longer half-life (atorvastatin and rosuvastatin), transient cessation of therapy, and usage of an alternative statin or other lipid-lowering agent. In cases where muscle symptoms are progressive or creatine kinase is more than X10 the upper limit of normal (ULN), the statin treatment should be stopped. In rare cases of necrotizing autoimmune myopathy, steroids and immunosuppression may be needed. There is no clear evidence that Co-enzyme Q10 treatment is beneficial in statin-induced myotoxicity, because small randomized trials displayed equivocal results.

Mild elevations of hepatocellular liver enzymes are commonly seen in clinical practice. However, liver failure in statin users is rare and is similar to that in the overall population. In cases where hepatic aminotransferase levels are >3 times the ULN values, it is recommended to withhold statin treatment, reassess liver tests, and consider other causes of liver damage. Nevertheless, routine periodic monitoring of liver function tests in patients taking statins is no longer recommended, because it does not appear to be effective for detecting or preventing serious liver injury.

Randomized trials, including recent meta-analyses, have demonstrated a

consistent relationship between statins, elevation of blood glucose level, and a modest increase in the risk of incident diabetes.[27] This association seems to be dependent on the dose and potency of the statin. Individuals prone to statin-induced diabetes were shown to have major risk factors for diabetes that were similar to those in the general population, including multiple components of the metabolic syndrome and impaired fasting glucose. The benefits of statins in reducing cardiovascular events outweigh the potential risk for developing new-onset diabetes in patients who are at moderate or high risk for cardiovascular events and in secondary prevention.

Although some patients in observational data and small randomized trials were reported to experience ill-defined memory loss and confusion, recent large meta-analyses and systematic reviews have shown no evidence of increase in the risk of cognitive impairment.

NONSTATIN LIPID-LOWERING THERAPIES

Ezetimibe selectively inhibits cholesterol absorption from the intestine by blocking the transport protein Niemann–Pick C1-Like 1 transporter (NPC1L1) in the brush border of enterocytes, lowering plasma LDL-C levels by 15% to 20%. Ezetimibe is usually used in combination with statins, enhancing LDL-C lowering effect, with a good safety profile. The recently published IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) showed that when added to simvastatin therapy, ezetimibe resulted in incremental lowering of LDL-C levels and improved cardiovascular outcomes after ACS, demonstrating that lowering LDL-C to levels below previous targets provided additional benefit.[28] This landmark study is the first to show a cardiovascular benefit in adding a nonstatin lipid-modifying agent to statin therapy, reaffirming the LDL hypothesis suggesting that the reduction of LDL-C levels reduces the rate of CVD.

Medications for lowering triglycerides include fibrates, omega-3 polyunsaturated fatty acids (fish oil supplements) in pharmacologic dosages (DHA/EPA 2 to 4 g a day), and niacin. These medications have the ability to reduce 20% to 50% of triglyceride levels in blood and are indicated when levels are above 500 to 1,000 mg/dL in order to prevent acute pancreatitis. However, randomized trials showing the cardiovascular benefit of triglyceride reduction are scarce, and trials assessing fibrates and niacin as an add-on therapy against a background of statin treatment failed to show cardiovascular risk reduction. Therefore, in the statin era the routine use of fibrates and niacin is limited.

Nevertheless, subgroup analysis of outcome trials with the major fibrates showed significant relative risk reduction of cardiovascular events in patients with atherogenic dyslipidemia manifested by elevated triglyceride levels (>200 mg/dL) and low HDL-C (<35 mg/dL). Accordingly, fibrates might be considered in high-risk patients with atherogenic dyslipidemia, especially in diabetes and metabolic syndrome, as an add-on treatment to statins in order to reduce the risk for atherosclerotic CVD. Large-scale trials are awaited to provide conclusive evidence as to whether lowering triglycerides reduces the risk of CVD.

PCSK9 inhibitors are a new class of lipid-lowering medications. Binding of PCSK9 to the LDL receptor targets the receptor for lysosomal degradation. The recognition that inhibition of PCSK9 increases LDL receptor activity and the discovery of gene mutations affecting PCSK9 with clinical effects on cardiovascular risk have led to the development of human monoclonal antibodies against PCSK9, self-administered by subcutaneous injections. The PCSK9 inhibitors, approved by the U.S. Food and Drug Administration (FDA) in mid-2015 (evolocumab and alirocumab), when evaluated in numerous phase 3 trials, were found to reduce LDL-C levels up to 65% independent of background statin therapy and with a good safety profile, at least for the short term. However, information on whether PCSK9 inhibitors affect cardiovascular events or mortality is not yet available, and long-term outcome and safety studies are ongoing. Therefore, PCSK9 inhibitors are currently approved for use, in addition to maximally tolerated statin therapy, in patients with FH or clinical atherosclerotic CVD, who require additional lowering of LDL-C to achieve treatment goals.

DIET AND LIFESTYLE INTERVENTIONS

Nonpharmacologic, therapeutic lifestyle interventions are an essential part of the treatment of lipid disorders in both primary and secondary prevention of atherosclerotic CVD. This includes physical activity with an emphasis on aerobic exercise, weight loss, smoking cessation, moderation of alcohol intake, and adjustment of dietary patterns and nutrient intake (discussed separately). Patients with the metabolic syndrome, characterized by central obesity, impaired fasting glucose and insulin resistance, as well as hypertension and atherogenic dyslipidemia (hypertriglyceridemia, low HDL-C and small dense LDL particles), may benefit in particular from lifestyle interventions that were shown to significantly delay conversion to diabetes and its cardiovascular complications. The setting of hospitalization may serve as an ideal opportunity for initial dietary

and lifestyle counseling of high-risk patients. In addition, attention should be given to severe hypertriglyceridemia during hospitalization, because it may precipitate acute pancreatitis. Secondary causes of hypertriglyceridemia should be searched for and targeted; these include high carbohydrate intake (especially fructose) and calorie excess, ethanol consumption, central obesity, poor glycemic control, and medications such as systemic glucocorticoids (**Table 55.1**).

GUIDELINES FOR THE TREATMENT OF DYSLIPIDEMIA

Guidelines provide consistency in care, aiming to incorporate new evidence and guide clinical decision making. In 2013, after more than a decade, the American College of Cardiology (ACC) and the American Heart Association (AHA) published a set of guidelines on the control of blood cholesterol to reduce atherosclerotic CVD risk.[20] The AHA/ACC guidelines differed from previous widely adopted national and international guidelines, and thus have been a subject of controversy. Major changes included the abandonment of numerical LDL-C treatment targets, focusing instead on the intensity of statin therapy (**Table 55.2**), and the formation of a newly developed *Pooled Cohort Equations* calculator for estimating 10-year atherosclerotic CVD risk. In addition, in comparison to the previous Adult Treatment Panel III (ATP III) lipid guidelines, the risk threshold for considering statins in the primary prevention setting was lowered to a 10-year absolute atherosclerotic CVD risk of 7.5%. **Table 55.3** compares the similarities and differences in treatment recommendations between the ACC/AHA 2013 guidelines and the most recent European guideline for the management of dyslipidemias.[29] Recently, an ACC expert consensus panel attempted to provide practical guidance for clinicians and patients regarding the use of nonstatin therapies as an add-on to statins, to further reduce CVD risk in situations not covered by the guidelines.[30] An algorithm for the management of lipids in ACS is provided in **Figure 55.1**.

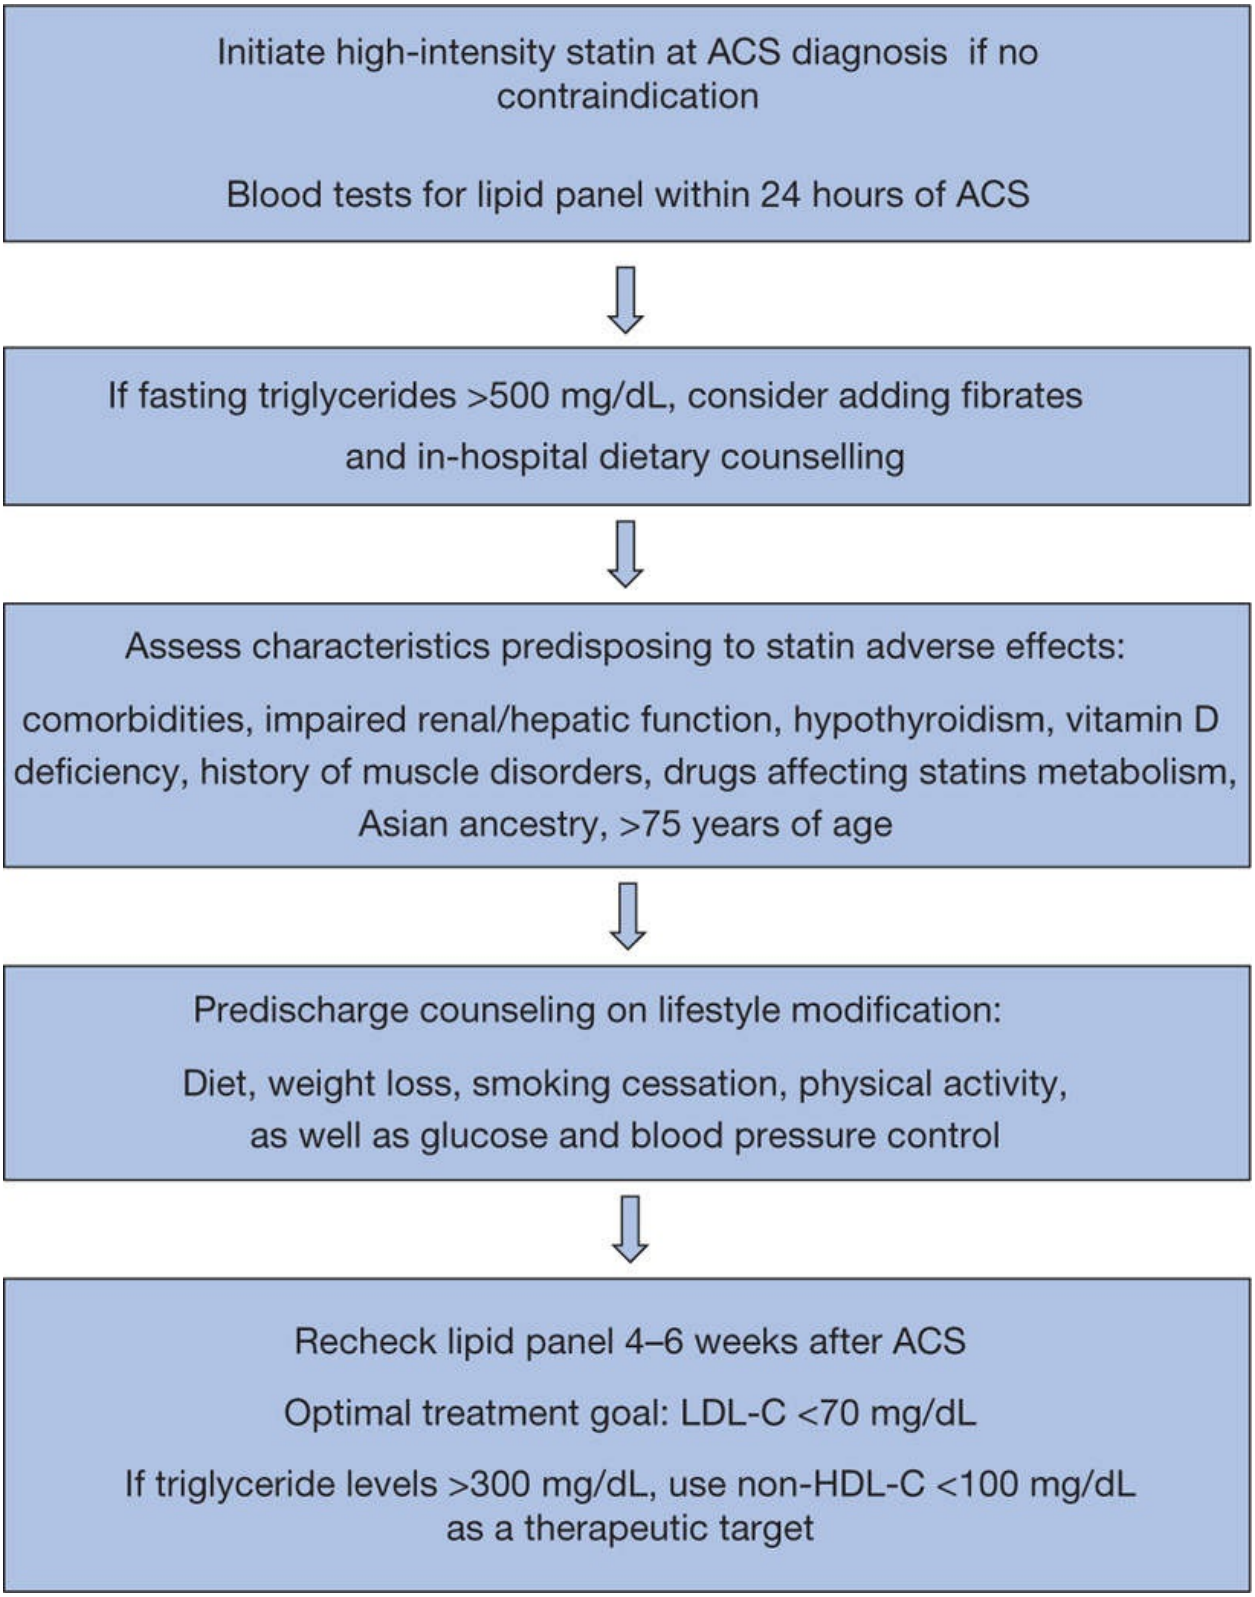

FIGURE 55.1 Algorithm for the management of hyperlipidemia in acute coronary syndrome (ACS). HDL-

C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

TABLE 55.2 Statin Therapy Intensity and LDL-C Reduction

STATIN INTENSITY	HIGH INTENSITY	MODERATE INTENSITY	LOW INTENSITY
LDL-C lowering (daily dose)	≥50%	30%–50%	<30%
Drugs	Atorvastatin 40–80 mg Rosuvastatin 20–40 mg	Atorvastatin 10–20 mg Rosuvastatin 5–10 mg Simvastatin 20–40 mg Pravastatin 40–80 mg Lovastatin 40 mg Fluvastatin 80 mg Pitavastatin 2–4 mg	Simvastatin 10 mg Pravastatin 10–20 mg Lovastatin 20 mg Fluvastatin 20–40 mg Pitavastatin 1 mg

TABLE 55.3 Comparison Between Lipid Treatment Guidelines

ACC/AHA (2013) GUIDELINE ON THE TREATMENT OF BLOOD CHOLESTEROL TO REDUCE ASCVD RISK		ESC/EAS (2011) GUIDELINES FOR THE MANAGEMENT OF DYSLIPIDEMIAS	
RISK CATEGORIES	**TREATMENT**	**RISK CATEGORIES**	**TREATMENT**
Clinical ASCVD[a]	High-intensity[b] statin Age > 75 or safety concern: Moderate-intensity[b] statin	**Cardiovascular disease[a]**	LDL-C < 70 mg/dL and/or ≥50% reduction.
Diabetes: Type I or II Age 40–75 LDL-C 70–189 mg/dL	*High-risk*: (10-y ASCVD risk ≥7.5%): High-intensity statin *Low-risk*: Moderate-intensity statin	**Diabetes (type II or type I with target organ damage) or moderate to severe CKD (GFR ≤ 60 mL/min/1.73 m^2)**	LDL-C < 70 mg/dL and/or ≥50% reduction. Second goals: non-HDL-C< 100 mg/dL and apoB < 80 mg/dL.
Primary LDL-C ≥190 mg/dL	High-intensity statin Achieve>50% LDL-C reduction	**Familial dyslipidemia**	LDL-C < 100 mg/dL or maximal reduction with drug combinations and LDL apheresis.
None of the above (primary prevention; age 40–75): (a) 10-y ASCVD	(a) Moderate-to high-intensity	**None of the above: 10-y risk estimate of First fatal atherosclerotic CV**	(a) Very high risk: LDL-C < 70 mg/dL

risk ≥ 7.5% (b) 10-y ASCVD risk 5%–7.5% **(risk calculator based on the pooled cohort equations)**	statin (b) Consider moderate-intensity statin	**event:** (a) **SCORE > 10%** (b) **SCORE 5%–10%** (c) **SCORE 1%–5%**	(b) High risk: LDL-C < 100 mg/dL (c) Moderate risk: LDL-C < 115 mg/dL
If risk-based assessment uncertain, consider: • **Family history premature CVD** • **hsCRP ≥ 2.0 mg/L** • **CAC score ≥ 300 Agatston unit** • **ABI < 0.9** • **LDL-C ≥ 160 mg/dL** • **Lifetime ASCVD risk**		**Additional data modifying risk:** • **Elevated triglycerides** • **Social deprivation** • **Central obesity** • **Familial hypercholesterolemia** • **High lipoprotein (a) levels** • **Subclinical atherosclerosis** • **Chronic kidney disease** • **Family history of premature CVD** • **Low HDL-C**	
Additional recommendations: (a) Encourage lifestyle modifications. (b) Guidelines do not consider data on the use of lipid fractions other than LDL-C. (c) Statins are not routinely recommended for NYHA II–IV heart failure patients and those receiving hemodialysis. (d) Do not routinely measure and monitor ALT or CK, unless symptomatic.		Additional recommendations: (a) Encourage lifestyle modifications (b) Non-HDL-C and apoB should be considered an alternative risk marker and second treatment target in metabolic syndrome and diabetes (class IIa indication). (c) Statins are not indicated in patients with moderate or severe heart failure. Statins are indicated in moderate to severe CKD (LDL-C<70 mg/dL). (d) ALT should be measured before treatment, 8 weeks after starting treatment or dose increase, and annually thereafter. CK should be measured before starting treatment, but not necessary for monitoring.	

ABI, ankle-brachial index; ALT, alanine transaminase; ApoB, apolipoprotein B; ASCVD, atherosclerotic cardiovascular disease; CAC, coronary artery calcium; GFR, glomerular filtration rate; HDL-C, high-density lipoprotein cholesterol; hsCRP, high-sensitivity C-reactive protein; CK, creatine kinase; LDL-C, low-density lipoprotein cholesterol.

[a]ACC/AHA clinical ASCVD definition includes acute coronary syndromes, previous myocardial infarction, stable/unstable angina, arterial revascularizations, ischemic stroke or transient ischemic attack, and peripheral arterial disease presumed to be of atherosclerotic origin. ESC/EAS Cardiovascular disease definition includes, in addition, preclinical evidence for atherosclerotic disease on the basis of any imaging modality.

[b]High-intensity statin: daily dose lowers LDL-C by ≥50% (rosuvastatin 20 mg [40 mg]; atorvastatin 40/80 mg). Moderate-intensity: daily dose lowers LDL-C by 30% to 50%.

Patient and Family Information for: LIPID MANAGEMENT IN THE CARDIAC CARE UNIT

HYPERLIPIDEMIA

Increased level of lipids (fats) in the blood is termed hyperlipidemia and includes both elevated cholesterol and triglycerides. Hyperlipidemia is a major cause of atherosclerosis, a term that refers to the buildup of fats and other substances in the walls of the arteries in the body, leading to the formation of plaques that can restrict blood flow. Hyperlipidemia significantly increases the risk of developing CVD, damaging the blood vessels supplying the heart, causing coronary artery disease and heart attacks. It may similarly lead to vascular disease in the limbs (peripheral vascular disease) and in the arteries supplying the brain (cerebrovascular disease).

LIPID PROFILE

BLOOD CHOLESTEROL

Cholesterol is a substance found in lipid particles in cells and body fluids, which is important to the cell structure and function and is a precursor to various metabolic pathways. High blood cholesterol is a major risk factor for developing heart disease. Low-density lipoprotein (LDL) particles are the main transporters of cholesterol throughout the body. The retention of LDL cholesterol in the walls of the arteries and the buildup of atherosclerotic plaque may narrow the coronary arteries supplying blood to the heart and cause symptoms such as effort-induced chest pain. Rupture or erosion of plaque in the coronary arteries may precipitate

thrombi formation that obstructs the blood vessel and causes heart attack.

Many people are unaware that their cholesterol levels are high. A common genetic disease named “familial hypercholesterolemia” is associated with markedly elevated cholesterol levels and premature heart attack and stroke. Because this genetic disorder may pass to half of first degree relatives, it is important to measure the lipid profile in the blood at a young age in individuals with a family history of high blood cholesterol or premature heart disease, and in everyone at the age of 20. Lowering the cholesterol levels lessens the risk for developing heart disease.

Total Cholesterol Levels

- Desirable: <200 mg/dL
- Borderline high: 200 to 239 mg/dL
- High: ≥ 240 mg/dL

LDL Cholesterol Levels

LDL cholesterol, often called the “bad cholesterol,” is directly associated with the risk of developing heart disease, and is therefore the primary target for drug therapy in individuals at risk.

- Optimal: <100 mg/dL
- Mean levels: 100 to 129 mg/dL
- Borderline high: 130 to 159 mg/dL
- High: 160 to 189 mg/dL
- Very high: ≥190 mg/dL

TRIGLYCERIDES

Triglycerides are a form of fat used as an energy source by the body and usually stored in fat cells. High triglyceride levels are often associated with obesity and diabetes and are a risk factor for developing heart disease. Triglyceride-rich lipoprotein particles are broken down by enzymes to smaller particles termed “remnant cholesterol,” which are rich in cholesterol and are also atherogenic. Triglycerides should be measured after prolonged fasting of 12 hours.

Triglyceride Levels

- Normal: less than 150 mg/dL
- Borderline high: 150 to 199 mg/dL

- High: 200 to 499 mg/dL
- Very high: 500 mg/dL and above

Triglycerides above 500 mg/dL are a risk factor for developing pancreatitis, which may cause abdominal pain and multiple health complications. Therefore, very high triglyceride levels are an indication for making aggressive lifestyle changes and taking medical treatment.

HDL CHOLESTEROL

HDL cholesterol is the cholesterol carried in particles called high-density lipoproteins (HDL), known as the "good cholesterol," with protective antiatherogenic properties, carrying harmful cholesterol away from the vessel wall back to the liver for metabolism and clearance, a process termed reverse cholesterol transport. Desirable HDL cholesterol levels in blood are above 40 mg/dL in men and 50 mg/dL in women. Low HDL cholesterol is often associated with high triglyceride levels, and both are features of the metabolic syndrome, characterized also by elevated blood pressure, large waist circumference (central obesity), and high glucose levels. Likewise, smoking is associated with reduced HDL cholesterol level and function.

NON-HDL CHOLESTEROL

Non-HDL cholesterol is simply calculated as total cholesterol minus HDL cholesterol. The measurement of non-HDL cholesterol does not require fasting. Non-HDL cholesterol is a good predictor of cardiovascular risk, especially in metabolic syndrome and diabetes. Desirable levels of non-HDL cholesterols and goals for therapy are 30 mg/dL above the LDL cholesterol goals.

CALCULATING RISK FOR DEVELOPING HEART DISEASE

In addition to lipid disorders, major risk factors associated with atherosclerosis and developing heart attack include age, cigarette smoking, high blood pressure, and diabetes. Obesity, physical inactivity, and family history of early heart disease and stroke are also conditions associated with greater risk. Moreover, disorders associated with chronic inflammatory states, such as rheumatoid arthritis and psoriasis, may aggravate atherosclerosis if severe and untreated at an early stage.

Several cardiovascular risk calculators were developed over the years on the basis of large epidemiologic and population studies. These calculators are based on age and common risk factors and aim to predict the 10-year risk for developing atherosclerotic CVD and/or cardiovascular death. The goal of risk calculators is to support clinicians in optimizing individual cardiovascular risk reduction and to make an informed decision about the necessity of drug treatment for prevention of CVD. The most commonly utilized risk calculators are the atherosclerotic cardiovascular disease risk estimator (ASCVD), by American heart societies, and SCORE risk charts, by the European Society of Cardiology. Both risk calculators have a web-based interactive interface available for use online.

MANAGEMENT OF LIPID DISORDERS

WHEN AND WHOM TO TREAT?

The decision to start lipid-lowering treatment is a function of lipid levels, presence of concomitant risk factors, and diagnosis of CVD. Studies have demonstrated that lipid lowering is beneficial in coronary heart disease and significantly reduces the risk of recurrent cardiovascular events. Accordingly, it is common practice today to start cholesterol-lowering medications (ie, statins) in all people with coronary heart disease. Moreover, studies have shown the additional benefit of initiation of high-intensity statin while in the hospital, during the acute coronary event, and preferably before performing cardiac catheterization. In individuals with coronary artery disease, the positive effects of statins are regardless of the baseline LDL cholesterol levels. People with vascular disease of atherosclerotic origin in other arterial blood vessels, such as the carotid arteries and brain (ischemic stroke) and peripheral artery disease, are considered coronary disease equivalent and are therefore eligible for lipid-lowering therapy with statins for secondary prevention of CVD, similar to patients with coronary heart disease. In addition to treating all patients with atherosclerotic CVD with high-intensity statins, international guidelines recommend achieving a target LDL cholesterol level below 100 mg/dL and even less than 70 mg/dL in very high-risk individuals.

In people without a history of CVD, the benefit from lipid-lowering therapy depends on the global risk of developing CVD. People with diabetes or chronic kidney disease are at high risk for heart disease and are entitled to primary

prevention therapy with statins. In addition, individuals without diagnosed CVD but with a high predicted risk of developing heart attack according to risk calculators are recommended for initiating statin therapy (eg, a 7.5% risk of developing CVD over 10 years is the threshold suggested for initiating statin therapy for primary prevention in the ASCVD calculator). Additional groups that are recommended for statin therapy regardless of other risk factors are those with very high LDL cholesterol levels, > 190 mg/dL, without apparent secondary reversible cause.

Very high triglyceride levels are also an indication for making aggressive lifestyle changes and taking medical treatment to prevent pancreatitis. Although high triglyceride levels are not the primary treatment target for preventing CVD, in some situations health care providers may recommend specific treatment for this indication, such as in high-risk diabetic patients with increased triglycerides and low HDL cholesterol under statin therapy.

MANAGEMENT OF HIGH CHOLESTEROL

Lifestyle changes are important in the treatment of high cholesterol levels. Losing weight, performing regular physical activity, and diet alterations, including reduction in saturated fats and cholesterol intake, may help reduce blood cholesterol levels. In addition, enrichment of nutrition with soluble dietary fibers is beneficial. Plant stanols and sterols are compounds naturally found in plants and available commercially as food products and dietary supplements, which may further reduce blood cholesterol by 10% to 15%. However, there are no significant data demonstrating a reduced risk of heart disease in people who consume plant sterols and stanols.

Decision making regarding initiation of medications for lowering cholesterol is carried out in accordance with the degree of risk of developing heart attacks or death from heart disease.

Drugs available for cholesterol lowering:

- **Statins:** a powerful group of drugs that are able to reduce LDL cholesterol levels by 30% to 55%. Statins work by inhibiting the production of cholesterol in liver cells and consequently increasing the expression of LDL receptors on the cells' surface, which causes the liver to remove more cholesterol from the blood to disassemble in the liver. Numerous studies in a wide range of populations at various cardiovascular risks have demonstrated over the years the ability of statins to significantly reduce heart attacks, stroke, and cardiovascular death. Accordingly, statins are the drugs of choice in the

treatment of high cholesterol levels.

Some side effects of statins are possible and vary from person to person. The more common side effects include muscle pain or cramps, constipation, and stomach pain. In addition, statin therapy may result in elevation in liver function tests, muscle enzymes, and glucose levels in blood, which are usually mild without clinical implication. Overall, statins have a good safety profile, and serious side effects are very rare.

- **Ezetimibe**: reduces blood cholesterol levels by 15% to 20%, by inhibiting dietary cholesterol absorption in the small intestine. Ezetimibe is most often used in combination with a statin drug.
- **PCSK9 inhibitors**: a novel class of injectable drugs that inhibit PCSK9, an enzyme that is a regulator of the LDL receptor and helps the liver to absorb more cholesterol from the blood when inhibited. Both evolocumab (Repatha) and alirocumab (Praluent) are human monoclonal antibodies against PCSK9 that were recently approved by the FDA for use in people with very high levels of cholesterol, and in people with a history of coronary disease or who are intolerant to statin therapy and cannot attain lipids treatment goals. These new drugs are very efficient, reducing LDL cholesterol levels by 60% when injected subcutaneously twice a month. Clinical trials with PCSK9 inhibitors are ongoing, to evaluate long-term safety and the ability to improve cardiovascular outcomes.
- **Additional drugs**: bile acid sequestrants, which lower cholesterol indirectly by binding to bile acids, and niacin (nicotinic acid), which has a positive effect on all lipid components, are less commonly used today because they are less potent than statins and have more significant adverse effects.

HDL cholesterol levels are inversely associated with CVD, and low HDL cholesterol is a marker of increased cardiovascular risk. Lifestyle changes may help in raising HDL cholesterol. This includes aerobic exercise most days of the week, smoking cessation, weight loss with maintaining healthy body weight, and diet with alteration of intake of carbohydrates and fats (decreasing refined carbohydrates, avoiding sugary beverages, reducing trans fat, and consuming unsaturated fats). Although some medications such as niacin may increase HDL cholesterol levels, in the statin era, there is no good evidence that raising HDL cholesterol levels pharmacologically on top of statin therapy is beneficial in reducing heart disease.

MANAGEMENT OF HYPERTRIGLYCERIDEMIA

Healthy lifestyle choices have the ability to significantly lower triglycerides:

- **Diet**: dietary changes associated with reduction in triglycerides levels include: (a) reducing saturated fats and trans fats, (b) eating less processed and fast food, (c) increasing fiber intake by consuming more vegetables and whole grains, (d) limiting refined carbohydrates, fruit juices, sugars, and sweets, (e) increasing omega-3 intake, such as in fish like salmon and tuna, and (f) reducing alcohol intake.
- **Exercise**: increasing occupational and leisure-time physical activity; minimum of 150 minutes per week, on most days, preferably aerobic activities.
- **Weight loss**: losing weight by adoption of healthy diet and regular exercise. Even 5% to 7% reduction in weight may significantly improve triglyceride levels and glucose balance.

Drugs available for triglycerides lowering:

Prescription medications aimed at reducing triglyceride levels include fibrates (such as fenofibrate) and niacin. In addition, high-dose fish oil supplements significantly lower triglyceride levels. High blood sugars and uncontrolled diabetes are common precipitators of high triglycerides and should be treated accordingly.

Smoking Cessation in the Cardiac Patient

INTRODUCTION

For patients with coronary heart disease, quitting smoking is associated with a 36% reduction in all-cause mortality,[1] yet 1 year post–acute myocardial infarction (AMI), two-thirds of patients given low-intensity counseling have resumed smoking.[2] The decline of cardiovascular mortality in the United States is attributed largely to the reduction in smoking prevalence from about half of US men and a third of US women to 20.5% and 15.3%, respectively.[3,4] Because the benefit is of immediate onset, and because there are effective tools available, smoking cessation for the cardiac patient is an essential component of care.[5] Quitting smoking reduces the risk of coronary events to that of a nonsmoker within 3 years and reduces mortality by half after a heart attack over 3 to 5 years.[6,7] For patients with left ventricular (LV) dysfunction after myocardial infarction (MI), smoking cessation is associated with a 40% lower hazard of all-cause mortality over a median follow-up of 42 months.[8] Smoking post-MI is a powerful independent risk factor for reinfarction and death.[1,9,10] Those who quit have the same risk of sudden death as those who have never smoked.[9] The impact of smoking cessation in this population is therefore of at least the same

magnitude as that of angiotensin converting enzyme (ACE) inhibitors (19% relative risk decrease), β-blockers (23% relative risk decrease), and aldosterone antagonists (15% relative risk decrease).[10–12] It is vital that this information be imparted to the Cardiac Care Unit (CCU) patient who has been a smoker.

The effects of smoking on heart rate, blood pressure, cardiovascular blood flow, myocardial oxygen demand, and thrombosis are largely reversible. In this chapter, we review how cigarettes induce cardiac disease, the role of nicotine in this process, the pharmacologic tools available, their safety profile in the cardiac patient, and the basics of behavioral modification for the smoking addiction. Helping patients quit smoking is certainly more challenging than simply ordering a medication. Understanding the biology involved assists us in helping our patients break this notoriously severe addiction.

HOW DOES SMOKING CAUSE HEART DISEASE?

Although the entry portal for cigarette smoke is the lung, where the chemicals present in the smoke are quickly and easily absorbed, the resulting inflammatory cascade has a profound effect that extends well beyond the confines of the lung (**Figure 56.1**). The systemic effects of cigarette smoking include a variety of complicated processes that induce, in the genetically susceptible individual, vascular and hematologic abnormalities that can result in accelerated atherosclerosis as well as the acute events of MI and sudden death.

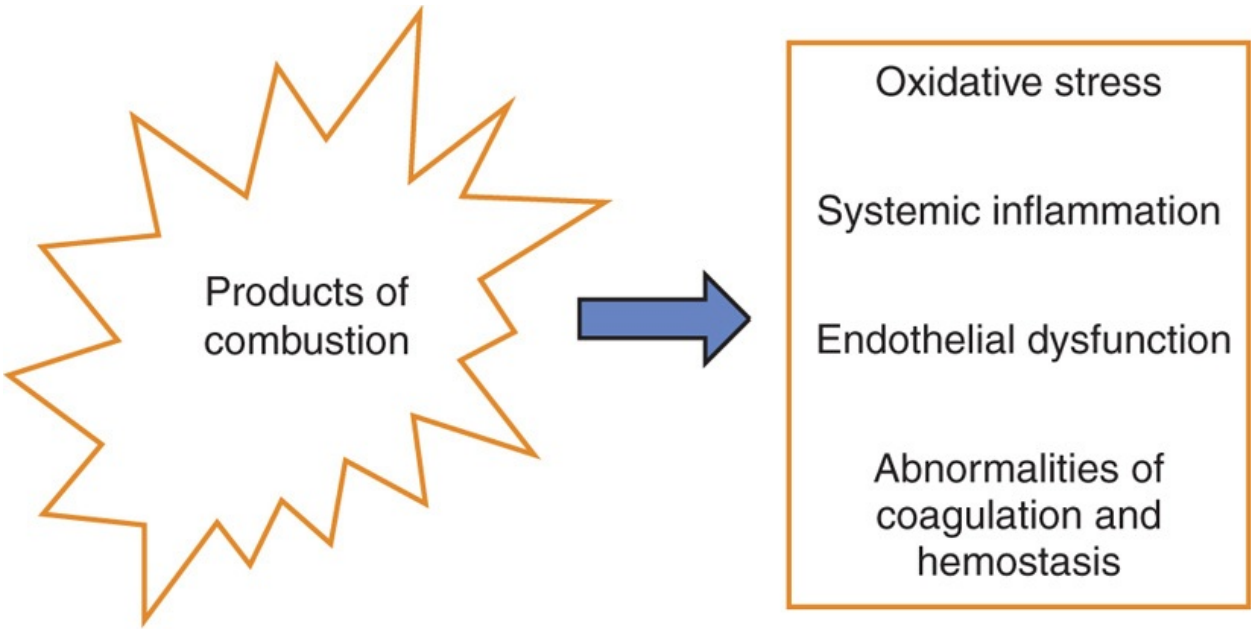

FIGURE 56.1 How smoking causes heart disease.

The main responsible constituents are combustion products that are inhaled and induce (1) oxidative stress, increasing free radicals and lipid peroxidation; (2) systemic inflammation with activation and release of both inflammatory cells and inflammatory mediators; (3) endothelial dysfunction; and (4) abnormalities of coagulation and hemostasis.[13–15]

1. *Oxidative stress*. The particulate (tar) phase of cigarette smoke contains over 10^{17} free radicals/gram, and the gas phase contains over 10^{15} free radicals/puff. Many of the damaging effects of smoking are induced by these molecules. The sustained release of reactive free radicals from the tar and gas phases of smoke imposes an oxidant stress, inducing a variety of chemical injuries, including the formation of proatherogenic oxidized particles, specifically oxidized low-density lipoprotein cholesterol. Also, the inhaled oxidant molecules significantly deplete the body's antioxidant defense system.[13,14]
2. *Systemic inflammation.* Long-term cigarette smoking increases total white blood cell (WBC) counts. There is an increased early bone marrow release of polymorphonuclear leukocytes (PMNs) and platelets into the circulation. These activated inflammatory cells then produce a variety of inflammatory mediators, acute phase proteins, and cytokines, among them C-reactive protein (CRP), fibrinogen, IL-6, and tumor necrosis factor. Some of the

inflammatory mediators and hematologic effects of smoking decline rapidly after smoking cessation. However, CRP can remain elevated for 10 to 19 years.[10] These mediators may not be just markers of disease but may be actively involved in the proinflammatory and proatherogenic effects of chronic smoke exposure.

3. *Endothelial dysfunction.* Smoking induces endothelial dysfunction though a variety of biochemical, physiologic, and metabolic factors. Both oxidizing chemicals that are the products of combustion present in cigarette smoke and nicotine appear to be involved. Vasoregulation and changes in endothelial and platelet function affect the microcirculation. Decreased production or availability of NO results in impaired vasodilatory function at the macrovascular level (eg, coronary arteries) as well as at the microvascular level.[16,17] NO is also affected by cigarette smoke via the changes induced on low-density lipoprotein (LDL). In cigarette smokers, LDL gets oxidatively modified by the inhaled oxidant molecules. The modified LDL then interferes with the protective effect of NO on the arterial wall. The result is increased inflammatory cell entry into the arterial wall. The oxidatively modified LDL is taken up by the macrophages that enter the arterial wall; cholesterol esters are deposited and foam cells form.
4. *Abnormalities of coagulation and hemostasis.* Smoking cigarettes induces a hypercoagulable state that is a major factor in acute vascular events in smokers. Viscosity is increased, with increased levels of fibrinogen, lipoproteins, and hematocrit. Antithrombotic and prothrombotic factors and platelet function are affected. There is impaired release of the tissue plasminogen activator (t-PA), the main fibrinolytic activator resulting in impaired fibrinolysis. Hypercoagulability is responsible for 25% to 50% of the link between smoking and coronary artery disease (CAD)[9] and is especially involved in acute cardiac events. This is borne out in multiple clinical situations:
    - Smoking increases the risk of MI and sudden death much more than it increases the risk of angina, reflecting the importance of acute thrombus formation.[18]
    - Similarly, the prognosis after thrombolysis is better in smokers than in nonsmokers. This reflects the greater part that clots play in the disease process.[19]
    - Sudden cardiac death is correlated with the presence of acute thrombosis and not the level of plaque burden.[18]

- Smokers who continue to smoke after thrombolysis or angioplasty have a substantially increased risk of reinfarction or reocclusion.[20,21]
- At least a part of the thrombotic effects of smoking are induced by even passive smoke.[22,23] The remarkable sensitivity of the coagulation system to the effect of cigarette smoke[24] mandates that the cardiac patient must cease all smoking, not just curtail their habit.[25] Patients should be taught the seriousness of this issue.

Although some of the effects of smoking on inflammatory markers may persist for years, a great portion of these effects are reversible by stopping smoking.

WHAT IS THE ROLE OF CO IN THIS PROCESS?

CO acutely poisons the oxygen delivery system, placing the patient at risk for arrhythmia and MI.[18] In patients with CAD, CO induces ischemia at lower levels of work.

HOW DOES NICOTINE PARTICIPATE IN THIS PROCESS?

The major cardiovascular effects of nicotine are mediated through sympathetic neural stimulation as well as the enhanced release of various neurotransmitters. Smoking produces a transient rise in blood pressure and an increase in myocardial work. In patients with coronary disease, smoking constricts epicardial coronary arteries and reduces coronary blood flow.

NICOTINE ADDICTION

After inhalation, nicotine rapidly reaches the nicotinic cholinergic receptors, found in both the peripheral and central nervous systems, resulting in the release of a variety of neurotransmitters, including dopamine, glutamate, γ–aminobutyric acid, norepinephrine, acetylcholine, serotonin, and endorphins, which may contribute to the effects of nicotine on blood vessels but also play an important role in the development of addiction in the susceptible individual. The pleasure derived from the dopamine release contributes to the addictive process.

It is important for the provider to discuss with the patient that nicotine dependence is highly heritable and metabolically driven.[26] Over 50% of the vulnerability to nicotine dependence is in large part a genetically determined

phenomenon based on the type of nicotine receptors that the patient has. The type of nicotine receptors the patient has determines its pleasurable effects, its rate of metabolism, its withdrawal syndrome, and the susceptibility to neural plasticity that causes the learned behaviors that become triggers. One of the primary genes involved is the *CYP2A* gene, which is a controller of the rate of metabolism of nicotine, vulnerability to tobacco dependence, and response to smoking treatment and is involved with lung cancer risk. The α3β4 nicotinic acetylcholine receptor is believed to mediate the cardiovascular effects of nicotine.[27] Thus, depending on the type of nicotine receptors they have, for some patients it is easy to quit, whereas for others it is incredibly difficult. For those who are smoking with known cardiovascular disease, the level of addiction is intense. Understanding that this is a biologically driven process and that, very much like diabetes, it is a chronic illness needing long-term lifestyle modification and medication for support is vitally important. Addressing the interplay of physical addiction and learned behavior is a key feature of therapy (**Figure 56.2**).

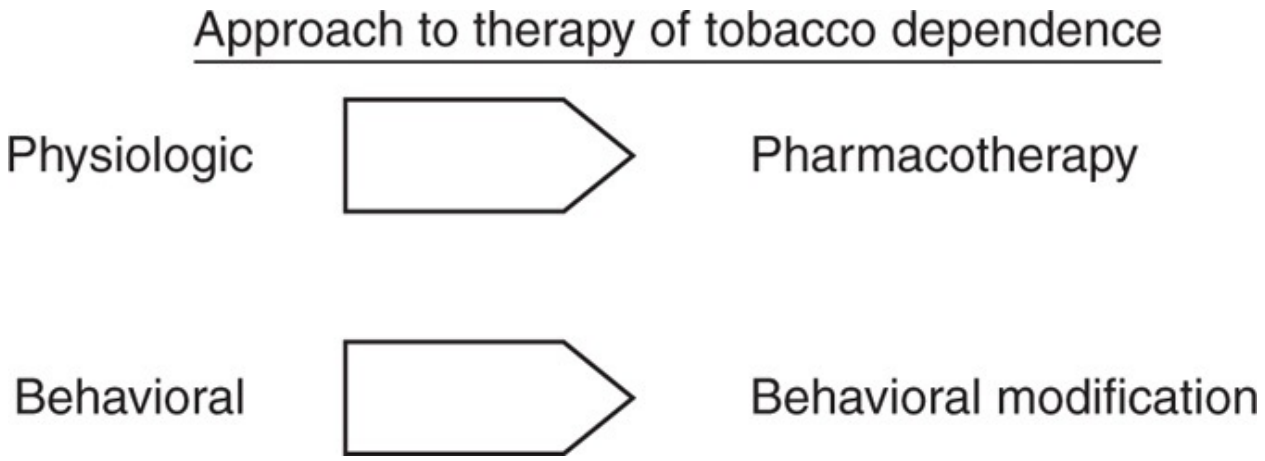

FIGURE 56.2 Approach to therapy of tobacco dependence.

With repeated exposure, nicotine tolerance develops via a desensitization of the receptors to the effect of nicotine and an increase in the number of nicotine receptors. Nicotine withdrawal is a complex process, not unlike that of withdrawal from alcohol, cocaine, opiates, and cannabinoids, that results in a state of anxiety, stress, generalized discomfort, inability to concentrate, and depressed mood.[27]

Thus, smokers learn to use the cigarette’s nicotine as a modulator of anxiety,

concentration, depressive symptoms, and pleasure as a major tool for handling life's stresses. In addition, those who are genetically susceptible to the addiction, after a relatively short period of use, become trapped by an inability to function without the satisfaction of the increased number of less responsive nicotine receptors. Not only does smoking relieve the intense discomfort of withdrawal within 10 seconds, but the relief is also accompanied by significant pleasure and ability to cope.

With time, the smoker associates certain situations with smoking: after a meal, drinks with friends, coffee, stress, etc. This association is learned and contributes significantly to the activity of the nicotine receptors and the expectation of immediate relief. These conditioned responses, also called neural plasticity, play a significant role in maintaining the addiction and become a significant impediment to the process of quitting. These triggers are to be avoided, and understanding the biology elucidates the importance of the behavioral component of smoking cessation.[27] As we will see from the studies on smoking cessation in the cardiac patient, the behavioral component of therapy is as important as the pharmacologic component (**Figure 56.2**). The permanence of the receptors, and the persistence of the learned behavior, makes the incidence of relapse very high; thus the importance of "learning" new sources of pleasure, stress management, concentration, and mood regulation.

WHAT IS THE ROLE OF NICOTINE IN THE DEVELOPMENT OF CARDIOVASCULAR DISEASE?

Sympathetic overactivity is a significant factor by which smoking, and at least in part nicotine, induces cardiovascular disease.[18] Nicotine releases catecholamines, increases heart rate and cardiac contractility, constricts cutaneous and coronary blood vessels, and transiently increases blood pressure.[28] There is an increase in myocardial work and oxygen consumption through an increase in blood pressure, heart rate, and myocardial contractility.[29] Nicotine also reduces sensitivity to insulin and may contribute to endothelial dysfunction.[30,31] How much of the sympathetic overactivity induced by smoking is due to the effect of nicotine in the cigarette is unclear, but this is of obvious concern when we are considering using nicotine replacement therapy (NRT) in the cardiac patient. Interestingly, the effect of nicotine on autonomic ganglia is

dose dependent and biphasic. Small doses stimulate all autonomic ganglia. With larger doses, initial stimulation is followed by blockade of catecholamine release and increased splanchnic nerve stimulation, thus resulting in nausea. The dose response curve for the cardiovascular effects, such as heart rate acceleration or the release of catecholamines, is flat, and, consequently, even adding nicotine medication to smoking produces no further effect.[29]

Pharmacologic therapy is strongly recommended. The 2008 U.S. Clinical Practice Guidelines for Treating Tobacco Use and Dependence recommends counseling and medications to help all hospitalized tobacco users maintain abstinence and treat withdrawal symptoms. Three forms of medication are available: nicotine replacement, bupropion, and varenicline. Each medication has advantages and disadvantages, and the choice should be tailored to the patient's individual clinical profile. Although not widely available now, in the future, identifying slow nicotine metabolizers will predict those who respond best to NRT versus bupropion or varenicline. Resistance to the use of medication is not uncommon but, as we have discussed, for the cardiac patient the stakes are too high to risk failure. Medication use doubles the success rate.

IS THE USE OF NRT SAFE?

After initial concerns regarding the safety of NRT, studies have shown the safety of NRT even as a high-dose patch, with combination NRT and concurrent smoking.[32–34] In a 2010 meta-analysis of adverse events associated with the use of NRT among 177,390 participants, Mills et al.[35] found that NRT is associated with an increased risk of GI complaints and insomnia. There was an observed risk of skin irritation and, with orally administered NRT, oropharyngeal complaints. Although NRT was associated with an increased risk of heart palpitations and chest pain, there was no increased incidence of heart attack or death. Their conclusion was that NRT is associated with adverse effects that may be discomforting for the patient but are not life-threatening. Again, in a more recent meta-analysis that was largely limited to smokers without preexisting heart disease, nicotine replacement therapies had a statistically significant risk of cardiovascular disease events that was driven primarily by less serious effects such as tachycardia. When analysis was limited to major cardiovascular disease events, there was no evidence of harm with NRT.[36] When their review was limited to high-risk patients, the trend toward having an increased risk of overall cardiac events (including tachycardia) remained, but the relative risk decreased

and the confidence intervals became wider, not reaching statistical significance.[36]

NICOTINE REPLACEMENT THERAPY

When recommending NRT to a patient, especially one with cardiac disease, multiple questions arise, shown later with responses (**Figure 56.3**).

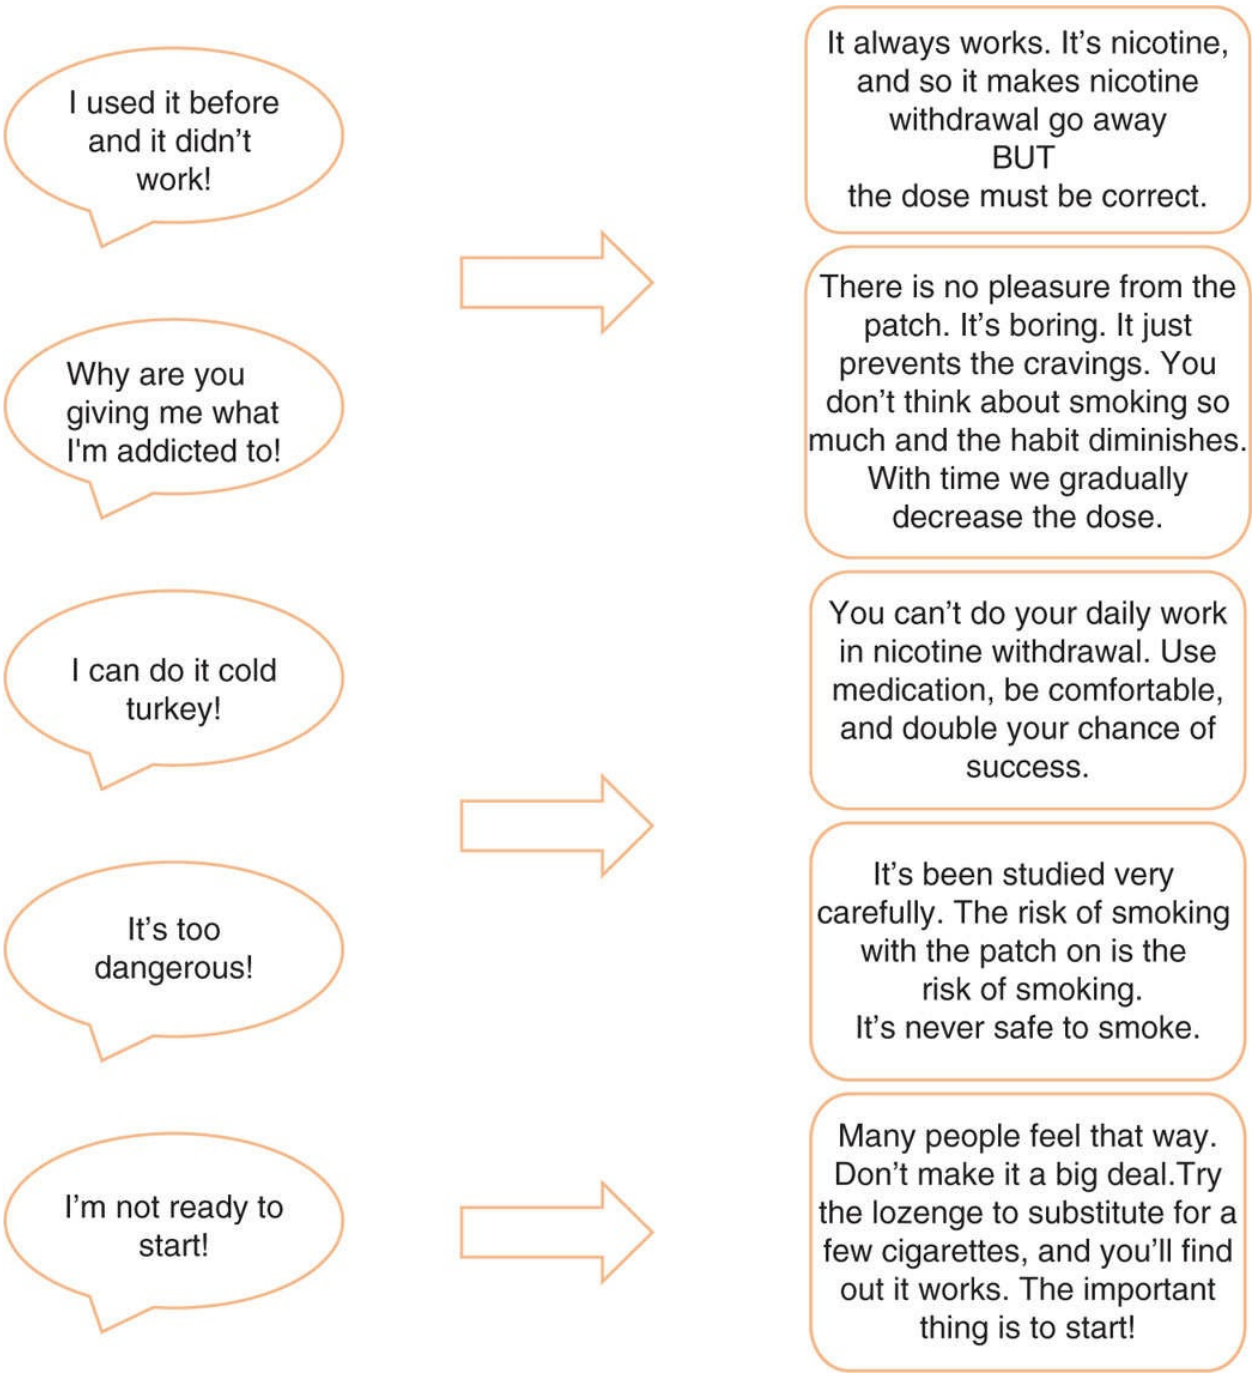

FIGURE 56.3 Common patient concerns regarding use of NRT and answers to these concerns.

Nicotine Replacement Comes in a Variety of Delivery Systems

Nicotine Patch

The nicotine patch comes in three strengths—21, 14, and 7 mg—and is equivalent to a full pack a day, half a pack a day, and a third of a pack a day.

Variations in the intensity of smoking and differing metabolic rates of nicotine among individuals may necessitate dosing adjustment from these guidelines. If the patch is too strong, the patient experiences nausea, dizziness, and headache. If it is too weak, there are cravings. Adjust the dose to comfort. The patch takes an hour to reach level, which is still well below the level of arterial spike achieved by the cigarette. The gradual delivery allows the body to equilibrate with its effects, contributing to its safety profile. It is applied in the morning and removed at bedtime to avoid potential nightmares. Adjust the dose to comfort. Change the location daily. Some patients are allergic to the adhesive and are unable to use it because they develop blisters.

Nicotine Gum

The delivery system of the gum is meant to allow a controlled release of nicotine. If it is chewed, it delivers too much nicotine too fast, resulting in nausea, hiccups, and vomiting. Only crack the coating open: it comes in 2- and 4-mg pieces and can be used every hour if needed. The patient can “bite and park,” placing it in the cheek and waiting. This is a much faster delivery system compared to the patch, and the patient is aware of a “hit.” It is very useful in combination with the patch for craving relief, especially in the morning before the patch has begun to work (**Figure 56.4**).

FIGURE 56.4 Nicotine gum.

Nicotine Lozenge

This is similar to the gum in delivery. Allow it to slowly dissolve on the tongue. It can be used alone or in combination with the patch.

Nicotine Inhaler

Puffing on this device delivers straight nicotine to the oral mucosa. It is not meant to be inhaled, but only puffed into the mouth. It can satisfy some of the ritual the smokers may desire. The patient may use six cartridges per day if needed, and each cartridge lasts 30 minutes.

NRT Safety Profile

The use of NRT has presented long-standing safety concerns although the blood level of nicotine achieved with a NRT does not approach the rapid arterial bolus achieved with the cigarette. Multiple studies have shown the safety of NRT even as a high-dose patch, combination patch and gum therapy, and patch and concurrent smoking (10 to 12 Mills and Thornland) (**Figure 56.5**).

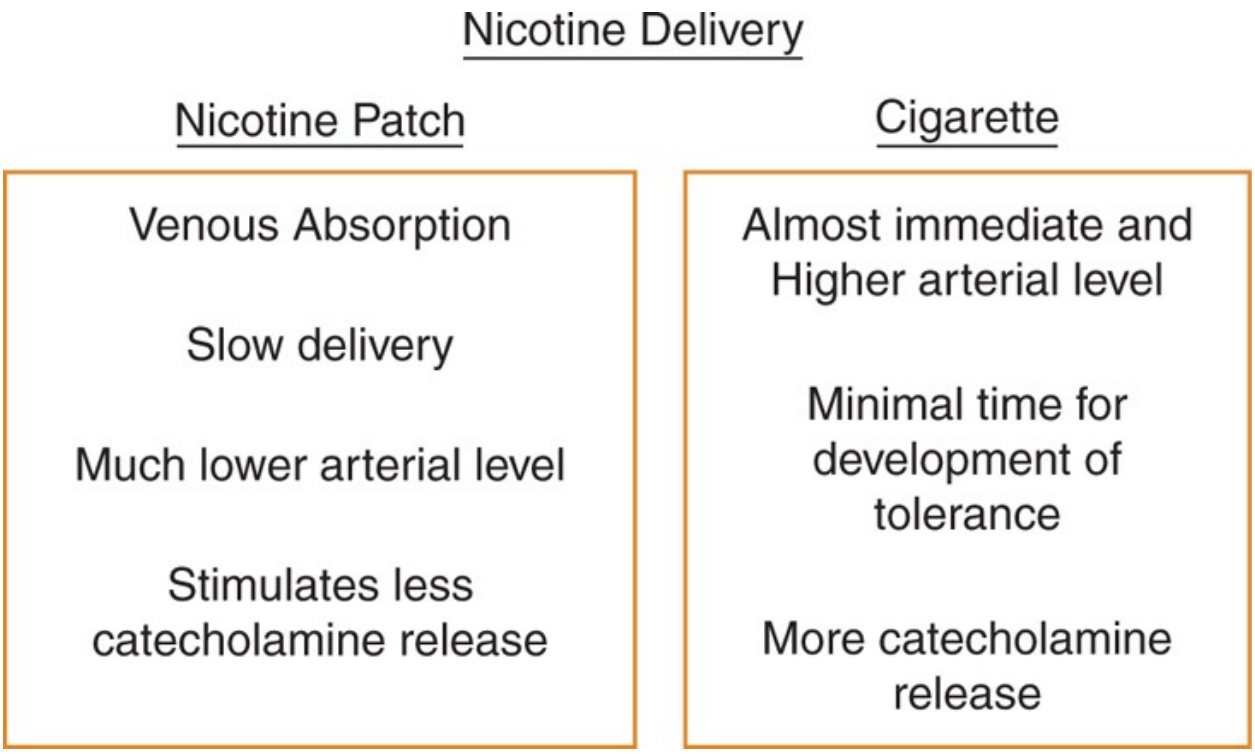

FIGURE 56.5 Nicotine delivery in patch vs. cigarette.

In a 2010 meta-analysis of adverse events associated with the use of NRT among 177,390 participants, Mills et al.[35] found that NRT is associated with increased risk of gastrointestinal (GI) complaints, reflecting the previously noted splanchnic nerve stimulation, along with insomnia. There was an observed risk of skin irritation and, with orally administered NRT, oropharyngeal complaints. Although NRT was associated with an increased risk of heart palpitations and chest pain, there was no increased incidence of heart attack or death. Their conclusion was that NRT is associated with adverse effects that may be discomforting for the patient, but are not life-threatening.

In a more recent meta-analysis that was largely limited to smokers without preexisting heart disease, Mills et al analyzed the data for evidence of cardiac toxicity from NRT. They subdivided the cardiac events into two categories: (1) all cardiac events and (2) major cardiovascular events (MACEs) defined as cardiovascular death, nonfatal MIs, or nonfatal stroke. Although they identified a significant increase in minor events such as tachycardia, there was no increase in MACEs (Mills and Thorlund). This remained true for a subgroup analysis of high-risk patients, although the numbers were small.

IS THE USE OF NRT IN THE CARDIAC PATIENT SAFE?

Early case reports suggested cardiovascular risk associated with use of NRT, especially if the patient smoked while using nicotine replacement. Data are now available[18,32,37–41] from randomized controlled trials, efficacy studies, observational data, and physiologic studies, supporting the safety of NRT used in the stable cardiac patient. There was no increased risk of angina, MI, stroke, arrhythmia, or death. These studies looked at patients with stable cardiovascular disease who had no cardiac event requiring an intervention in the prior 2 weeks.

Although NRT is cautiously prescribed for relief of withdrawal symptoms for cardiac patients in the CCU, there is a lack of randomized evidence to support its safety in the early period after an MI. As previously discussed, nicotine increases heart rate, BP, and myocardial contractility, and has the potential to cause endothelial dysfunction and coronary vasoconstriction. There is only one study[42] that looks at use of NRT among patients who were admitted for acute coronary syndromes (ACS) and who received transdermal NRT during that hospitalization. In this retrospective propensity analysis from Duke University, patients who had undergone a cardiac catheterization for an ACS and received NRT were retrospectively compared with comparable patients from their

database. After a propensity-matched analysis, they found no difference in short- or long-term mortality in patients who did or did not receive the patch. There was no significant difference between the groups in the need for undergoing coronary artery bypass graft surgery (CABG) or percutaneous transluminal angioplasty. Nonetheless, nicotine does have hemodynamic effects that could contribute to acute cardiovascular events.

There are two troubling retrospective reports regarding the use of nicotine replacement in critically ill patients. One is among medical intensive care unit patients[43] and the other among patients undergoing CABG.[44] In each study, the use of NRT was associated with an increased mortality. Unfortunately, because of the retrospective nature of the studies and their small size, they could not control for associated comorbidities, thus limiting the weight that we can place on them. However, they most definitely indicate the need for further studies and raise a need for caution.

As far as the e-cigarette is concerned, there is insufficient literature available to address its use in the cardiac patient. There is literature on exposure to both the aerosol and the particulate components that they generate.[45] Using 20 e-cigarette refill solutions from five manufacturers in cultured rat cardiac myoblasts, the aerosols from three solutions were found to be cytotoxic to the cardiac myoblasts. Although tests on e-cigarettes show much lower levels of most toxicants, they do not show reduced levels of particulate matter when compared with that of conventional cigarettes. The distribution of particulate matter generated by the e-cigarette is similar to that of the traditional cigarette. They are small enough to reach deep into the lung and cross into the systemic circulation. Toxicity thresholds are not known, but we know that exposure to ultrafine particles from tobacco smoke or air pollution turns on systemic inflammatory processes and increases the risk of cardiovascular death.[46–48] Overall, although the e-cigarette is likely to be less toxic than the cigarette, the products are unregulated, contain toxic chemicals, and have not been proven as cessation devices. Should the patient insist on e-cigarette use, they should be urged to set a quit date and not plan on using it indefinitely.[45]

Overall, the clinically relevant hemodynamic effects of NRT appear to be very mild, and its use in the stable cardiac patient appears to be quite safe. Clinical trials have not examined the efficacy of NRT in the AMI patient population. However, given the significant health consequences of smoking after MI, and analyzing current data, Benowitz and Prochaska have suggested an approach including, in addition to intensive counseling and follow-up, a personalized

prescription of medication that may include NRT to relieve withdrawal symptoms and provide an effective transition from inpatient to outpatient smoking cessation.[49]

BUPROPION FOR SMOKERS WITH CARDIOVASCULAR DISEASE

Bupropion, an atypical antidepressant with a structure related to amphetamine, has, like nicotine replacement, been shown to be an effective smoking cessation tool. After approximately 10 days on treatment, the desire to smoke diminishes significantly. In addition, it prevents the depression that not uncommonly surfaces in patients who stop smoking. The contraindications include a seizure history, alcoholism, bipolar disorder, bulimia nervosa, and panic attacks. The side effects include dry mouth, headache, agitation, and insomnia. Hypertension has been described, especially in patients taking both bupropion and the nicotine replacement. The treatment is usually begun at bupropion 150 mg sustained release (SR) and can subsequently be increased to 150 mg SR twice a day. The side effects are dose dependent, and some patients may obtain an adequate therapeutic benefit with the 150-mg-daily dose. The drug is metabolized in the liver, so dose adjustment is advised with significant liver disease. The drug inhibits the activity of CYP2D6 isoenzyme, which metabolizes β-blockers, antiarrhythmics, certain antidepressants, SSRIs, and antipsychotics.

Bupropion approximately doubles quit rates in otherwise healthy smokers and patients with stable cardiovascular disease.[2] There have been a number of case reports of death and severe adverse cardiovascular reactions occurring in patients taking bupropion,[50] but in the meta-analysis of Mills and Thorlund[35] in a high-risk population (cardiac disease and COPD), bupropion was safe with a MACE relative risk approaching 1. A 2008 clinical practice guideline issued by the U.S. Department of Health and Human Services suggests that bupropion can be safely used in the acute post-MI period.[51]

Although the safety data are encouraging, in the meta-analysis of Mills and Thorlund,[35] efficacy was questioned. Three trials of bupropion therapy that had begun in the CCU did not support significant efficacy at 1 year, with only a 5% improvement in quit rate versus placebo at 1 year.[2,52,53] However, Benowitz and Prochaska point out in their editorial[49] that the 12-month quit rate difference of

5% that was achieved with bupropion over placebo would have a meaningful public health impact for a group at such high risk for ongoing cardiovascular events. There is one randomized trial for smoking cessation comparing bupropion SR 150 mg BID with placebo in outpatients with stable cardiovascular disease,[54] demonstrating improved 1-year quit rates. At 1 year, the quit rates were 27% for the bupropion arm versus 11% for the placebo arm. Safety profile was once again validated.

Duration of therapy with bupropion appears to be a significant factor that needs to be considered in the acute cardiac patient for whom relapse has a particularly high risk. In a five-hospital, double-blind placebo-controlled trial, patients who were admitted with acute cardiovascular disease were randomized to receive either bupropion SR 150 mg BID and intensive counseling or placebo and intensive counseling for 3 months. Bupropion's safety profile was supported for smokers hospitalized with acute cardiovascular disease. The bupropion group did have improved short-term quit rates (37.1% vs 26.8%) but not improved long-term quit rates (25% vs 21.3%) over intensive counseling. After 30 days off the drug, there was a borderline significant increase in cardiac events, and 75% of the subjects were smoking before the event. The patients enrolled in the study were significantly addicted, and 40% of them had been smoking with known CAD before admission, making them a highly addicted group. In addition to supporting the safety of the use of bupropion in the CCU patient, this study raises the question of a need for longer-term therapy with bupropion to help maintain the abstinence advantage seen at 3 months.[53]

In studies of bupropion SR being used as an antidepressant in patients with cardiac disease, few cardiac adverse effects were seen. There was occasional hypertension, but no effect on cardiac conduction or ejection fraction. A black box warning remains on bupropion regarding suicide risk.

Despite the concern raised by case reports, current evidence suggests that bupropion SR is a safe and possibly efficacious treatment for smoking cessation for patients with cardiovascular disease. Full evaluation of bupropion SR in patients with cardiac disease is needed. Bupropion may be used in combination with nicotine replacement. The success rate of this combination has not been shown to be statistically superior[55,56] and has not been evaluated in the cardiac patient. It is suggested that while on combined therapy, blood pressure should be monitored.

WHAT IS THE ROLE OF VARENICLINE FOR THE CARDIAC PATIENT?

Varenicline is a highly effective smoking cessation medication that is both a partial nicotine agonist and an antagonist. After taking this drug for a week, the patient experiences little to no cravings, and if they do smoke they derive no pleasure. Common side effects include insomnia (19%), nausea (16%), abnormal dreams (9%), and constipation (5%). Seizure disorder is a contraindication. Although this drug has had the highest quit rates among healthy individuals, postmarketing data raised concerns regarding the risk of depression, aggressive behavior, suicidal ideation, and suicide. It is well known that depression may surface in patients attempting to quit smoking. Many patients use the nicotine in cigarettes to treat a full-blown or borderline depression, and when they stop smoking, depression may be uncovered. Subsequent studies of varenicline and the risk of depression and suicidal ideation have not substantiated this risk; however, it remains a subject of ongoing research.

More recent studies have validated the use of varenicline in combination with NRT, with a significantly improved quit rate at 24 weeks.[58] In addition, the drug has now been approved for 6 months of therapy. Furthermore, recognizing that gradual reduction may be preferred by some smokers, varenicline has been used in a graduated smoking reduction plan versus placebo with quit rates of 27% versus 9.9% at 1 year.

For the cardiac patient considering use of varenicline, two questions arise. First, is there any excess cardiovascular risk? Second, what is the risk of depression? This is of special concern in this often depressed population.[57]

Theoretically, varenicline should have little to no cardiovascular effects. The sympathomimetic cardiovascular effects of nicotine are mediated primarily by binding to α3β4 nicotinic acetylcholine receptors. Because varenicline binds to a different nicotinic receptor, α4β2, it was theorized not to have cardiovascular effects. In 2010, Rigotti et al.[59] published a multicenter randomized, double-blind placebo-controlled trial comparing the efficacy of 12 weeks of varenicline with counseling versus counseling alone in 714 smokers with stable cardiovascular disease. At the end of a year, the quit rate was 19.2% for the varenicline group versus 7.2% for placebo. Although the trial was small, there was no increase in cardiovascular events or mortality. For this study, patients had to be otherwise well, including no psychiatric history. Mood was not

systematically assessed, but there was no difference in spontaneously reported psychiatric symptoms in the varenicline versus placebo group.

Although a meta-analysis by Singh[60] raised concern over the cardiovascular safety of varenicline, other meta-analyses[35,61,62] did not find an increased risk of cardiovascular events. However, in 2011 the FDA issued a safety alert regarding a numerically but not statistically greater rate of adverse cardiovascular events with varenicline compared with placebo. A more recent large retrospective cohort study found no increased risk of cardiovascular events, depression, or self-harm.[63] It appears that varenicline has a small, nonsignificant cardiovascular risk, if any. Similarly, psychiatric concerns have not been supported in the current literature, although the black box warnings persist and change of mood should be taken seriously.

The use of varenicline in the CCU in the acute AMI setting has been studied in the EVITA (Evaluation of Varenicline in Smoking Cessation for Patients Post–Acute Coronary Syndrome) trial, suggesting that 12 weeks of varenicline is both safe and effective in patients with ACS.[64] At 24 weeks, there was a 14.8% absolute difference in point prevalence abstinence for those in the varenicline (47.3%) versus the placebo group (32.5%). Less than a third of those receiving placebo were abstinent at 24 weeks.

Varenicline is our most effective pharmacotherapy for smoking cessation to date. Even though further work is needed to shed more light on the psychiatric risk and to ensure the cardiac safety profile, the risk benefit ratio weighs strongly on the side of this tool. The data provide a strong evidence base to support the safety and effectiveness of varenicline for cardiac patients, both those with stable cardiovascular disease and those in the acute setting of ACS. Questions that need clarification, beyond issues of safety, are the role of more extended courses or even long-term therapy for this chronic severe addiction and the role of integrating intensive behavioral therapy into the varenicline treatment plan.

WHAT IS THE APPROACH TO THE PHARMACOTHERAPY?

In the patient with ACS in the CCU, clinical judgment needs to guide the approach. Given the significant health consequences of smoking after MI, and based on the available current data, Benowitz and Prochaska have emphasized the importance of a personalized plan including behavioral modification along with the prescription of medication to relieve withdrawal symptoms and provide an effective transition from inpatient to outpatient smoking cessation.[49] NRT has

no safety data in the acute setting but abundant safety data for the stable cardiac patient. It has the advantage of immediate relief of withdrawal symptoms. The disadvantage of the delayed onset of action of both bupropion and varenicline is counterbalanced by substantial safety data in the acute setting. The improved effectiveness of varenicline along with its safety data gives support to its use in this group of patients. The ongoing, although decreasing, concern regarding psychiatric comorbidities remains. Until we have better randomized long-term control trials, the approach needs to be guided by informed clinical judgment.

Even when we have devised a plan, some patients may be unwilling to stop abruptly. Recent investigations have shown that gradual reduction may be effective, although in the cardiac patient this is not ideal.[65]

BEHAVIORAL MODIFICATION

Although 30% to 45% of smokers who suffer an initial cardiac event stop smoking,[66] 60% to 70% of them relapse within a year. No matter which pharmacologic therapy one uses to stop smoking, there is a 50% relapse rate. The problem is that nicotine addiction is permanent. The patient who smokes immediately on waking or who is uncomfortable in places where they cannot smoke for any length of time is very addicted. The faster and stronger the craving, the more addicted the patient. Other patients are able to wait hours before their first cigarette. They are less affected by the decreased nicotine level that occurs over a night without smoking. They have fewer or no cravings. They have a larger behavioral component to their habit and are less in need of medication to quit.

As previously noted, patients who are highly addicted need more than medication to have sustained success. They need to learn behavioral techniques to allow them to remain smoke free through a lifetime. We know that smoking cessation programs that do not include postdischarge counseling and that do not provide follow-up for more than a month are ineffective.[67–70] Follow-up of at least 3 months is indicated.[50,71] Cardiologists should attend to these simple techniques and the importance of lifestyle modification on an ongoing basis.[72,73]

WHAT ARE THE PRINCIPLES INVOLVED?

- Most importantly, convince the patient that he or she can succeed and that you are confident that they will. Put the patient on a positive footing. Identify areas of accomplishment. A cardiac patient who is smoking is often tremendously guilt-ridden. You, as their health care provider, will support them through the process. Medications and behavioral techniques will help control the withdrawal and the cravings.
- Allow them to lead the conversation regarding what aspect of smoking is of concern to them. Address their concerns, whether they are financial, social, or health related, to get the conversation going. Identify why they use the cigarette: for pleasure, relief of depression, boredom, anxiety, or stress; improved concentration, relief from cravings, or all of these? Together, consider alternative approaches to each of those problems, which requires identifying other pleasures, as well as addressing depression,[43] stress and anger management techniques, exercise, being otherwise occupied, and avoiding the situations that lead to the urge to smoke.
- Have the patient make a concrete plan for what he or she will do to cope with cravings (eg, gum, water, or deep breathing).
- Identify and plan for avoidance of triggers such as coffee, alcohol, friends who smoke.
- Identify substitutes that the patient likes and can look forward to, for example, movies, museums, friends who do not smoke, or magazines.
- Encourage the patient to be as busy as possible, especially immediately after meals.
- Most importantly, discuss with the patient the permanence of the addiction and the need to be on guard even years later, especially in situations of stress. Unfortunately, the thought of picking up another cigarette recurs for a very long time, and one puff can lead to full relapse.
- Patients should never allow others to smoke around them or endanger their sobriety. As their cardiologist, you are giving them the license to be an inconvenience to others who want to smoke around them, because of their cardiac health. Their success is so important that nothing should be allowed to endanger it.
- Web-based interventions are available. The http://www.smokefree.gov website of the National Cancer Institute (NCI) combines evidence-based guidelines tailored to readiness to quit with available professional assistance via instant messaging and quitline (1-877-44U-QUIT).
- Texting interventions show borderline results.

- Social media (Twitter and Facebook) have potential benefit, utilizing buddy groups.
- Monetary incentives have shown only short-term benefit.

Smoking cessation in the cardiac patient covers a spectrum of therapy from simple behavioral modification to complex decisions involving pharmacotherapeutic options. We have ample data indicating that the approach must be a combination of techniques, with months of ongoing support. Still, the relapse rate remains unacceptably high. As we have reviewed, the risks of ongoing smoking are high, as are the benefits from quitting. Clearly, we need more physician participation in this process, and who could be more effective in guiding the patient to success than their own cardiologist?

Patient and Family Information for: SMOKING CESSATION FOR THE CARDIAC PATIENT

As a cardiac patient who smokes, you have an urgent need to understand not only how much cigarettes endanger your survival, but also how rapidly and thoroughly stopping smoking will improve your health and outcome. For patients with coronary heart disease, quitting smoking produces a 36% reduction in death from any cause. As you well know, cigarette addiction can be very intense for many people. But despite the intensity of this addiction, with your own determination and a little help from medication and behavioral techniques, you really will succeed.

HOW DOES IT BEGIN?

You most likely began smoking as a teenager, when you were very vulnerable to the addictive properties of nicotine. You tried a cigarette and found that it gave you a certain degree of confidence and pleasure. That feeling came from a substance called dopamine, which the nicotine in cigarette smoke causes to be released in the brain. Quickly, as you developed tolerance to nicotine, you found that in order to get the same effect you needed two cigarettes. Eventually, you found that you needed a cigarette to get going in the morning. Nowadays, it is hard to function without that morning cigarette and maybe a cup of coffee. The discomfort before that first cigarette in the morning is called withdrawal, and when you first felt it you were hooked.

WHY CAN SOME PEOPLE STOP “COLD TURKEY” AND I

CANNOT?

The level of addiction varies from person to person. It is determined genetically, by how your body handles nicotine, the addicting substance in the cigarette. Some people can be “social” smokers and just have an occasional cigarette. They experience the harmful effects of the cigarette, but they are not addicted. Their bodies handle nicotine differently. They do not have the genetic makeup that causes them to be susceptible to the addictive properties of nicotine. Why is this important to understand? Accepting that your smoking is an addiction is a heavy burden, but it is important for you and your loved ones to understand it, accept it, and look forward to getting you the help that you need to quit.

HOW DO YOU KNOW IF YOU ARE ADDICTED?

The easiest way to know if you are addicted to cigarettes is to ask yourself how soon after you wake up you have your first cigarette. If it is within minutes, you are very addicted and quitting may be tough for you. We therefore suggest that for you, quitting will be most successful if you combine medication with behavioral changes. Participating in a program with ongoing support, such as a smoking cessation clinic, is likely to be a major help.

WHAT IS NICOTINE WITHDRAWAL?

Nicotine withdrawal is a real physical brain dysfunction. You cannot do your day’s work. You get irritable, unable to concentrate. And what makes cigarettes so addicting is that within 10 seconds of smoking, not only is that uncomfortable feeling gone, but you experience real pleasure.

IS IT TOO LATE TO QUIT?

Absolutely not! Much of the effect of smoking on the heart and circulation is reversible and, within 3 years of quitting, the risk of recurrent coronary events becomes that of someone who never smoked. The benefits begin immediately.

Within hours of quitting smoking, the carbon monoxide that poisons your oxygen delivery system and the chemically induced tightening of your blood vessels dissipate.

An important part of what happens when a person has a heart attack is caused by the development of clots in the coronary arteries. That is why your doctor is giving you medicines like aspirin and other anticoagulants to thin your blood. Smoking, however, causes your blood to clot, and that effect is not blocked by aspirin. The clotting system is so sensitive to the effect of smoking that even one cigarette causes it to be disrupted. It is therefore very important to understand that it is not enough to cut down on your smoking. You must quit entirely. Even one cigarette endangers your survival. The good news is that your clotting system renews itself very well and fairly rapidly, so the benefits of quitting begin almost immediately.

Smoking also contributes to vascular damage over the years; damage not just to your coronary arteries, but to all the vessels in your body. If you are also diabetic, this effect is further enhanced with an increased risk of blindness, kidney damage, stroke, and loss of limb.

HOW DO I STOP?

There are two parts to this process: medication, for the physical withdrawal, and behavioral change for the habit. You may be disturbed by the idea of taking another medication and believe that you can do this without pharmacologic support. The truth is, if you are addicted, you double your chance of success with treatment, and stopping smoking is as important for your cardiac health as taking some of your cardiac medications, ACE inhibitors, or β-blockers.

MEDICATION

Your doctor will speak with you about using medication to help with nicotine withdrawal. It may be a nicotine patch or gum or even an inhaler, a medication called bupropion, which can be used with or without nicotine replacement or varenicline, which is used alone.

If you have been a heavy smoker and are using nicotine replacement therapy, you will need higher doses of nicotine replacement or possibly a combination of

medications such as the patch and gum. If you used nicotine replacement before and felt that it did not help, be aware that the dose must be just right for you. Also, it may seem strange to take nicotine to quit smoking when it is nicotine that you are trying to get away from. The reason this works is that the patch satisfies your need for nicotine without giving you any pleasure. It also breaks the ritual of the smoking habit, doubling your chance of success. As you become comfortable not smoking, the dose of nicotine is gradually reduced and finally stopped.

Your doctor may prescribe bupropion, which helps with the desire to smoke, cravings, as well as with depression. If you have been depressed, it is important to let your doctor know, because bupropion may be very helpful.

There is also a newer, highly effective medicine for stopping smoking called varenicline. It may cause nausea and strange dreams, but after taking it for 7 days you will not feel like smoking. You continue to take varenicline for several months. Unfortunately, some people can become very depressed and even suicidal while taking it. Your doctor may ask a family member to be aware of this and monitor you for any change of mood. If you do experience any change of mood, you need to stop varenicline immediately and speak with your doctor. Although warnings of mood change and depression are concerning, the effectiveness of this drug is very real. You and your doctor need to discuss this option in light of previous quit attempts, level of addiction, and the vulnerability of your cardiac status.

No matter which pharmacotherapy you use, a year later the relapse rate is the same. Something more is needed to remain smoke free, and this is called behavioral therapy: learning new life skills to cope with the issues that made you want to smoke in the first place.

WHAT IS THE BEHAVIORAL PART OF MY TREATMENT?

In addition to dealing with the nicotine withdrawal, you must have a plan for handling the behavioral part of your addiction. Do you use cigarettes for stress, boredom, anger, pleasure, socializing? It is important to look at the reasons for your smoking in order to plan a lifetime change, not just while you are taking medication, but a whole new approach to handling those situations that make you want to smoke.

Develop a clear plan for limiting your stress, avoiding situations that upset

you. Exercise regularly, giving yourself real rewards. Put relaxation into your day. Develop hobbies that you can substitute for the pleasure that you derived from cigarettes. Bring a magazine to work for what used to be your smoking break. Have a game on your cell phone to play when you are waiting for the bus. Music, reading, meditation, yoga, sketching, deep breathing, whatever gives you pleasure.

Some tips:

- Develop a list of activities that you can use to keep yourself busy, happy, and relaxed.
- Do not let anyone interfere with or endanger your success. No one can smoke around you!
- Avoid alcohol: it is the strongest trigger.
- For some, coffee is a trigger. Get a substitute, tea or juice or chocolate, at least for the first few days, to change your routine and make it easier to quit.
- Purchase healthy snacks and keep them on hand to relieve the cravings and avoid weight gain.

Pick a quit day and have all your tools ready to go. Choose a busy, nonstressful day; have no cigarettes in the house; throw out all your ashtrays. Keep very busy and go to bed early. If this thought is overwhelming, you are not alone. Some need to begin in a more stepwise fashion. Try using the nicotine lozenge to substitute for a few cigarettes for a few days to get started. Discuss this with your doctor. For the cardiac patient, this is not ideal because all cigarettes are dangerous, but the important message is to start.

Cigarette addiction can be overcome, but it never goes away completely, even as your body becomes much healthier. If you do have a relapse, get back to your plan immediately. Relapse is very common, but it is best to think of it as a learning opportunity—how you could handle that situation differently in the future. It is all part of the process of becoming smoke free.

Women's Heart Disease in the Cardiac Care Setting

Case Presentation

A 44-year-old woman presents to the emergency room complaining of chest pain. The patient began to experience chest discomfort during lunch and initially thought it was heartburn. The patient was awoken from recurrent chest pain later that evening around 4 pm and called emergency medical services. In the emergency room, the patient was found to have <1 mm ST elevations in leads aVR, V1, and V2. The patient's initial troponin level was 0.12 ng/mL. Blood pressure and heart rate were within normal limits. Bedside echocardiogram demonstrated left ventricular ejection fraction (LVEF) of 50% and no overt segmental wall motion abnormalities. The patient was admitted to the telemetry floor.

The following morning, the patient's troponin level was <0.03 ng/mL, and the patient was scheduled to have a stress echocardiography. During the stress test, the patient began to experience chest pain and had ST elevations in leads aVR, V1, and V2. Echocardiogram showed new segmental wall motion abnormalities during stress in the basal anterior, anteroseptal, and septal regions. Chest pain and ST elevations resolved quickly with the termination of the stress test. The patient was transferred to the cardiac intensive care unit.

She remained hemodynamically stable and was scheduled for cardiac angiography that evening.

Cardiac catheterization was completed and did not demonstrate significant angiographic stenosis. Nitrate medication was initiated, and the patient was scheduled to follow up with a cardiologist as an outpatient.

This case broaches the question “why were there ST elevations and normal coronary anatomy?”

INTRODUCTION

Women with signs and symptoms of cardiac ischemia will undergo cardiac angiography. Many of these patients are found to have normal-appearing coronary arteries. Several studies have demonstrated that up to 40% of patients who undergo cardiac catheterization will not have angiographically significant coronary stenosis.[1] Historically, these patients were said to have cardiac syndrome X. Cardiovascular disease accounts for about 1 in 3 female deaths. For women presenting for evaluation of suspected ischemic symptoms, a diagnosis of normal coronary arteries is 5 times more common than for men.[2] A substantial percentage of these patients have coronary microvascular dysfunction (CMD). In the past two decades, in part because the National Heart, Lung and Blood Institute initiated the Women’s Ischemia Syndrome Evaluation in 1996, an extensive amount of research has focused on coronary microvasculature. CMD is now acknowledged as a cause of cardiac ischemia and can occur alone or along with macrovascular coronary artery disease (CAD). Patients with CMD have a significantly higher rate of hospitalization, heart failure, sudden cardiac death, and myocardial infarction (MI).[3] CMD can affect the cardiac vasculature in a number of ways that essentially disrupt the coronary arteries’ vasodilatory ability and therefore hinders coronary blood flow (CBF), causing ischemia.[4]

MYOCARDIAL ISCHEMIA IN WOMEN IN THE CRITICAL CARE SETTING

All patients with acute coronary syndrome (ACS) are evaluated for placement in the cardiac care unit (CCU). Patients who are believed to have high-risk lesions,

such as left main coronary disease, will be appropriately monitored in the CCU until further diagnostic procedures can be obtained. As with the patient in the case presentation, because of the ST elevations in leads aVR, V1, and V2 and concordant echocardiographically demonstrated wall motion abnormalities during exercise stress, it was thought that there was a high likelihood of left main coronary disease. Optimal medical therapy for women experiencing ACS does not differ from that for men. In the absence of absolute contraindications, aggressive therapy should be initiated with antiplatelet therapy with aspirin, a platelet $P2Y_{12}$ receptor blocker, anticoagulation therapy, β-blockade, and lipid-lowering medication. Cardiac angiography would be the next diagnostic approach to assess the coronary arteries. It is well known that about 50% of patients who undergo clinically indicated coronary angiography will not have obstructive CAD. Of the patients without obstructive CAD, more than half are believed to have CMD. The importance of the diagnosis of CMD lies in its poor prognosis.

PROGNOSIS

In women who present with ACS, it is not uncommon for the angiogram to demonstrate nonobstructive CAD. National data have shown that the odds for obstructive CAD in the ACS setting are 50% lower in women when compared with men.[5] However, in the setting of ACS, nonobstructive coronary anatomy does not carry a benign prognosis. Studies have shown that women with signs and symptoms of ischemia and no obstructive CAD have elevated major adverse cardiac event (MACE) rates, including MI and cardiac death. In some patients, the worse prognosis is attributed to advanced age and comorbidities, but younger women in particular do worse. This may be due to underutilization of lifesaving therapies and medications.[6] CMD can occur secondary to either endothelial-dependent or non–endothelial-dependent regulatory systems. Endothelial-dependent CMD is defined as impaired vasomotor response to acetylcholine. Endothelial-dependent CMD has been shown to be an independent risk factor for MACE.[7] Non–endothelial-dependent CMD is diagnosed when there is reduced coronary flow reserve (<2.36), and it is significantly associated with MACE in 5-year follow-up from initial diagnosis.[3]

TAKOTSUBO CARDIOMYOPATHY

Stress cardiomyopathy, also known as Takotsubo cardiomyopathy or broken heart syndrome, is a syndrome characterized by regional systolic dysfunction of the left ventricle (LV) where the presentation mimics troponin-positive ACS or ST-elevation MI, but lacking obstructive disease on cardiac angiography.[8] There are several forms of Takotsubo cardiomyopathy, the most common presentation being apical ballooning of LV apex, with hypokinesis of the mid-and apical segments and hyperkinesis of the basal segments of the LV[9] (**Figure 57.1**). This syndrome is more common in women, and the pathogenesis, although not fully understood, is postulated to be secondary to catecholamine release, coronary spasm, or microvascular dysfunction. These patients, although lacking obstructive CAD, demonstrate abnormal myocardial perfusion.[10] Several findings argue that Takotsubo cardiomyopathy is consistent with CMD, including abnormal coronary flow reserve (CFR) measured by echocardiography and improvement of LV function with the administration of adenosine.[11,12]

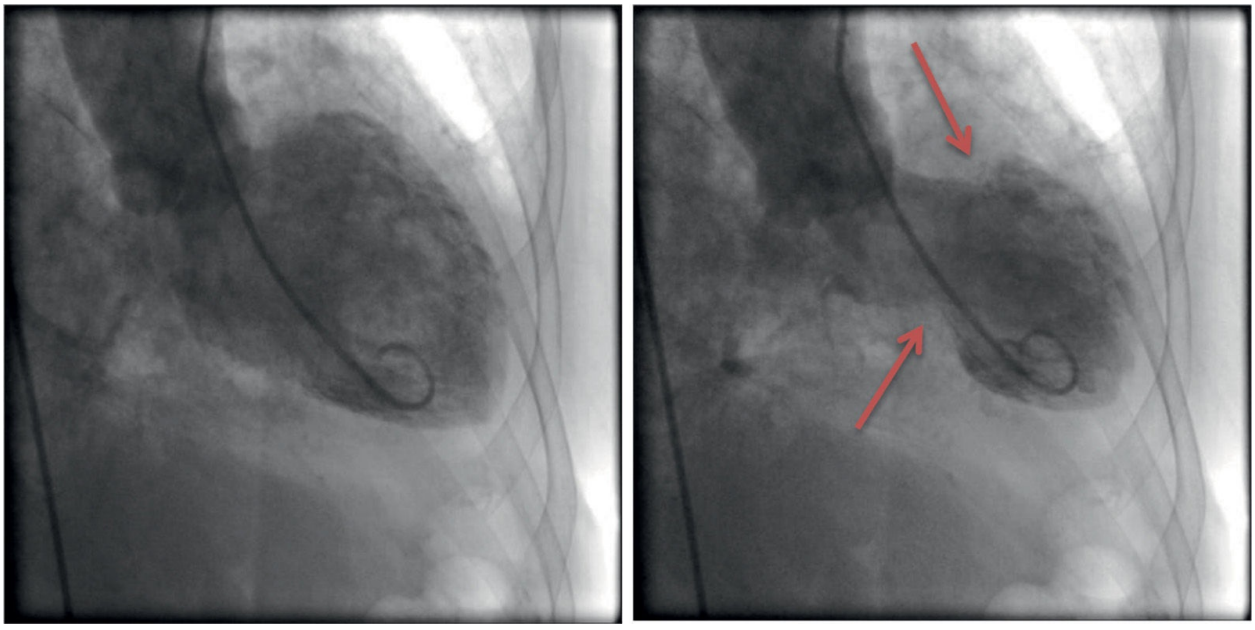

FIGURE 57.1 Takotsubo cardiomyopathy on cardiac angiography. Arrows indicate the hinge points between hyperdynamic basal segments and akinetic mid- and apical segments.

DIAGNOSIS

STRESS TESTING

Exercise stress testing is commonly used to assess CAD. However, stress testing is not very sensitive or specific in detecting heart disease in women. Currently, there are no methods to directly visualize the coronary microvasculature. Indirect assessment of the coronary microvasculature is made through functional testing. CFR is one method that provides vasodilator response to adenosine. CFR is calculated as the ratio of the CBF at maximal dilation to the CBF at rest and can be obtained through various imaging modalities. There is not an absolute cutoff for the CFR in defining CMD; however, most are considered to have CMD if the CFR is <1.5.[13]

POSITRON EMISSION TOMOGRAPHY

Cardiac positron emission tomography (PET) scanning is used for myocardial perfusion scanning as a technique to identify perfusion defects, which in turn reflect CAD. In nonobstructive CAD, perfusion defects reflect microvascular ischemia along distribution of the three main coronary arteries.[14]

CONTRAST ECHOCARDIOGRAPHY

Assessing the coronary arteries with cardiac angiography can be challenging in a critically ill patient. Contrast echocardiography can be safely used at the bedside.[15] Features of ACS are commonly seen in critically ill patients, including ECG changes, troponin elevation, and angina. These features of ACS are frequently seen in conditions other than obstructive CAD, such as Takotsubo cardiomyopathy and CMD. Cardiac microvasculature in the endocardial regional has the lowest flow reserve and is more susceptible to ischemia than the epicardium possibly because of the larger epicardially placed coronary arteries.[16] Therefore, in CMD there may be a reduction in the blood flow in the endocardial myocardium to a greater extent than in the epicardial myocardium (**Figure 57.2**), which can be seen with reduced perfusion during contrast echocardiography.[15]

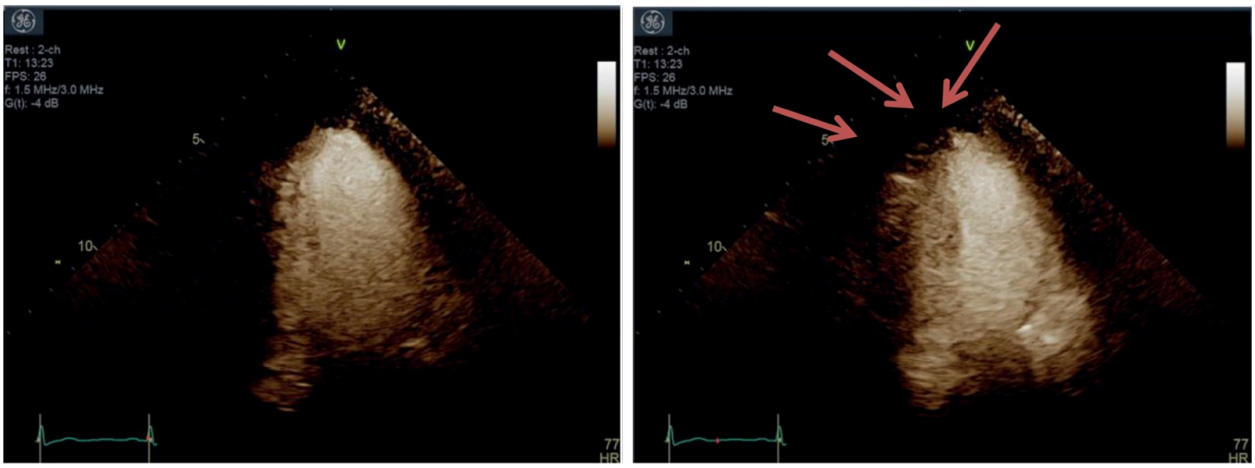

FIGURE 57.2 Contrast echocardiography demonstrating decreased circulation at the apical segment (arrows).

CARDIAC MAGNETIC RESONANCE IMAGING

Myocardial scar can be detected by cardiac magnetic resonance imaging (CMRI) late gadolinium enhancement (LGE) and is a known predictor of MACE. Women with signs and symptoms of ischemia and no obstructive CAD have been shown to have a prevalence of myocardial scar detected by CMRI LGE, with a predominant traditional MI pattern (**Figure 57.3**) indicative of CMD. The amount of ischemia can be assessed on the basis of the intensity of gadolinium that is perfused in the myocardium.[17] The use of CMRI has confirmed that many of these women can have irreversible myocardial injury, which appears to be clinically underdiagnosed.[18]

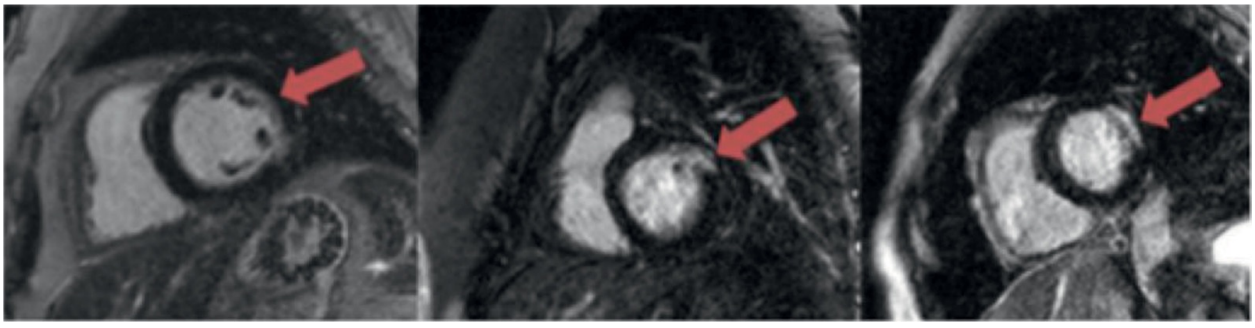

FIGURE 57.3 Cardiac magnetic resonance imaging with late gadolinium enhancement (arrows): Typical infarction pattern along the coronary arteries seen in coronary microvascular dysfunction.

CORONARY REACTIVITY TESTING

The gold standard for diagnosing CMD is through coronary reactivity testing.

This is done while the patient is having a cardiac angiography. Adenosine is used to assess endothelial-independent dysfunction, and acetylcholine is used to assess endothelial-dependent dysfunction. Coronary flow is quantified before the adenosine injection and again after administration. In non–endothelial-dependent dysfunction, the CFR, in response to adenosine, will be ≤2.5.[19] Endothelial-dependent dysfunction is seen when there is less than 50% increase in coronary blood flow after the bolus of acetylcholine.[20] Coronary spasm can also be assessed with acetylcholine if the patient has chest pain in addition to ECG changes and if the change in the coronary artery diameter is less than 90%.[21]

TREATMENT

Currently, there are no guidelines to treat CMD. Treating CMD begins with risk factor control and lifestyle modification. Treatment should be aimed at reducing ischemic disease to reduce the risk of adverse cardiac events, ameliorating symptoms to improve quality of life and to decrease the morbidity from unnecessary and repeated cardiac catheterization.

Patients with endothelial dysfunction should be counseled on smoking cessation, which is known to improve endothelial dysfunction and therefore CMD.[22] Adrenergic modulation seems to play an important role, and therefore exercise should also be encouraged in this population. Angiotensin-converting enzyme inhibitors and statin medications improve endothelial dysfunction and should be used as first-line therapy. Statins lower cholesterol and have anti-inflammatory properties that have been shown to increase CFR.[23]

Patients with non–endothelial-dependent CMD benefit from β-blocker and nitrate medications. Nitrates help with angina by decreasing preload with venous dilation. β-Blockers are beneficial in that they decrease myocardial oxygen demand and increase diastolic filling time.

Ranolazine is a medication that is used to treat angina with varying results. Ranolazine inhibits the late sodium channels and reduces intracellular calcium, leading to improved ventricular relaxation.[24] Patients who have refractory angina despite being on maximal medical therapy should have a trial of Ranolazine to see if their symptoms improve.

CONCLUSION

Myocardial ischemia has specific sex differences. Despite having a lower prevalence of obstructive CAD, women have a higher prevalence of symptoms, ischemia, and mortality relative to men. Diagnostic testing can be used to accurately assess for myocardial ischemia in symptomatic women, in addition to providing important prognostic information. Women who are critically ill because of unstable angina or ACS and who do not have obstructive CAD should not be dismissed from care without further workup. Many of these women have been shown to have CMD that has been proven to be associated with high mortality, and, therefore, CMD is important to consider when diagnosing and treating these patients.

Patient and Family Information for: WOMEN'S HEART DISEASE IN THE CARDIAC CARE SETTING

Coronary microvascular disease (CMD) is a disease that affects the small vessels of the heart that branch off from the larger coronary arteries. Patients often have signs and symptoms that are consistent with a blockage of the larger coronary arteries, but after cardiac angiography are not seen to have blockage. CMD is defined as damage to the inner walls of the blood vessels that can lead to spasms and decreased blood flow to the heart muscle. CMD affects more women than men. Despite not having obstructive disease of the large vessels of the heart, patients with CMD have a high risk of recurrent hospitalization, chronic chest pain, heart attack, and sudden cardiac death.

Stress-induced cardiomyopathy, also known as Takotsubo cardiomyopathy, is thought to be partially secondary to CMD. Patients who have experienced stressful situations, which could include anything from the loss of a family member to an illness or any general life hardship, can be affected by this type of cardiomyopathy. The pump function of the heart decreases in stress-induced cardiomyopathy because the apex of the heart will not contract as it should. Most often, this cardiomyopathy is reversible if treated properly.

The diagnosis of CMD has been evolving over the past two decades. There are noninvasive imaging modalities that can be used, such as positron emission tomography, echocardiography, and cardiac magnetic resonance imaging. Invasive testing can be done during cardiac angiography to see how the small vessels respond to certain medications to determine if there is a dysfunction within the lining of the blood vessels.

There are no specific guidelines on the treatment of CMD. All patients with CMD should undergo risk adjustment with lifestyle modification. Smoking

cessation is essential because cigarette smoke affects the lining of the small blood vessels and exacerbates the symptoms of CMD. Exercise should be encouraged because it increases blood flow throughout the body, including to the small vessels. Medications that increase blood flow to the small vessels should be considered. These include angiotensin receptor blockers, β-blockers, nitrates, and Ranolazine, each having their respective mechanism of action. Cholesterol-lowering medications should be started because they both lower cholesterol and have anti-inflammatory properties, which are thought to aid in the treatment of symptomatology.

To conclude, women with chest pain should have a thorough workup done by a cardiologist. Women who have been admitted to the hospital for an acute coronary syndrome but have not been found to have obstructive coronary disease of the large vessels should not go without follow-up because if they do have CMD and go undiagnosed and untreated, the prognosis is often poor.

Lifestyle Management after the Diagnosis of Heart Disease

As the 20th century approached, pneumonia, tuberculosis, and diarrhea/enteritis were the leading causes of death in the United States. However, marked advances in our understanding of the determinants and transmission of diseases were beginning to reduce the mortality risk from acute illnesses. These included such measures as sanitation, chlorination, the introduction of measures to ensure a safer food supply, and the development of vaccines against acute illnesses, which by 1900 included vaccines against cholera, tetanus, typhoid fever, and bubonic plague. By the 1920s, chronic diseases were replacing acute illnesses as the major causes of mortality, with cardiovascular disease (CVD) as the leading cause of death. Thus, a “war” against CVD was initiated by the American medical community.

Initial success was slow because of a limited understanding of the disease and its risk factors. CVD increased in epidemic proportion before peaking in its incidence in the late 1960s. Since then, the reversal of disease has been remarkable. In the late 1960s, heart disease dwarfed cancer as a cause of death, and strokes were all too common. Since 1970, however, the mortality rates from cardiac disease and stroke have fallen by 70%, and the death rates from heart disease and cancer are now comparable (**Figure 58.1**).[1]

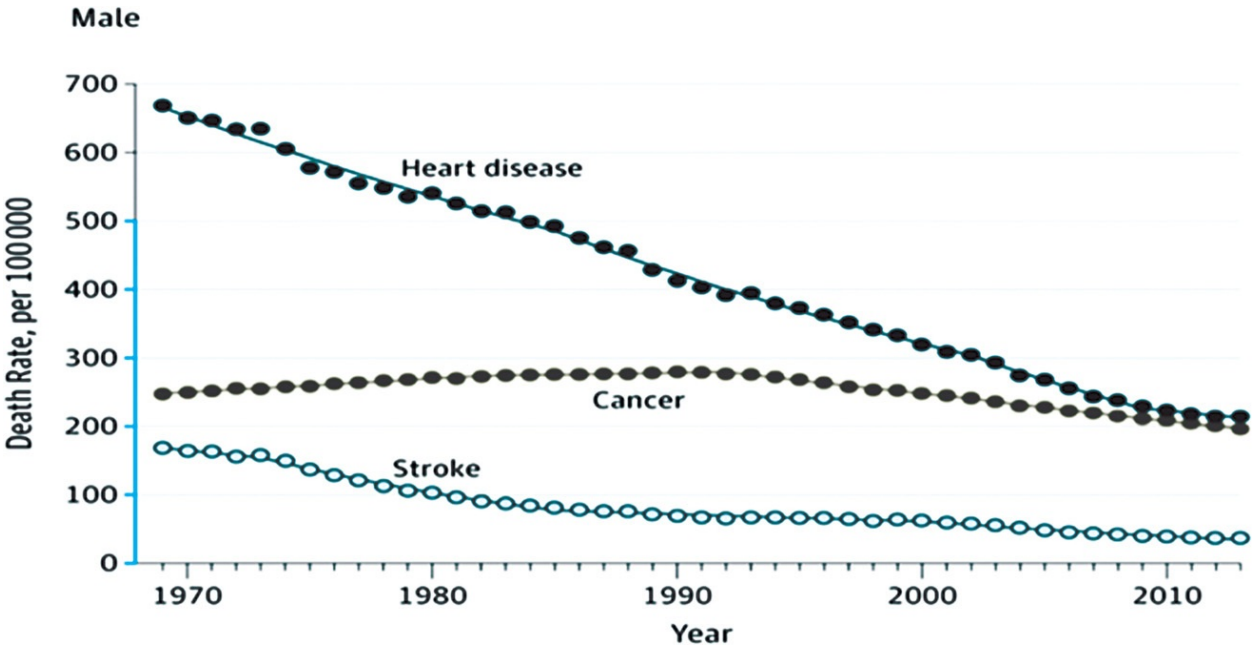

FIGURE 58.1 Temporal decline in death rates from heart disease, cancer, and stroke since 1969. (From Ma J, Ward EM, Siegel RL, Jemal A. Temporal trends in mortality in the United States, 1969–2013. *JAMA*. 2015;314:1731-1739.)

Two broad factors have accounted for this success: remarkable improvements in the treatments for heart disease and important advances in CVD prevention. Each of these factors is estimated to account for approximately 50% of the decline in heart disease.[2]

The medical advances have been broad based, including the initiation of cardiac care units, introduction of stress testing, development of cardiac bypass surgery and percutaneous coronary interventions, echocardiography, radionuclide stress testing, defibrillators, pacemakers, ablation procedures for arrhythmias, cardiac transplant, and the development of many effective classes of cardiac medications. The increasing sophistication of treatment has led to the development of many cardiac subspecialties, such as in cardiac imaging, electrophysiology, interventional cardiology, heart failure, and preventive cardiology. In each of these arenas, there have been continual advances that have improved care and survival. For instance, in the early introduction of angioplasty, reocclusion was a common problem. Improvement came with the development of bare metal stents, but in-stent restenosis remained a problem. The subsequent introduction of drug-eluting stents reduced the incidence of in-stent stenosis and allowed the performance of more complex procedures. Now fully bioabsorbable stents have been approved for use and will be tested for their

added efficacy. Similarly, the treatment of heart failure has been revolutionized by ever safer ventricular assist devices and resynchronization devices. Cardiac imaging has expanded to include cardiac MRI, coronary artery calcium scanning and coronary CT angiography, as well as continued advances in echo and nuclear cardiology. Other important recent advances include the expanding use of trans-aortic valvular replacement (TAVR), hypothermia for cardiac arrest, and many new drug therapies, such as those used to treat diabetes, the introduction of PCSK 9 inhibitors for hyperlipidemia, and novel anticoagulants.

The improvements in CVD prevention have also been broad based and impressive. An important advance in this regard was the initiation of the famous Framingham Study in 1948, which was dedicated to determining what risk factors accounted for heart disease in the town of Framingham, Massachusetts. By the early 1960s, the study had revealed that high cholesterol, hypertension, smoking, and diabetes were all important risk factors for CVD. At that time, nearly 45% of Americans smoked, often with great frequency, and many others were subject to secondhand smoke. The greatest single advance in cardiac prevention that has occurred since that time has been the dramatic drop in smoking rates (**Figure 58.2**),[3] aided by societal measures to prevent individuals from being exposed to secondhand smoking. Second, dietary guidelines and change in eating habits, such as the reduction in animal lard use and trans fats, have helped reduce serum cholesterol levels (which began even before the statin era) (**Figure 58.3**).[4] In addition, the advent of statins to treat dyslipidemia and powerful medications to control hypertension and diabetes has markedly improved our ability to prevent CVD.

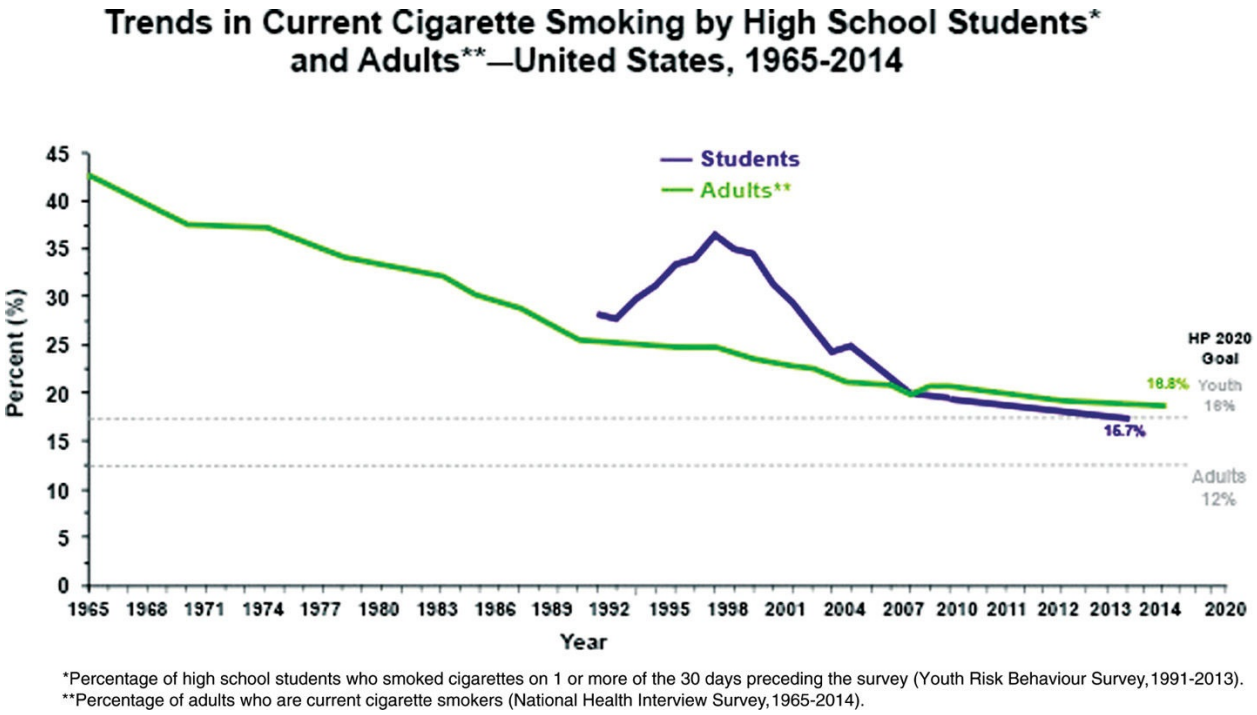

FIGURE 58.2 Temporal decline in the prevalence of smoking in the United States since 1965 for adults (green line) and students (blue line). (From Trends in current cigarette smoking among high school students and adults, United States, 1965–2014. Atlanta, GA: Office on Smoking and Health, National Center for Chronic Disease Prevention and Health Promotion; March 2016.)

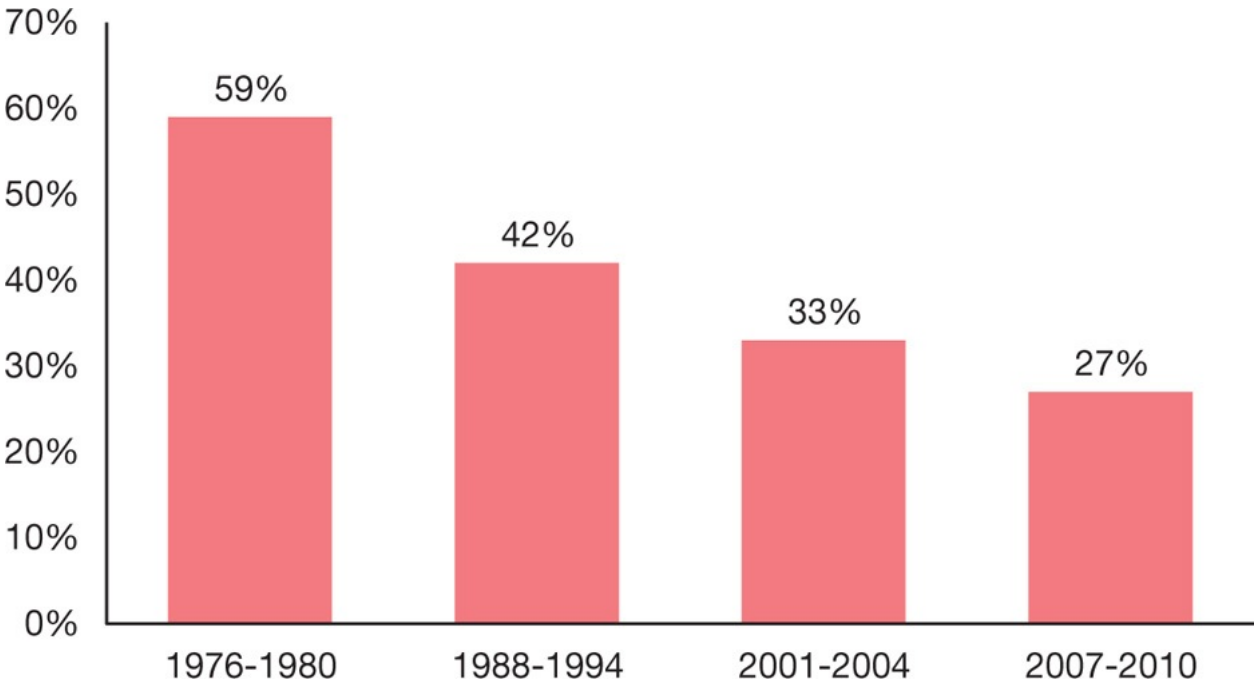

FIGURE 58.3 Temporal decline in the prevalence of high LDL cholesterol levels in the United States as assessed over four temporal periods. (From Kuklina EV, Carroll MD, Shaw KM, Hirsch R. Trends in high

LDL cholesterol, cholesterol-lowering medication use, and dietary saturated-fat intake: United States, 1976–2010. Atlanta, GA: National Center for Health Statistics Brief No. 117; March 2013.)

Because of these remarkable advances in prevention, there has been a marked decline in sudden cardiac death, and both the frequency and magnitude of myocardial infarction have declined.[5,6] So too has the incidence of peripheral vascular disease.[7] There has also been a marked decline in the frequency of inducible myocardial ischemia among patients presenting to stress labs for the workup of suspected CVD (**Figure 58.4**).[8] In sum, heart disease today is not only less frequent but also milder than yesteryear.

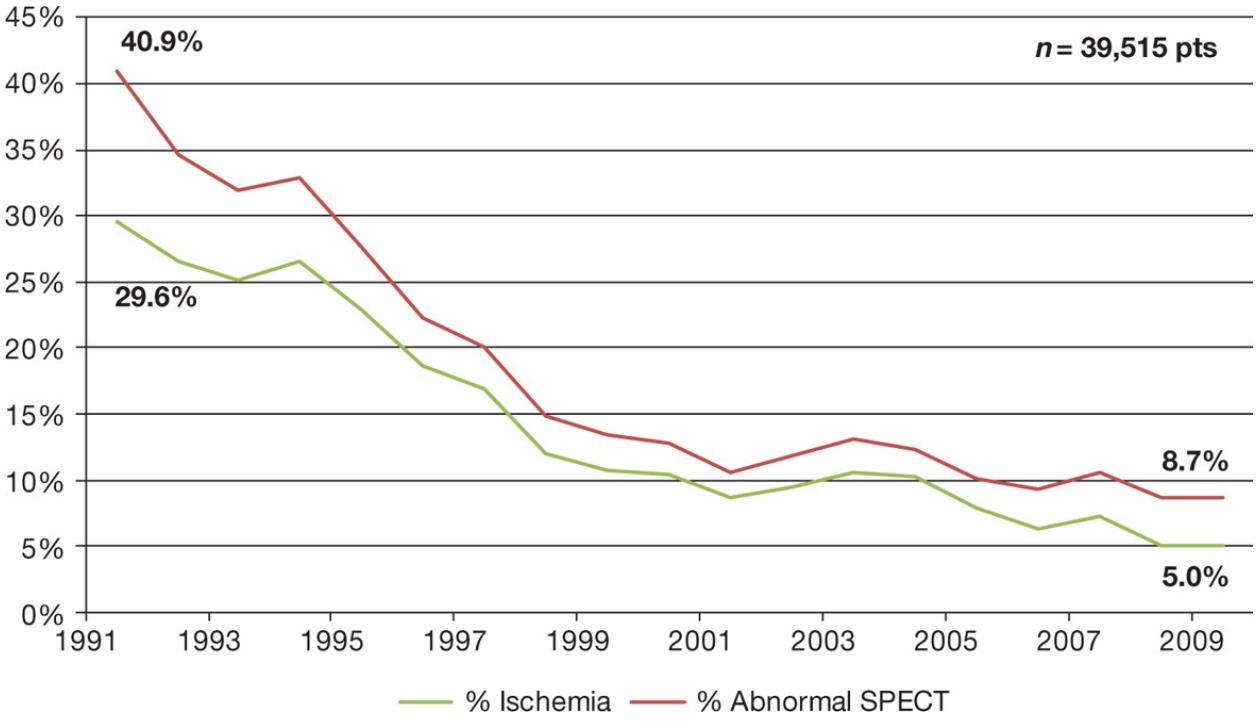

FIGURE 58.4 Temporal decline in the frequency of abnormal stress-rest myocardial perfusion SPECT studies (red line) and frequency of inducible ischemia (green line) between 1991 and 2009 among 39,515 patients referred for testing at a single medical center because of suspected CAD. (From Rozanski A, Gransar H, Hayes SW, et al. Temporal trends in the frequency of inducible myocardial ischemia during cardiac stress testing: 1991 to 2009. *J Am Coll Cardiol*. 2013;61:1054-1065.)

Nevertheless, despite all of this progress, CVD remains the number one cause of death in the United States, among both men and women.[9] Further progress will depend on addressing two interrelated problems. First, although the medical advances cited earlier have remarkably altered the course of CVD, they have also markedly increased the cost of cardiovascular health care, which has been

projected to triple between 2010 and 2030 (**Figure 58.5**).[9] Thus, efforts to reduce CVD costs have become an important driving force in health care policy. Second, although some risk factors for CVD have declined, three important risk factors have increased in frequency: obesity, sedentary behavior, and diabetes.

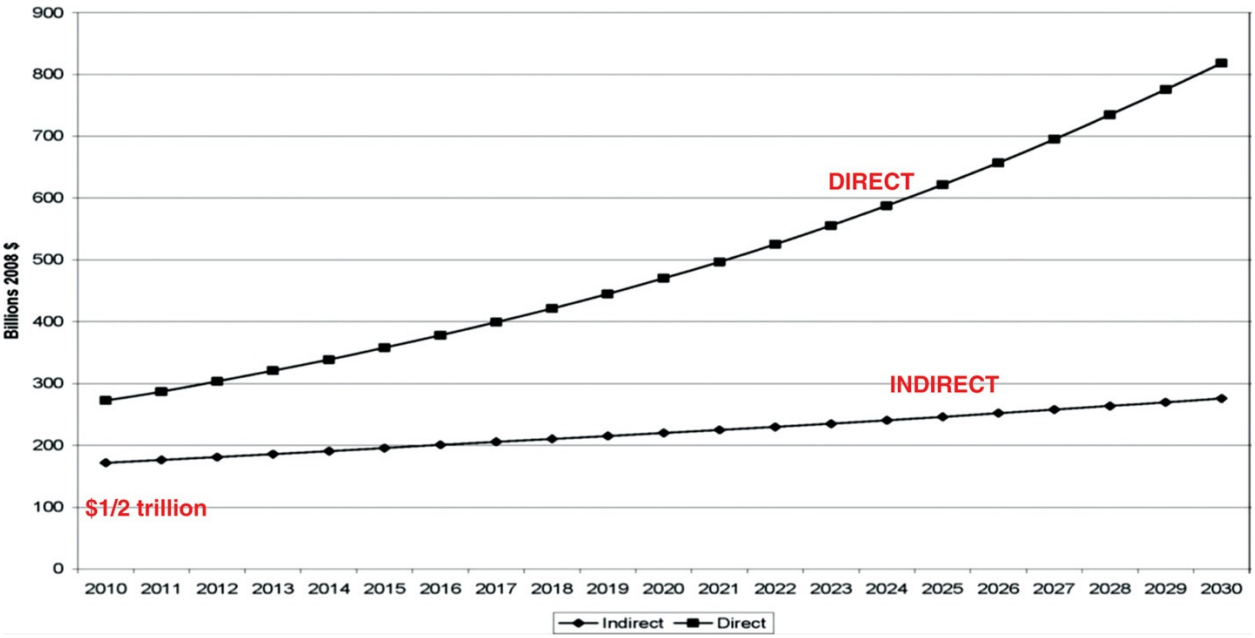

FIGURE 58.5 Projected direct and indirect medical costs for cardiovascular care in the United States between 2010 and 2030, according to an American Heart Association analysis. (From Heidenreich PA, Trogdon IG, Khaugov OA, et al. Forecasting the future of cardiovascular disease in the United States. A policy statement from the American Heart Association. *Circulation*. 2011;123:933-944.)

Since the 1980s, obesity has increased around the world in epidemic fashion. To exemplify the problem, the Centers for Disease Control and Prevention (CDC) maps the prevalence of obesity by state on a yearly basis. For instance, **Figures 58.6** and **58.7** show the U.S. obesity maps for 1990 and 2010. In 1990, not one state had a prevalence of obesity that was >15%.[10] By contrast, in 2010, a mere 20 years later, approximately one-quarter of states had obesity rates >30%. Today, approximately 30% of Americans are overweight and >30% are obese. It is widely recognized that this sudden rise in obesity is not due to genetic change, but rather to societal and environmental changes that have occurred since the 1980s, including such factors as eating more refined grains, changes in how food is processed, advertising of unhealthy foods, increasingly sedentary behavior, growth of convenience stores, increasing size of food portions, and decreasing sleep patterns. The poor diet of Americans is a large

part of this story. The American Heart Association has identified seven components of “ideal” cardiovascular health, on the basis of diet, physical activity, body mass index, abstinence from tobacco use, blood pressure, cholesterol, and blood glucose levels.[11] Of these factors, Americans’ poor diet is a particularly challenging one, with the vast majority of Americans scoring poorly on their diet metric.

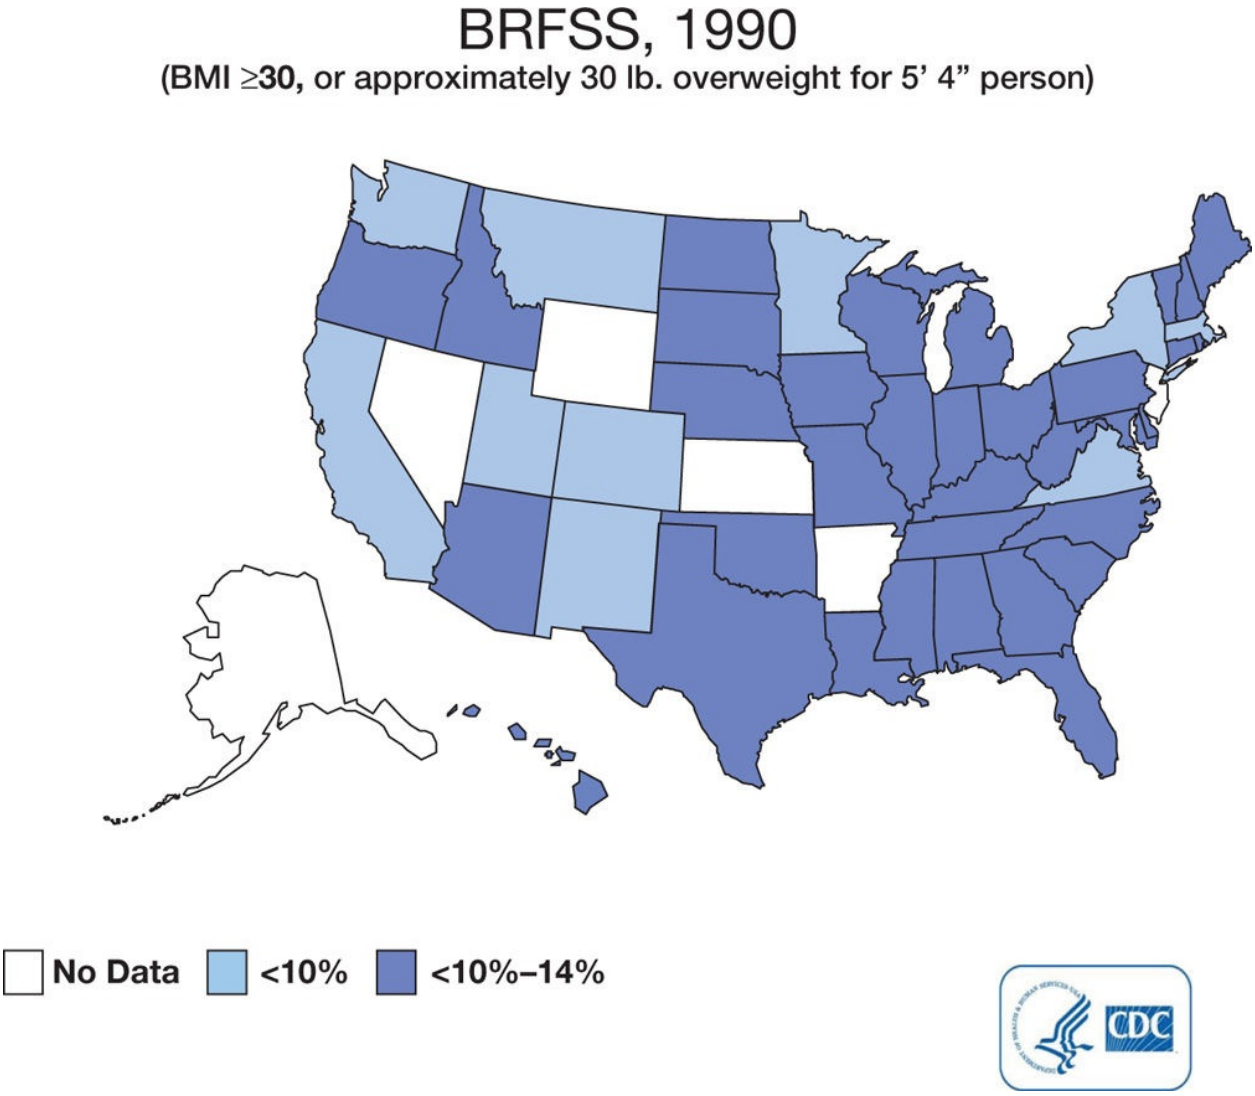

FIGURE 58.6 Prevalence of obesity in the United States, by state, according to a Behavioral Risk Factor Surveillance System (BRFSS) analysis in 1990. As shown on the color maps, no state exceeded a 15% prevalence of obesity.

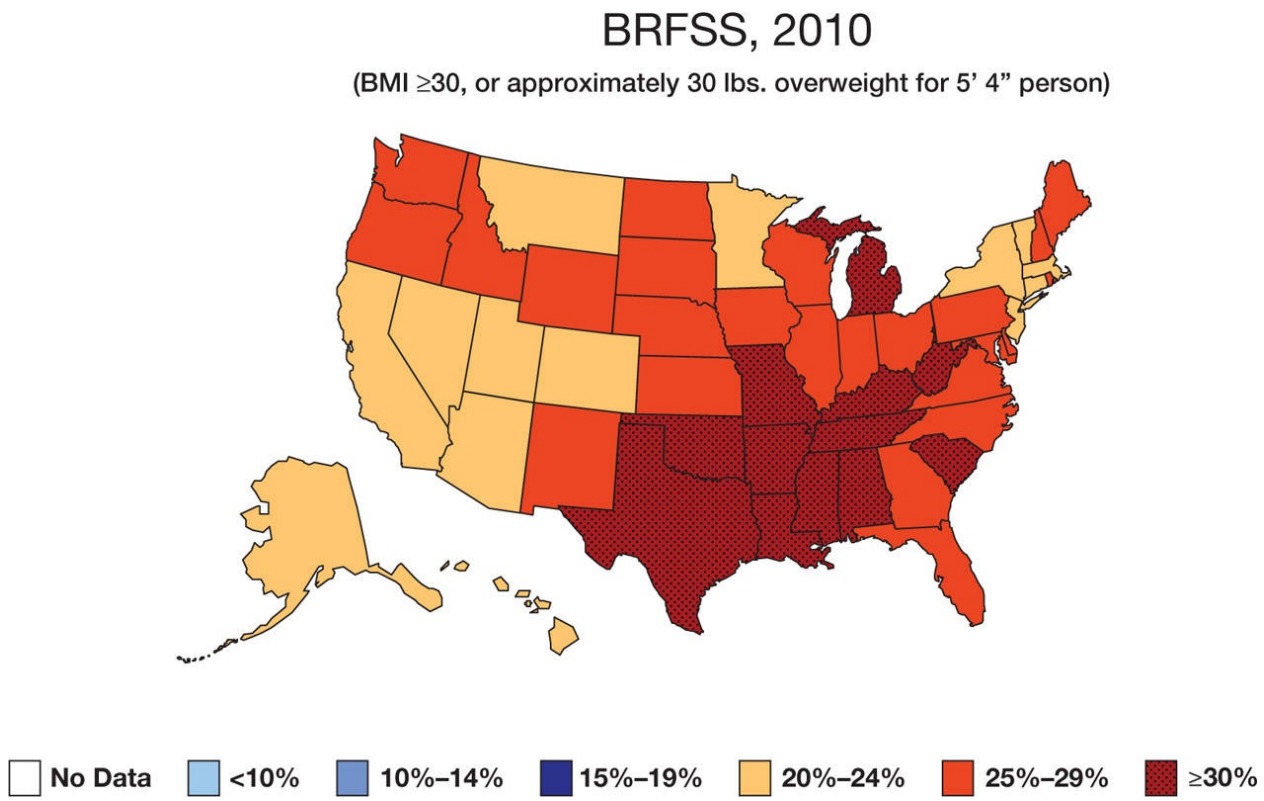

FIGURE 58.7 Prevalence of obesity in the United States, by state, according to a Behavioral Risk Factor Surveillance System (BRFSS) analysis in 2010. As shown on the color maps, 12 states exceeded a 29% prevalence of obesity.

Sedentary behavior has become normative in our society and may be increasing because of various societal trends. Excessive TV watching, increasing screen time, sedentary pastimes (eg, video games), a shift to more sedentary jobs,[12] convenience devices that have led to less physical activity at home (**Figure 58.8**),[13] less maternal time spent engaged in physical activity (**Figure 58.9**),[13] and a drop in physical activity among teenagers (**Figure 58.10**),[14] a time when physical activity habits are being set, are among the reasons for too little physical activity in today's society. Today's society has also become more fast paced and time pressed, resulting in greater difficulty for finding time to exercise among many people.

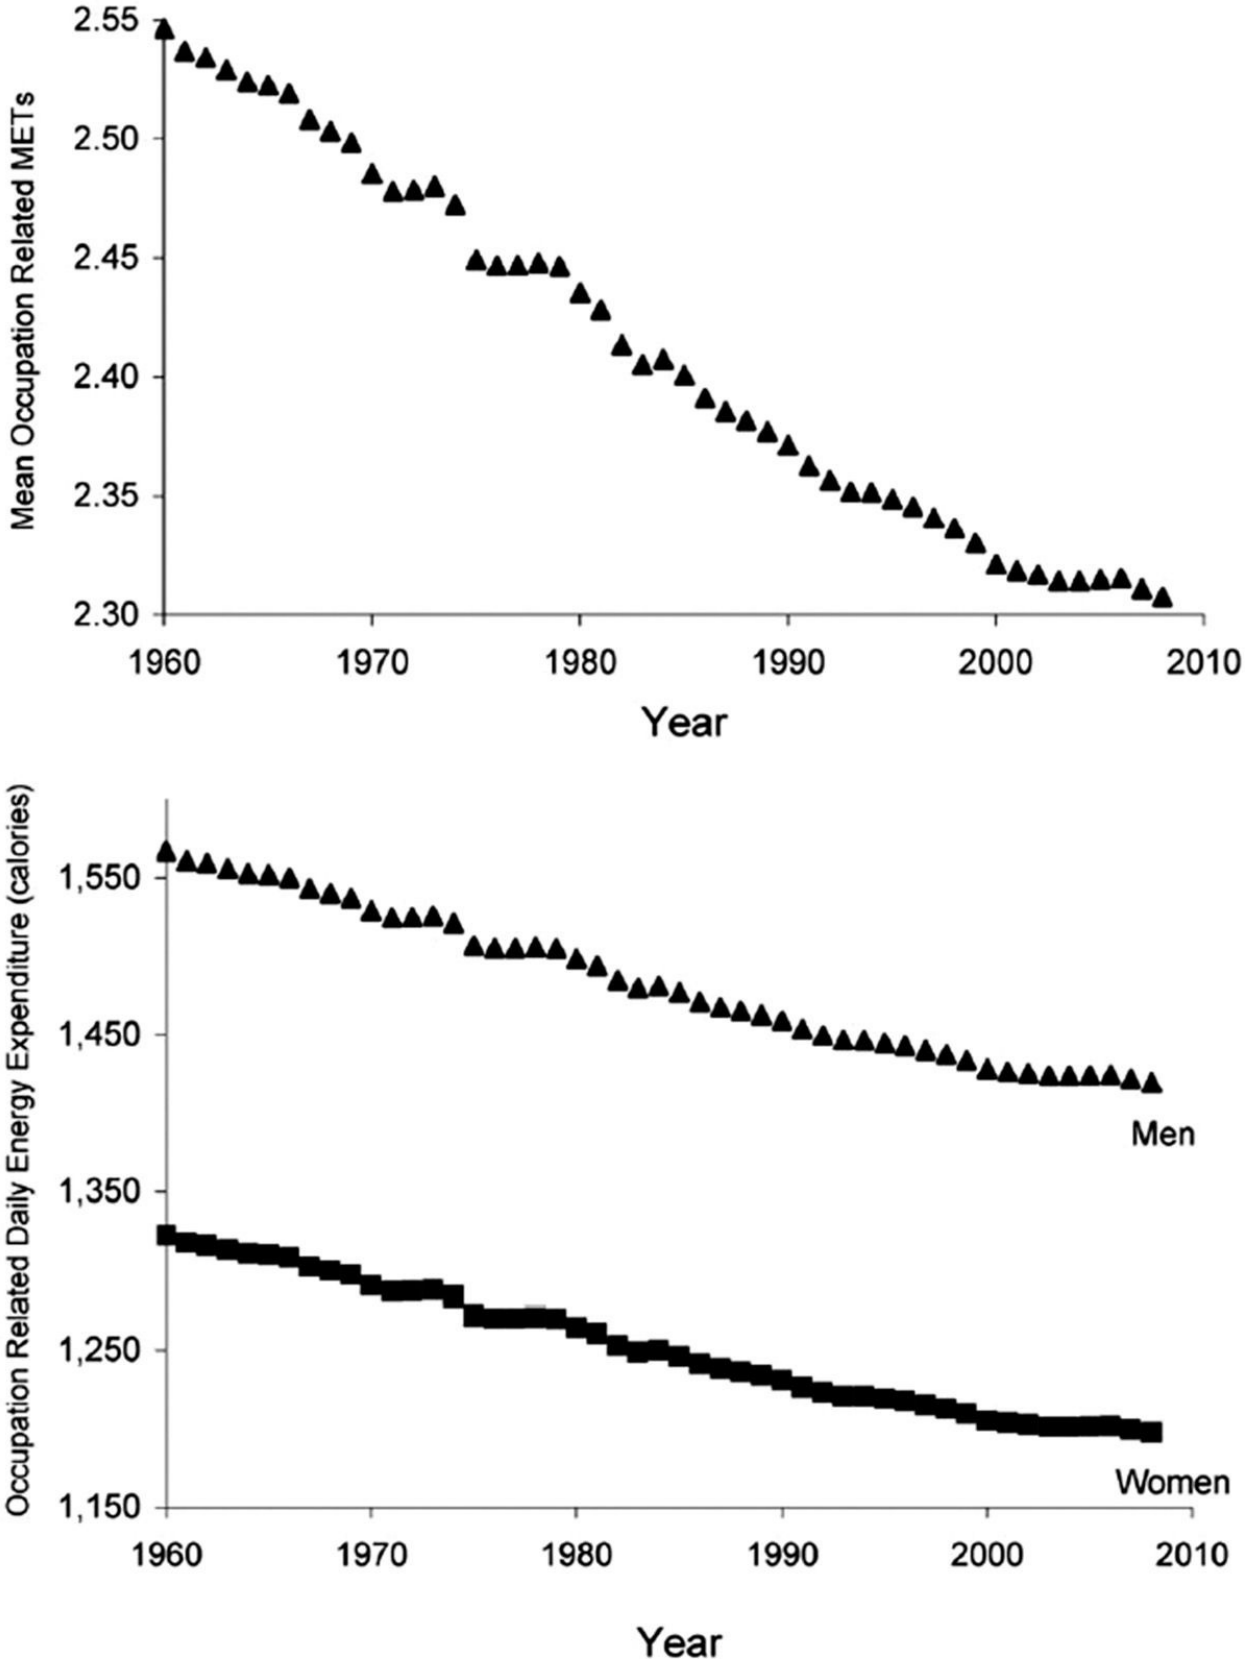

FIGURE 58.8 Decline in household levels of energy expenditure over a 45-year period. (From Archer E,

Lavie CJ, McDonald SM, et al. Maternal inactivity: 45-year trends in mothers' use of time. *Mayo Clin Proc*. 2013;88[12]:1368-1377.)

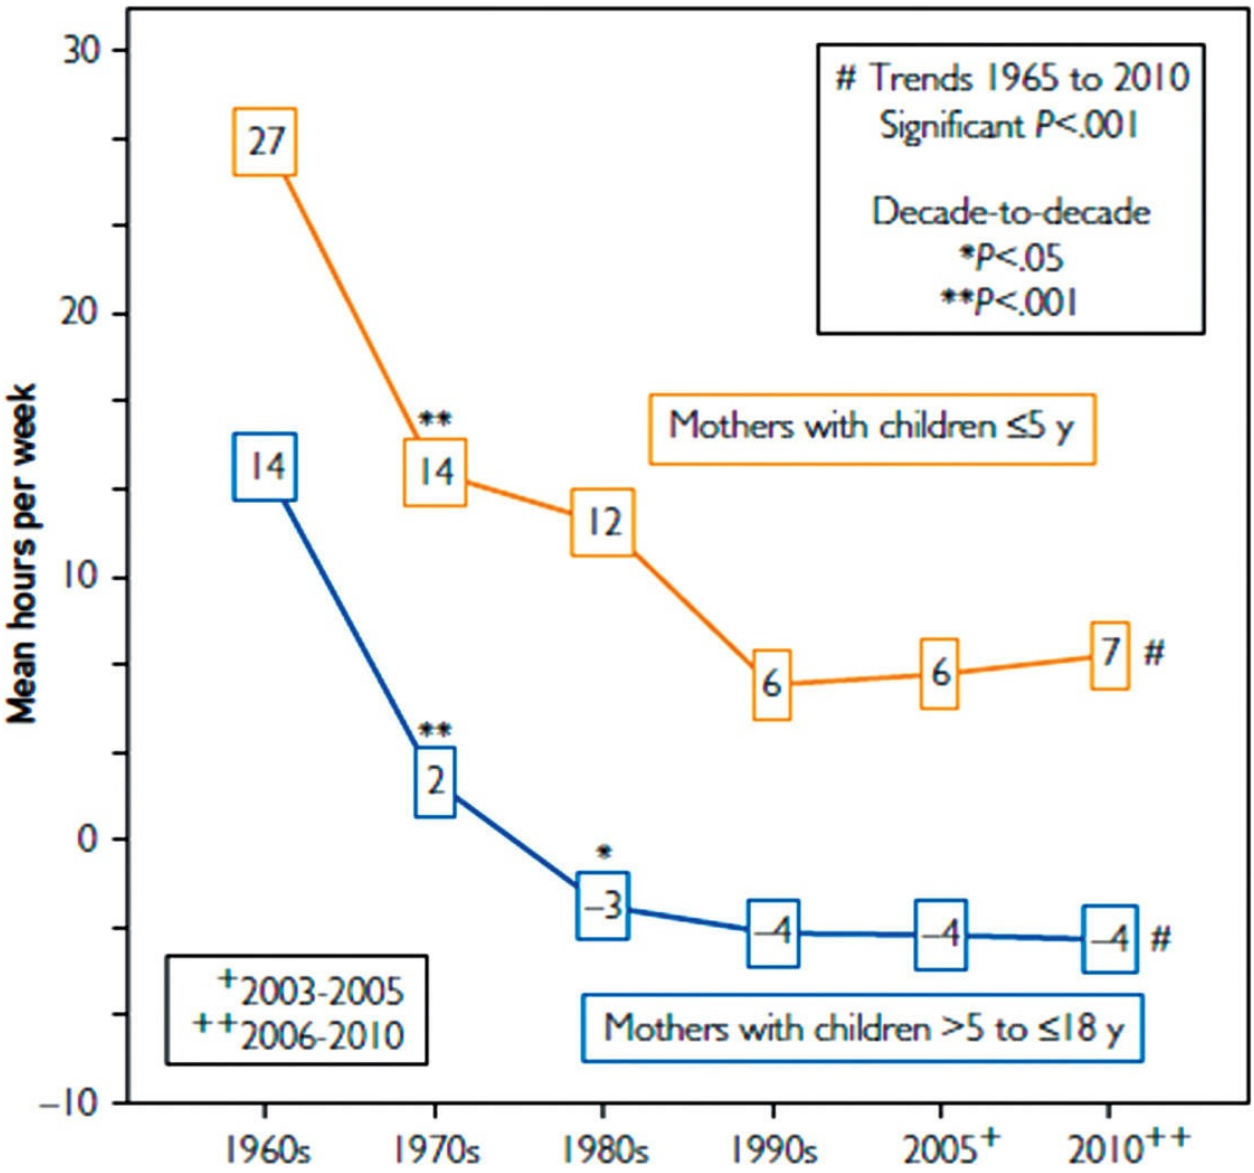

FIGURE 58.9 Time reallocation (mean hours per week spent in physically active behaviors minus hours per week spent in sedentary behaviors; numbers rounded to the nearest whole number) in US mothers, 1965–2010. Negative values denote more time spent in sedentary than in physically active behaviors. (From Archer E, Lavie CJ, McDonald SM, et al. Maternal inactivity 45-year trends in mothers' use of time. *Mayo Clin Proc*. 2013;88[12]:136-1377.)

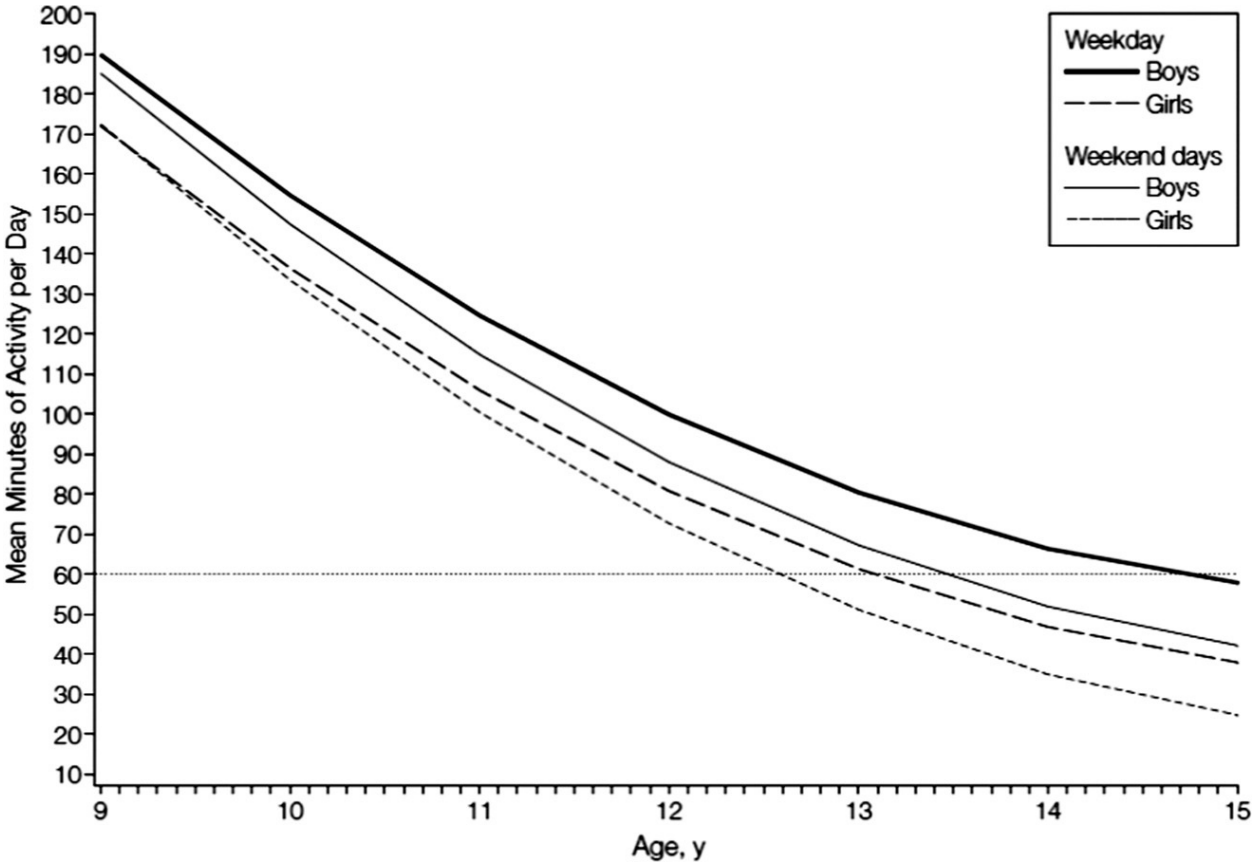

FIGURE 58.10 Daily minutes of physical activity for children between the ages of 9 and 15, for boys and girls, including weekdays and weekends. Note the marked decline in physical activity during the teenage years. (From Nader PR, Bradley RH, Houts RM, McRitchie SL, O'Brien M. Moderate-to-vigorous physical activity from ages 9 to 15 years. *JAMA*. 2008;300[3]:295-305.)

The result of poor nutritional habits, the rise of obesity, and the decline in physical activity have fueled an epidemic rise in diabetes (**Figure 58.11**), which now affects nearly 30 million Americans (approximately 9.3% of the population), and nearly 85 million Americans over the age of 20 are also considered prediabetic.[15] The presence of these three risk factors has helped to sustain our continued high rate of CVD, and these risk factors also lead to many other chronic medical conditions, as shown for obesity in **Figure 58.12**. It is estimated that the majority of chronic diseases could be obviated if people would adopt healthy lifestyle habits.[16,17] For this reason, increasing emphasis now needs to be placed on the promotion of healthy nutrition, exercise, and successful weight management.

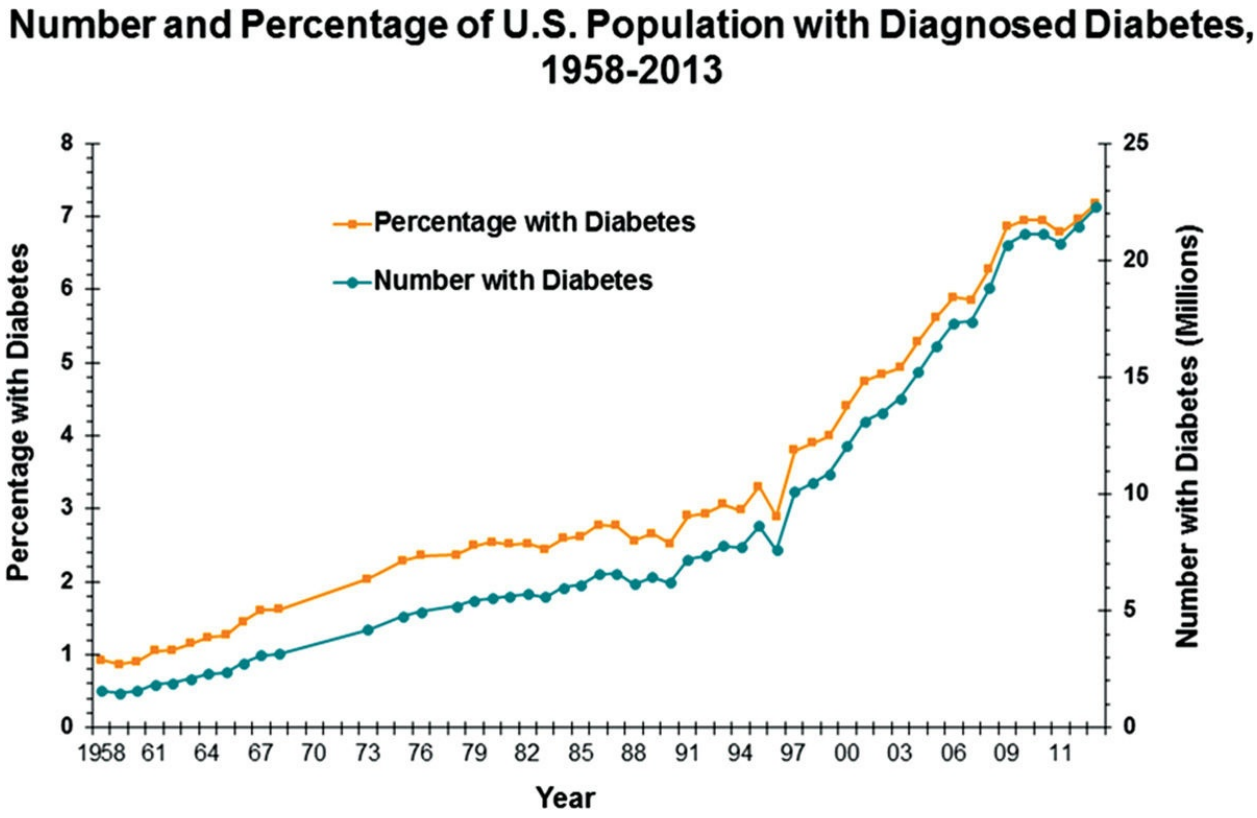

FIGURE 58.11 The number (blue) and percentage (gold) of Americans with diagnosed diabetes between 1958 and 2013. (From Centers for Disease Control and Prevention. National diabetes statistics report: estimates of diabetes and its burden in the U.S., 2014. Atlanta, GA: U.S. Department of Health and Human Services; 2014.)

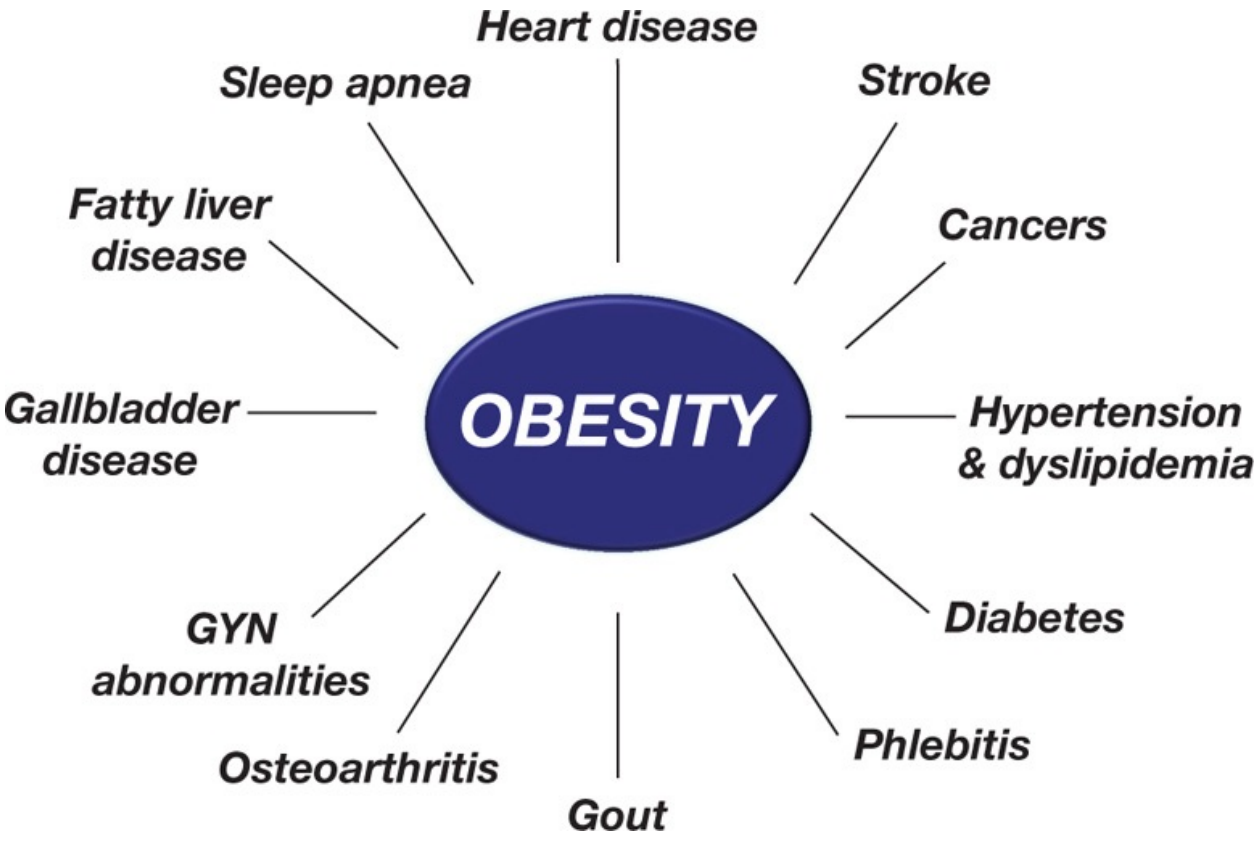

FIGURE 58.12 Medical conditions that are increased in frequency because of obesity.

However, changing negative health habits is not simple. Even adherence to medication change is often difficult for patients. Thus, a new field of behavioral cardiology has emerged, which is dedicated to studying the behavioral and psychosocial determinants of cardiac disease and the behavioral approaches to modifying negative health habits.[18,19] This field has made rapid strides in recent decades.[20] The field is based on a psychosocial model of health that recognizes that psychosocial factors both contribute to negative health habits and help cause disease directly through various pathophysiologic mechanisms. The field is also dedicated to the application of psychological principles for aiding patients to change their negative lifestyle behaviors.

To illustrate the development of behavioral cardiology and its application to patients following myocardial infarction, we present the story of David, a patient recovering from myocardial infarction, in the next three chapters. The first chapter deals with David's dietary management based on a new body of scientific literature that has identified which foods and dietary patterns are associated with better health and a reduced risk of CVD.[21] The second chapter focuses on the growing science of exercise physiology and epidemiology and

how it might apply to a patient like David.[22] The third chapter focuses on a dramatic growth in the field of behavioral cardiology: identification of the psychosocial risk factors that help contribute to the development of CVD and the increasing application of psychological principles for the management of negative health habits and psychosocial risk factors for CVD.[23] Together, these three chapters provide growing insights into the application of behavioral cardiology for the betterment of patients' lifestyles following the occurrence of cardiac events.

Nutrition and Weight Management in Cardiac Patients

David is a 52-year-old male who until recently felt well. One day, however, he developed sudden chest pain, prompting him to go to the local hospital. Much to his surprise, he was diagnosed with a heart attack and needed a coronary stent placed to open up a blocked artery. Although David had been told by his doctor for years to lose weight, change his diet, and start exercising in order to avoid developing medical conditions that can predispose to heart disease, he just didn't have the necessary time to commit to these lifestyle changes. Having three teenage children and a working wife, David had a very demanding job that required long hours, a long commute, and expectations to work from home. In David's mind, it was more important to work hard and provide for his family than to tend to these lifestyle changes, which he mentally thought of as something one does after retirement.

David's heart attack was real and life changing. As he sat recuperating in his hospital bed, he thought about all the things he could have done differently to avoid this major medical event that, for better or worse, has now affected his life and put a burden on his family, coworkers, and friends. Thankfully, David's hospitalization was unremarkable, and he was given an excellent prognosis. As he was being discharged to his home, David felt a deep sense of responsibility to himself and his family to make all the important lifestyle

changes necessary to regain his sense of health and vitality. The only problem was he didn't know where to start. As a first step, he established care with a local cardiologist and began asking questions: "How can I change my diet and poor eating habits? What is the most safe and effective way to lose weight? How do I initiate an exercise program? What is the best way to manage the stress in my life?"

David's first visit with the cardiologist started out with a general assessment of his health. Although he felt well, during the hospitalization David found out that he had mild hypertension and high cholesterol, both of which required medical therapy for adequate control. He was also told that he was overweight with a body mass index of 28 and was prediabetic with a fasting blood glucose of 110 mg/dL and a HbA1C of 6.2%. His blood pressure was controlled on medication, and his physical exam and ECG were unremarkable. David expressed his reluctance to take medications and asked if he could manage his heart condition with only diet and exercise. His cardiologist explained that the medications were essential to stabilizing his condition after the heart attack and preventing recurrent problems from developing in the future. In fact, research indicates that many of the medications David was taking can lower his risk of a recurrent heart event by 20% to 30%. That being said, however, his cardiologist went on to explain that medications can only do so much and that changing his lifestyle would be the only way to achieve and maintain health and vitality.

After a prolonged discussion, David and his cardiologist agreed to focus first on diet and nutrition. He was referred to a local dietitian, who sent him a primer on nutrition before his first visit, with copies of articles that had been extracted for those who wanted to delve more closely into nutrition.

THE DIET CONUNDRUM

David took on his nutrition packet as a homework assignment. He quickly became aware of how vast the topic of nutrition is and how much information is out there. In an age when dietary advice is dispensed through so many sources, it should be easy for patients to know what constitutes a good diet. However, the easy access to information is also often a hindrance: much contradictory information is often provided. For years, diet information was based on scant data or poorly designed nutritional studies. But over the last 15 to 20 years, a

new evidence-based science of nutrition has emerged. In addition, an evidence-based set of principles have also emerged that help guide patients on the psychological barriers and approaches that can be used to implement a new diet.

WHY FOCUS ON NUTRITION?

At the beginning of his first session with the dietitian, she asked David why he was interested in meeting with her. David told her he had been frightened by his heart attack and wanted to do everything he could to improve his health. To reinforce the issue, the dietitian asked David what the potential health benefits of a good diet were. David answered that they included rising good cholesterol, decreasing bad cholesterol, preventing heart disease, and preventing obesity.

"Very good" responded the dietitian. "That is all correct. But the effects of diet on our physiology are actually even more extensive than that." She then showed him a diagram (**Figure 59.1**) that revealed the many ways in which the food we eat can affect our physiology. Besides the factors that David mentioned, these include effects upon our blood pressure, increase or decrease in systemic microinflammation, endothelial health of our blood vessels, and many other factors. She explained that people do not sufficiently realize that so much of what we can eat can affect our health either for the better or for the worse. Over time, the effects can be powerful. Intrigued, David asked her to explain more.

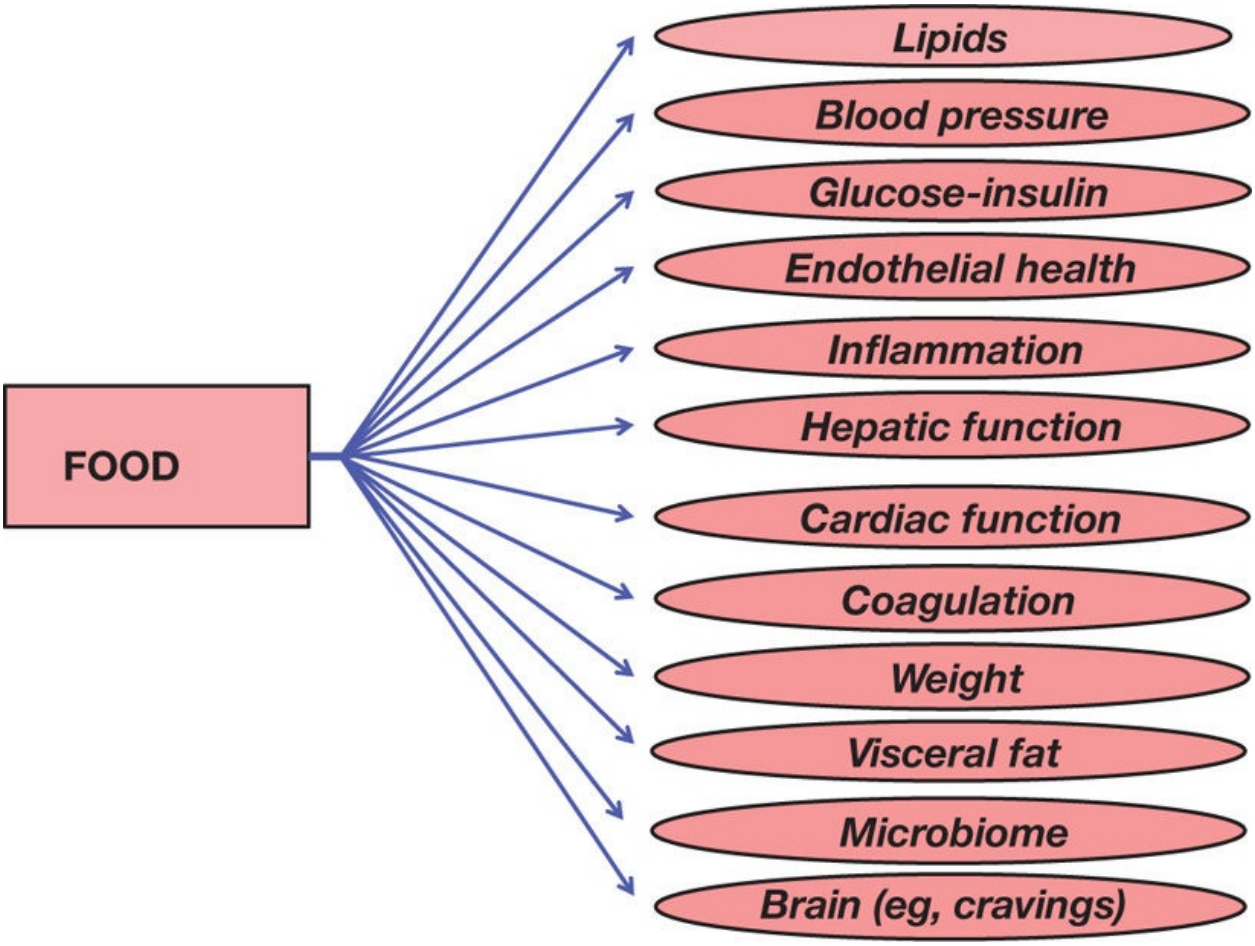

FIGURE 59.1 Illustration of how the food we eat impacts diverse bodily functions.

UNDERSTANDING THE BASICS OF NUTRITION

The dietitian then asked David if she could review with him some basic facts about nutrition. She understood that David did not have a science background, but there were a few central principles that she thought David and everyone should understand. She first discussed the concept of calories. She explained that our body requires a certain amount of energy each day to perform all of its basic functions—eating, working, playing, and even breathing. Energy for these basic activities is expressed in the form of "calories." She told David that in his case, on the basis of his age, height, and weight, he required about 2,000 calories per day in order to maintain his weight. If he consumed more than this (ie, more energy than his body needs to perform his daily activities), this would place him in "positive energy balance" and he would gain weight. If he consumed less than

this (ie, less energy than his body needs to perform his daily activities), he would be in “negative energy balance” and would begin to lose weight. She explained that food (in any form) represents energy (calories).

UNDERSTANDING THE MAJOR DIETARY COMPONENTS

She then introduced the topic of major dietary components, or what we term *macronutrients*and *micronutrients*. She explained that most people go straight to asking what diet or dietary pattern they should be on, but she felt understanding this first was essential.

There are three main macronutrients: fat, carbohydrate, and protein. The “typical” American diet is comprised of about 20% protein, 30% to 35% fat, and 45% to 50% carbohydrate. Of note, whereas the protein content of various diets remains relatively fixed, the fat and carbohydrate content can fluctuate greatly. In fact, it is the variation in fat and carbohydrate that often differentiates various popular diet patterns, as shown in **Table 59.1**. The dietitian then began to explain these macronutrients in more detail, beginning with fats.

TABLE 59.1 Types of Diets

	LOW-/VERY LOW–FAT DIETS (eg, ORNISH)	MODERATE-FAT DIETS (eg, MEDITERRANEAN, DASH)	HIGH-FAT DIETS (eg, ATKINS)
Fat	11%–19%	20%–40%	50%–55%
Carbohydrate	>65%	55%–60%	<25%
Protein	10%–20%	15%–20%	25%–30%

DIETARY FATS

The dietitian explained that there are three basic types of fat, which can be distinguished biochemically, according to the number of carbon–carbon double bonds that are present in their chemical structure. Saturated fats have zero double bonds, monounsaturated fats have one double bond, and polyunsaturated fats have two or more double bonds. Polyunsaturated fats are broadly categorized as either omega-6 or omega-3 fatty acids. Another type of fat, trans fat, is formed by taking a polyunsaturated fat and converting it through a process called hydrogenation into hydrogenated fat.

All fats contain 9 calories of energy per gram of fat consumed. By comparison, carbohydrates and proteins contain only 4 calories of energy per gram. Thus, fat represents the most energy-dense form of food.

The dietitian then showed David a chart that contained examples of saturated, monounsaturated, and polyunsaturated fats **(Table 59.2)**.

TABLE 59.2 Types of Fat

SATURATED FATS	MONOUNSATURATED FATS	POLYUNSATURATED FATS
Palmitic (palm oil, meat)	Oleic and palmitoleic (nuts, olives, avocado)	Omega-6 Linoleic (soybean, corn, and safflower oils)
Myristic (dairy foods)		Arachidonic (meats)
Lauric (coconut oil, palm kernel oil)		Omega-3 Alpha linolenic (soybean and canola oils, nuts, and flaxseed)
Stearic (meat, cocoa butter)		DHA/EPA (fatty cold water fish—trout, herring, salmon, sardines)

With this knowledge in hand, the dietitian then explained that on the basis of considerable scientific study, we now make a distinction between fats that are healthy, neutral, and unhealthy. The healthiest fats are polyunsaturated fats. Lipids have been most studied over the years for their effect on serum lipid values (low-density lipoprotein [LDL], high-density lipoprotein [HDL], and triglycerides), but the analysis of lipids is only one important effect of lipids. For example, not only do foods high in polyunsaturated fats lower LDL cholesterol and triglycerides and raise HDL, but they can also lead to improvement in blood pressure and endothelial function and reduce inflammatory biomarkers in the body. Monounsaturated fats also have beneficial effects on health. These fats have a neutral or even lowering effect upon total and LDL cholesterol, while having a lowering effect on triglycerides and a raising effect on HDL. At the other end of the spectrum are the trans fats, which are particularly atherogenic. Trans fats are known to raise total and LDL cholesterol as well as promote oxidation of lipids, a key step in atherosclerosis. These fats have strong and consistent associations with cardiovascular disease (CVD). Although recently banned by the Food and Drug Administration (FDA), trans fats have historically been present in packaged and processed foods including frozen pizza, pastries, deep-fried foods, and stick margarine.

After asking David if he had any further questions about fat, the dietitian then turned to the second major macronutrient: carbohydrates.

CARBOHYDRATES

Carbohydrates in their most basic form are sugars. Carbohydrates come in various forms ranging from simple sugars such as sucrose (table sugar), lactose (milk sugar), and fructose (fruit sugar), to more complex forms such as starch and fiber. As with fats, the quality of carbohydrates in one's diet is related to one's overall health. A complete understanding of what constitutes healthy carbohydrates centers around a variety of factors, including the glycemic response to digestion, the degree to which the carbohydrate is processed, and its fiber content.

The Glycemic Response to Digestion

The ease with which carbohydrates are broken down by the body into simple sugars often determines how it will affect blood sugar levels. For example, refined starches (eg, white bread, white rice, potatoes) can be quickly broken down to sugar, which can lead to spikes in blood sugar levels. Alternatively, unrefined carbohydrates rich in fiber (eg, whole-grain breads, brown/multigrain rice) take much longer to break down, thus leading to a slow and steady rise in blood sugar **(Figure 59.2)**.

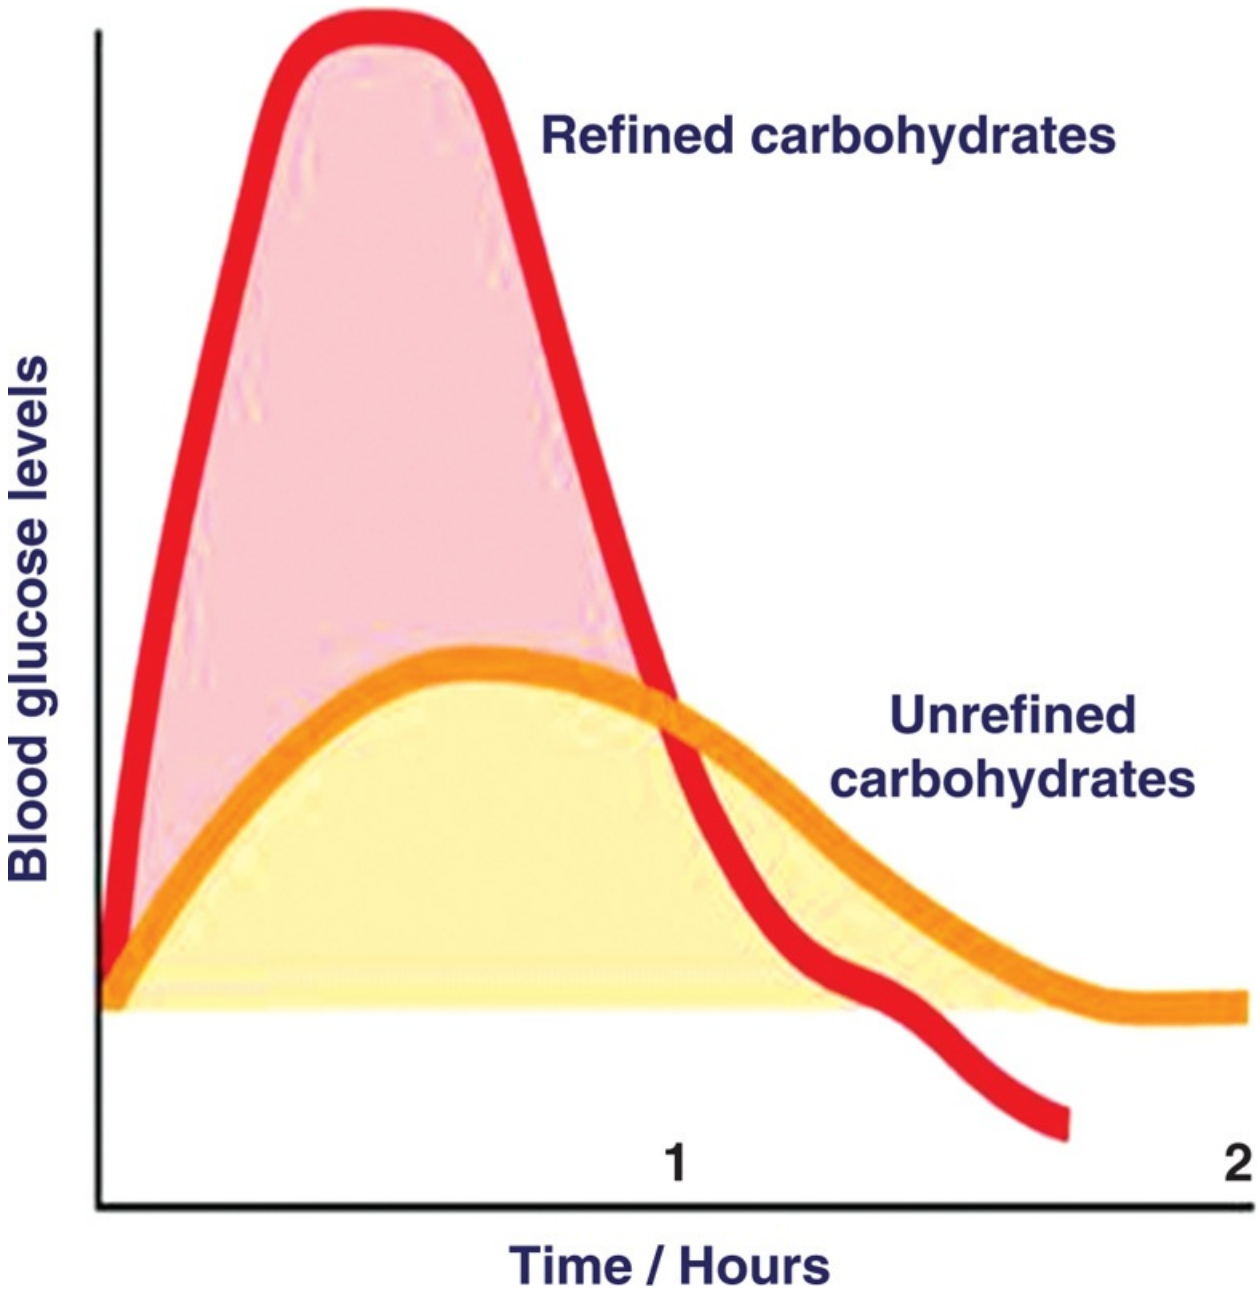

FIGURE 59.2 Impact of carbohydrate quality on blood glucose levels. Highly refined carbohydrates cause large spikes in blood glucose levels over a short period of time, often leading to periods of relative hypoglycemia. Unrefined carbohydrates, however, cause a slow and steady rise of blood glucose levels followed by a gradual decline to baseline. GI, glycemic index.

Among the dietary sugars, it is important to distinguish between those sugars consumed in their natural form, such as lactose or fructose, and those that are added to food during cooking, processing, or packaging. Sugars such as lactose and fructose, in moderation, can be a healthy part of one's diet. Milk contains not only lactose, but also protein, calcium, and vitamin D. Similarly, fruits

contains not only fructose, but also important vitamins, minerals, and fiber. On the other hand, added sugars, which are sugars that are added to foods to enhance flavor (eg, pastries, candy, soda, fruit juice, or other sugary drinks), have been consistently linked to weight gain, diabetes, and even CVD.

The Degree to Which the Carbohydrate is Processed

Similar to the differences between added sugars and natural sugars, there are important differences in how grains are prepared for consumption. Although wheat is among the more popular types of grains, there are, in fact, many other types of grains (**Table 59.3**). In its most basic, natural form, a grain of wheat is composed of the bran, endosperm, and germ (**Figure 59.3**).

Table 59.3	Examples of Whole Grains
Barley	Quinoa
Buckwheat	Rye
Corn	Spelt
Farro	Wheat
Millet	Wild rice
Oats	

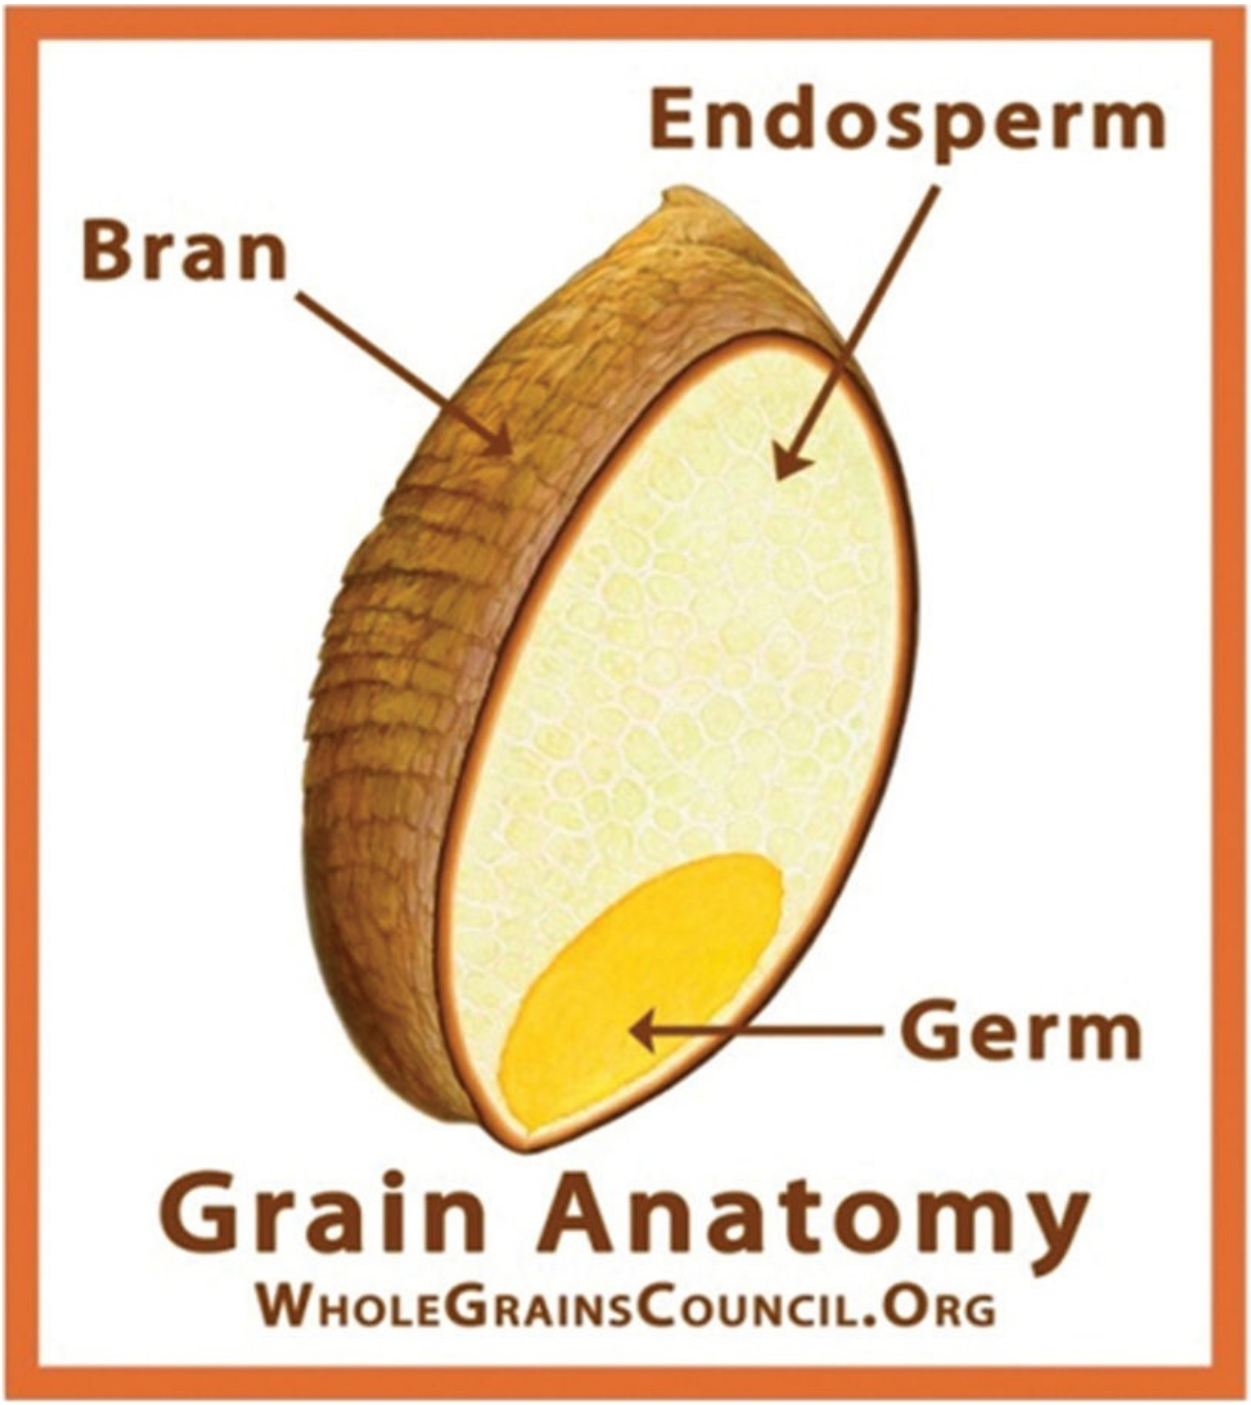

FIGURE 59.3 Anatomy of a grain with an outer coating of bran, a middle endosperm, and the germ at the core.

Diets containing excessive refined grains have been linked to diabetes, high triglycerides, metabolic syndrome, weight gain, and CVD.

When a food product contains whole-grain wheat, for example, it refers to the entire grain (bran, endosperm, and germ). Food products containing whole

grains (unrefined grains) are always preferred because they contain fiber (bran), starch (endosperm), and vitamins, protein, and fat (germ). Unfortunately, over the years whole grains have undergone extensive processing to promote mass production and prolonged shelf life. During the refinement process, whole grains are often stripped of the fiber-rich bran, and sometimes the germ, bleached to achieve a more visually appealing white color, and enriched with artificial forms of fiber, vitamins, and minerals. These refined grains are very easily digested, often leading to spikes in blood sugar.

Fiber Content

Diets rich in fiber can help lower cholesterol, blood sugar, and blood pressure, while helping increase satiety. It is recommended that most individuals consume diets with at least 25 g of fiber per day. Unfortunately, the “typical” American diet falls quite short of this recommendation. Good sources of fiber include (but are not limited to) whole grains such as whole wheat, brown/multigrain rice and quinoa, vegetables, fruit with the skin, nuts, and legumes.

In summary, although there is no single parameter that best characterizes carbohydrate content, attempting to minimize refined grains, added sugars, and starchy foods, such as russet or white potatoes, is highly recommended. Each of these foods produces a sharp rise in blood glucose and insulin, leading to multiple adverse effects, including a craving for more food.

Another useful index of carbohydrate quality is the total carbohydrate-to-fiber ratio (gram/serving). The lower the ratio, the healthier the carbohydrate. Generally, a ratio of <10:1 is preferable. **Figure 59.4** illustrates the important differences in fiber content (and the carbohydrate-to-fiber ratio) between two similar honey-flavored cereals.

PROTEIN

Protein is an essential component of our diets, required for normal growth, development, and metabolism. In broad terms, protein can originate from either plant or animal sources, as shown in **Table 59.4**. Although animal meat is a good source of protein, important differences in health outcomes exist. For example, poultry has a relatively health-neutral effect, whereas processed meats are consistently associated with negative cardiovascular outcomes. Unprocessed red meat, however, is more controversial. Some studies have found similar health-damaging effects as processed meat (albeit less damaging), whereas other studies have found relatively neutral effects.

MINOR DIETARY COMPONENTS: MICRONUTRIENTS

After this discussion, David felt like he had a basic understanding of macronutrients. He then asked, “What about things like salt, vitamins, and minerals, and where do they fit in?” To save time, the dietitian focused only on a few key points in response to David’s question. She stated that vitamins, minerals, and trace elements are considered minor dietary elements (ie, micronutrients), which are essential components of any diet, but present in small quantities. Among them, sodium is a mineral of considerable importance because it is required for normal cellular function throughout the body. Abundant in the food supply, sodium is found mainly in the form of sodium chloride (salt). According to national surveys, the average American consumes about 3,400 mg of sodium each day. By contrast, the American Heart Association recommends consuming 1,500 mg of sodium each day. Although most people think of salt as a seasoning, which is sprinkled on to foods after cooking to enhance flavor, by far the more common source of salt is in prepacked and processed foods, as well as fast food and chain restaurant foods. Although there is some controversy in the medical literature as to whether or not too much dietary salt can cause high blood pressure, there is universal agreement that the typical American diet contains excessive salt. Among individuals with high blood pressure, or other cardiac conditions, excessive dietary salt can lead to elevations in blood pressure, retention of water, and even congestive heart failure.

Besides her comments on salt, the dietitian raised the issue of supplements. These represent a broad category of substances that are taken to enhance one’s usual dietary intake and promote health and wellness. Examples include

vitamins, minerals, trace elements, herbs, and other substances. In general, it is always better to consume vitamins, minerals, and trace elements as a part of a healthy balanced diet, rather than supplements. Should additional supplementation be necessary for medical reasons, a health care professional should be consulted. If one is interested in taking supplements to promote health and wellness, it is still useful to consult with a health care professional first to ensure it is appropriate and will not interact with other medications.

A HISTORIC CHANGE IN OUR UNDERSTANDING OF NUTRITION

After completing their session, the dietitian told David to review his notes before the next session and come back with any questions. She said she would ask him to summarize his understanding at the beginning of the next session. When they next met, David remarked that not only he, but also his family and friends had presumed that too much fat was not good. In fact, many of his friends were currently on a high-carbohydrate/low-fat diet. Why were the recommendations so different now?

The dietitian explained. In the 1940s and 1950s, researchers working with the Framingham Heart Study discovered an association between various health conditions and heart disease. Among these "risk factors" were conditions such as high blood pressure, smoking, and high blood cholesterol. Later in the 1960s, work by Drs. Keys and Hegsted established a link between dietary saturated fat and high blood cholesterol. Subsequent to this, there were a number of large-population studies that confirmed the relationship between dietary saturated fat, high blood cholesterol, and heart disease–related events. It was this groundbreaking series of work that led to large-population–level public health campaigns against diets high in total and saturated fat.

Over the next 30 to 40 years, dietary fat became a major target for the primary and secondary prevention of CVD. In response to public and private sector efforts to promote lower-fat diets, the U.S. population effectively lowered its consumption of total and saturated fat. The lower U.S. consumption of fat was balanced by an increased consumption of carbohydrates (**Figure 59.5**). Over the same general period that the U.S. population was lowering their consumption of saturated fat and increasing their consumption of carbohydrates, epidemiologic studies indicated a rising prevalence of obesity (**Figure 59.6**) and diabetes

mellitus. Further examination of these trends revealed a higher consumption of refined grains and lower consumption of fiber (**Figure 59.7**).

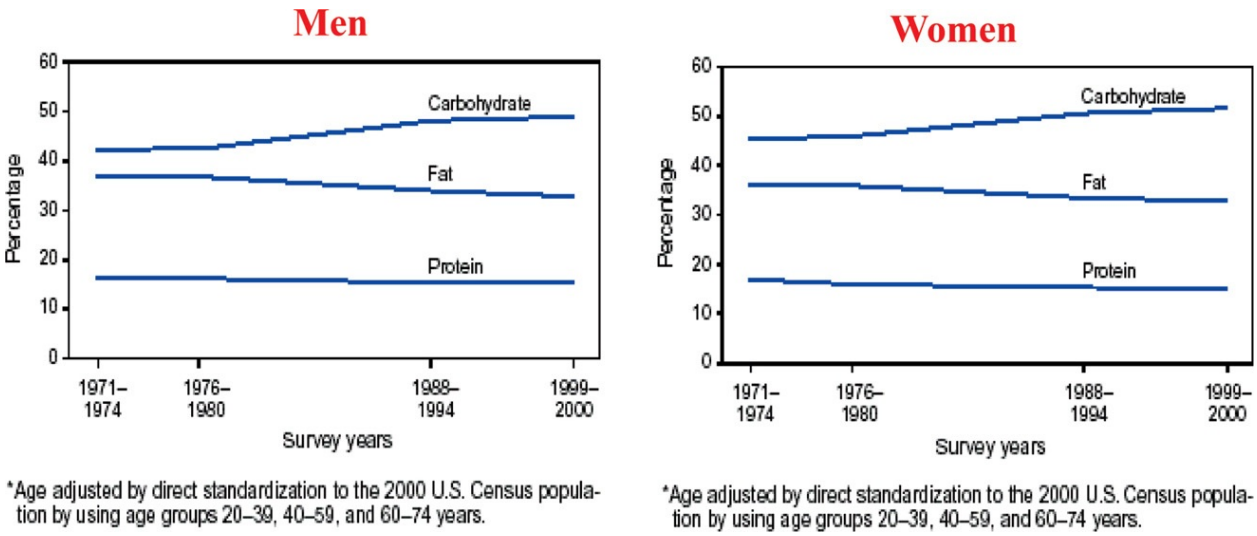

FIGURE 59.5 Survey data illustrating how the average fat content of the U.S. population declined over time, however, at the expense of a greater proportion of carbohydrates.

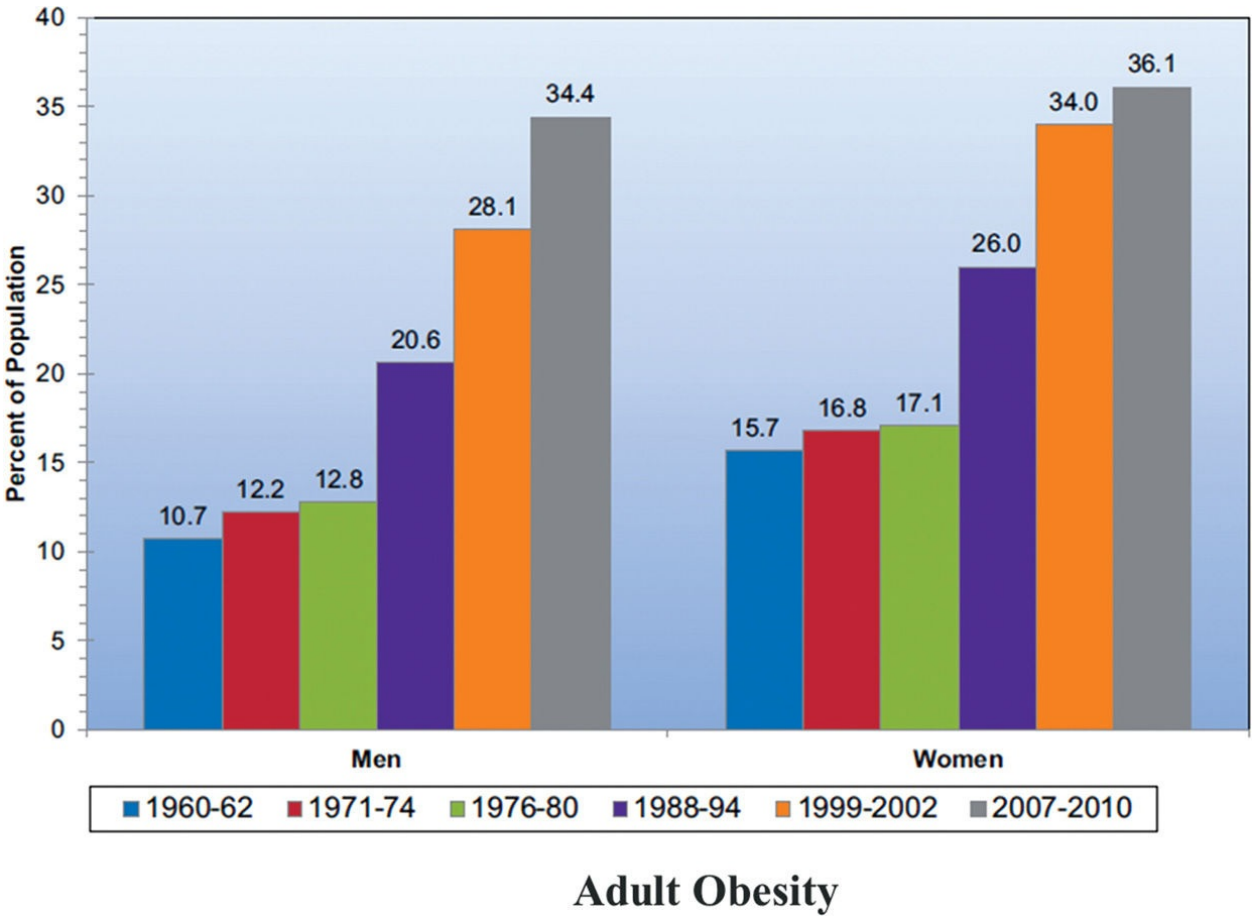

FIGURE 59.6 Survey data illustrating how the U.S. population has become more obese over time.

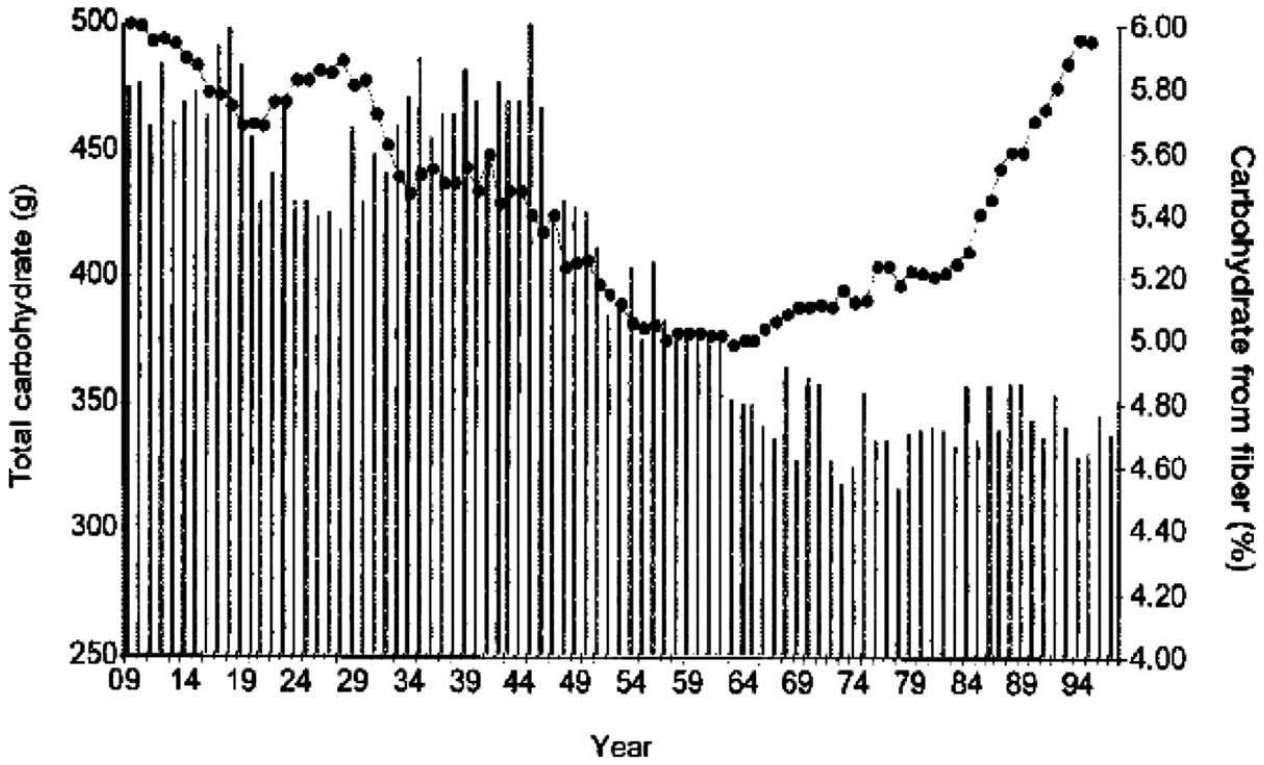

FIGURE 59.7 Survey data illustrating how the carbohydrate quality of the U.S. diet has changed over time. Although carbohydrate consumption was high in the early 1900s, most of it was high-quality carbohydrates rich in fiber. From the 1960s to 1990s, carbohydrate consumption was on the rise, but fiber consumption remained low, indicating that Americans were consuming poorer quality carbohydrates.

Thus, in our efforts to lower our collective risk of heart disease by reducing our intake of dietary saturated fat, we increased our consumption of highly processed, refined (poor-quality) grains, with the net effect of higher rates of obesity, diabetes mellitus, and the metabolic syndrome.

Subsequently, more authoritative studies revealed that there was no significant association between saturated fat and important health outcomes.[1] In related work,[2] investigators examined not only the CV effects of a reduced saturated fat diet, but also what macronutrient was being substituted for the fat. This was amplified by a study examining over 120,000 patients over 24 years, in which CVD risk was assessed according to the macronutrient that was being substituted for dietary fat.[3] The studies were concordant for observing the following:

- When dietary saturated fat was replaced with refined grains, CVD risk either remained similar to or was increased compared with that of saturated fat.
- If dietary saturated fat was replaced with whole grains or high-quality fats (ie, polyunsaturated fat), CVD risk was reduced.

Thus, simply reducing the saturated fat content of our diets is not sufficient,

the dietitian said. Rather, we must replace this fat with higher quality fats and/or higher quality carbohydrates to effectively reduce our risk of CVD.

At this point, the dietitian introduced a diagram summarizing what she had covered with David (**Figure 59.8**). Foods can be categorized as healthy to unhealthy on the basis of hard scientific evidence finding consumption of individual foods to cause heart disease, diabetes, stroke, and other adverse outcomes. The healthiest foods include fruits, vegetables, whole grains, and legumes. The unhealthiest foods include processed meat, refined grains, and added sugars. The neutral zone foods are to be consumed in moderation. These include milk, cheese, eggs, poultry, butter, and red meat (unprocessed).

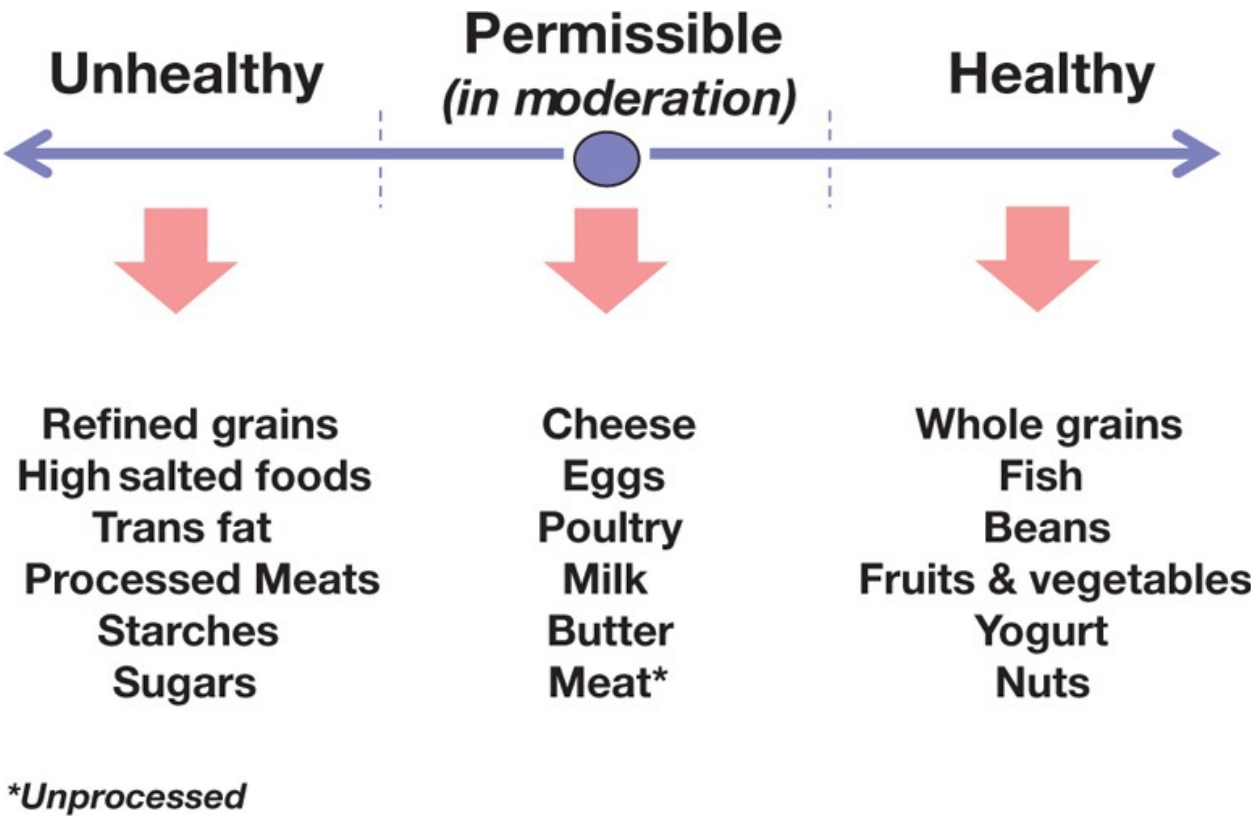

FIGURE 59.8 Illustration of how the food we eat lies along a spectrum from unhealthy to healthy. Dietary intake should be focused on those foods at the far right, with moderate consumption of foods in the middle and little consumption of foods at the far left.

FOCUSING ON DIETARY PATTERNS RATHER THAN SPECIFIC NUTRIENTS

At this point, the dietitian felt ready to establish a specific diet plan with David. She had just covered with him what foods are known to increase and decrease health risk. However, her training had taught her that most individuals follow a dietary pattern rather than focusing on any particular food group. She now decided to broach this subject with David.

She explained to David that the study of what constitutes healthy diet patterns has been an important breakthrough in nutritional science. Important insights have come from the use of food questionnaires, which inquire about the frequency and quantity of different foods (anywhere from 50 to 150 different foods) consumed over the prior week to month. Using a statistical method called principal components analysis, investigators have been able to ascertain which foods are consumed in high versus low quantities by a given population of subjects. This then allows for different dietary patterns that can be extrapolated and correlated with various clinical outcomes (eg, biomarkers, CVD, mortality).

The consistent finding from these epidemiologic cohort studies is that diets rich in fruits, vegetables, whole grains, legumes, high fiber, fish, lean meats, moderate alcohol, and low-fat dairy are consistently associated with a reduced risk for CVD.

Conversely, diets high in red and processed meat, refined grains, processed foods, soda, and other added sugars are associated with an increased risk for CVD.

Further study revealed that the “heart healthy” dietary pattern previously noted is most consistent with the diet consumed in most parts of the Mediterranean region—hence the term*Mediterranean diet*.

Importantly, a number of studies have since confirmed the beneficial effects of a Mediterranean-style diet, including a lower risk of heart disease, diabetes, cancer, and all-cause mortality.[4–6] **Figure 59.9** is an example of one of the landmark studies showing the reduction in cardiovascular events with a Mediterranean diet. As a result of this consistent body of literature, the FDA now recommends a similar (Mediterranean-style) diet pattern in the 2015 Dietary Guidelines for Americans.[7] It is important to remember, however, that these recommendations are only a guide, the foundation of which can be applied to individual tastes as well as cultural, ethnic, and religious preferences.

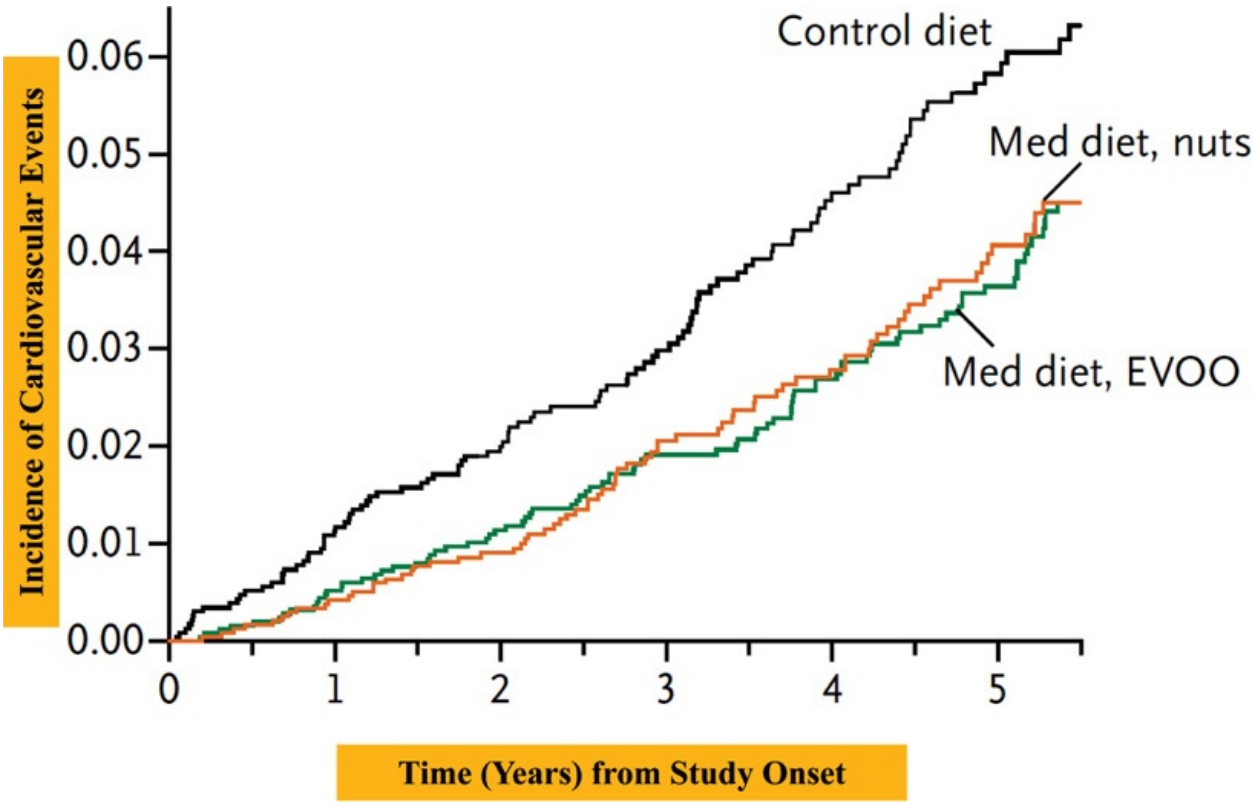

FIGURE 59.9 The PREDIMED study was a landmark clinical trial that demonstrated how consuming a Mediterranean diet (Med diet + nuts or Med diet with extra-virgin olive oil) was associated with a significant reduction in cardiovascular events relative to a low-fat diet. EVOO, extra virgin olive oil.

EATING AND SHOPPING HABITS

After discussing macro/micronutrients and diet patterns, the dietitian briefly turned to David's eating habits. In particular, she wanted to know which foods he liked and disliked, how much he liked to eat (calories per day), how he usually ate (distracted, mindless eating), where he usually ate (in front of the television or computer), why he ate (stress eating, social eating, food addictions), and when he typically ate (late-night meals, skipping meals). Furthermore, she inquired about participation in food shopping and meal preparation. Each one of these factors plays a crucial role in shaping one's dietary habits. On the basis of David's responses, she recommended that David take on a Mediterranean-style diet, focusing on foods that are rich in mono- and polyunsaturated fats, high-quality carbohydrates rich in fiber (found in whole grains), lean sources of protein (eg, fish, poultry), nuts, low-fat dairy, fruits, vegetables, legumes, and olive oil.

In conjunction with this recommendation, the dietitian wanted to make sure that David was sufficiently savvy in reading food labels. She explained that almost all foods have labels outlining the exact macronutrients, micronutrients, and ingredients they contain and that he could use this information to make more informed decisions about his food purchases. Much like reading a menu at a restaurant, it is important to read food labels to gain a deeper understanding of what is in the food (ie, key ingredients) and the nutritional value of the food. Some time ago, the FDA required labeling of all food products sold in stores and many chain restaurants. This has allowed consumers to become more aware of the nutritional value of individual foods, compare foods within similar categories, and make more informed decisions. Two examples of a nutrition fact sheet are shown in **Figure 59.4**. Although both foods are honey-flavored cereals, there are important differences in the nutritional content.

Whole Wheat Flour, **Unbleached Enriched Wheat Flour** (Flour, Malted Barley Flour, Reduced Iron, Niacin, Thiamin Mononitrate [Vitamin B_1], Riboflavin [Vitamin B_2], Folic Acid), Water, Sugar, Sunflower Seeds, Wheat Gluten, Wheat, Rye, Cellulose Fiber, Oats, Yeast, Soybean Oil, Ground Corn, Salt, Molasses, Buckwheat, Brown Rice, Calcium Propionate (Preservative), Monoglycerides, Triticale, Barley, Flaxseed, Millet, Calcium Sulfate, Datem, Grain Vinegar, Calcium Carbonate, Citric Acid, Soy Lecithin, Nuts (Walnuts and/or Hazelnuts and/or Almonds), Whey, Soy Flour, Nonfat Milk.

Whole Wheat Flour, Water, **High Fructose Corn Syrup**, Wheat Gluten, Sugar, Yeast, Contains 2% or less of each of the following: Soybean Oil, Calcium Sulfate, Salt, Dough Conditioners (May Contain One or More of the Following: Mono- and Diglycerides, Ethoxylated Mono- and Diglycerides, Sodium Stearoyl Lactylate, Calcium Peroxide, Datem, Ascorbic Acid, Azodicarbonamide, Enzymes), Wheat Bran, Guar Gum, Distilled Vinegar, Calcium Propionate (Preservative), Yeast Nutrients (Monocalcium Phosphate, Calcium Phosphate, Ammonium Phosphate), Corn Starch, Vitamin D3, Soy Lecithin, Milk, Soy Flour.

FIGURE 59.10 Examples of ingredient lists from two types of commercial breads. Although the products appear similar, important differences in wheat quality and sugar exist.

Of similar importance to reading nutrition fact sheets is reading ingredient lists for foods. Gaining a deeper understanding of the actual ingredients that make up the food is a necessary step to making better food choices. In most instances, the ingredient in highest proportion appears first, with the remaining ingredients in descending order of proportion. Examples of two ingredient lists are shown in **Figure 59.10**. Although both products are bread, important differences exist.

The dietitian suggested that David go food shopping this coming week, analyze food labels, and come into their next scheduled session with any questions that he experienced while reviewing the labels. David was very excited by the idea.

At their next session, David and the dietitian reviewed his success in following his new Mediterranean-style diet, his trip to the grocery store, and his

questions about food labels. David was pleased that he was now able to incorporate foods into his diet, such as eggs and cheese, that he had previously thought he had to avoid as a heart patient.

The dietitian concluded by imparting some additional advice on the basis of her previous screening of David's eating habits. Her suggestions included eating smaller, more frequent meals during the day, avoiding late-night meals or meal skipping, as well as adopting healthy mealtime habits—for example, eating to satiety and nondistracted, mindful eating. David thanked the dietitian for her counsel and left enthused with his newly acquired knowledge base and commitment to eating according to a healthy dietary plan.

WEIGHT LOSS AND WEIGHT MANAGEMENT

David had a follow-up visit with his cardiologist 2 weeks later. At this point, David was maintaining his new diet, but he had not lost any weight. The cardiologist had not set weight loss as an initial goal because he first wanted David to get on a healthy diet plan. He now explained to David that while specific foods and diet patterns have been shown to favorably impact blood pressure, cholesterol, and blood glucose levels, modest weight loss has also been associated with favorable changes in these risk factors. For example, he explains, in the Look AHEAD (Action for Health in Diabetes) study that involved over 5,000 men and women with a mean baseline weight of 100 ± 19 kg, weight loss of 5% to 10% was associated with significant improvements in blood glucose, blood pressure, high-density cholesterol (HDL), and triglyceride levels at 1 year.[8] Encouraged by this research, David asked for specific suggestions to modify his diet program to achieve weight loss. Although he was encouraged to follow up with the dietitian for more specifics, he was offered the following explanation by his physician.

A number of diet strategies exist to facilitate weight loss and weight maintenance, including fad diets (eg, Paleo), commercial weight-loss programs (eg, Weight Watchers), variable macronutrient composition diets (eg, low-fat diets), and dietary patterns (eg, Mediterranean diet). Although considerable public opinion exists as to which diet strategy is superior for achieving and maintaining weight loss, research suggests that calorie restriction is the common underlying mechanism responsible for the success of these diet programs rather than any particular food, macronutrient, or diet pattern. In a landmark study by

Williamson et al., 811 overweight adults were randomized to one of four diet plans varying in macronutrient composition.[9] On 2-year follow-up, there was no significant difference in achieved weight loss among the different macronutrient composition diets. Participants in all four diet programs achieved similar weight loss, which averaged 4 kg at 2 years. Of note, successful weight loss was also associated with greater participation in group counseling sessions.

His cardiologist emphasized that a gradual reduction in weight should be sought, with a goal of losing 2 to 4 pounds per month. To this end, he suggested that David attempt to reduce his daily caloric intake by about 250 to 500 calories per day, if possible. Both agreed that he should see the dietitian for further follow-up concerning his weight-loss goals. His physician also recommended that David begin an exercise program, both for overall health promotion and for facilitating his pursuit of successful weight loss and maintenance of weight loss. This program is the subject of the next chapter.

CONCLUSION

Reflecting on his journey over the past few months, David admits to undergoing a significant transformation. What started out as years of denial and misinformation has now evolved to a deep understanding of health and wellness. He has committed not only to obtaining the necessary information to make informed decisions about his health, but also to the process of lifestyle modification as it relates to diet, nutrition, and successful weight loss. David notes that his sense of self-esteem and vitality have both increased since he started his diet. While his initial heart attack was frightening to him, he now realizes that this event was a blessing in disguise. David now feels far more energetic than he did before his heart attack, as well as knowing that he is on a path to better health.

WHAT PATIENTS AND FAMILY NEED TO KNOW

1. Learn to become an educated consumer of food.
- Read food labels and nutrition fact sheets on food products.
- Participate in food shopping and meal preparation to promote healthier eating.

- Consider taking a healthy cooking class or subscribing to healthy eating magazines.

2. If you are overweight or obese, or have known or suspected heart disease, consider consulting with a dietitian to gain a deeper understanding of your dietary habits and how to make healthier choices to promote better health.
3. Consider adopting a Mediterranean-style diet as this type of dietary pattern has been consistently shown to be associated with a reduced risk of heart disease, diabetes, and cancer and improved longevity.
4. Foods with saturated fats can be eaten in moderation.
5. Sugars, refined grains, processed meats, and high-sodium foods should be avoided because of their harmful health effects.
6. As discussed later in the chapter on exercise, regular physical activity is an important part of lifestyle modification for high blood pressure, high blood cholesterol, and high blood sugar, as well as effective weight loss and weight maintenance.

Exercise and Physical Activity in Cardiac Patients

Six months after the initial hospitalization for a heart attack, David visited his cardiologist for a routine follow-up visit. David had not experienced any chest pain since his initial event, and reported success in maintaining a Mediterranean-style diet after his visits to a dietician. This had resulted in a nearly 10-pound weight loss, which David was proud of. All of David's laboratory work and his blood pressure, on medications, were now within normal limits. However, David had not taken up his physician's request to initiate an exercise program, citing the heavy workload at his job.

David's cardiologist, however, had gotten to know David well by now and felt that he was ready to add exercise to his routine. He suspected that David was not yet sufficiently motivated to start exercising because he did not realize the medical importance of being physically active. Further, David could probably benefit from formal instruction and supervision as to how to exercise. The cardiologist's institution offered two options for patients like David. One was a formal cardiac rehabilitation program that people like David could join. The other was a hybrid gym-based program, which involved initial supervision by a physical therapist who worked with their Rehabilitation unit. The Rehab facility offered an introductory lecture given by a physiatrist that met monthly. The next lecture was taking place in a few days. David's cardiologist

suggested that David attend this introductory lecture and then either call him or make an appointment for a follow-up visit a week afterward. David was more than eager to do so.

At the start of the lecture, the physiatrist asked each participant to write down on a piece of paper their daily work and physical activity routine, with as much detail as possible. David wrote that he did not currently engage in any planned physical activity. Although he had tried to engage in regular physical activity at various points over his life, he always seemed to find excuses not to go to the gym. In fact, David wrote, he found himself becoming increasingly sedentary with each passing year. David described his daily routine as one characterized by a great deal of sitting time with long periods of inactivity. Specifically, David spent an hour commuting to work each day, then worked at a desk job, sitting at his computer for most of the time during his 8 to 10 hour workday, and then commuting another hour back home. Once at home, David sat to eat dinner with his family and then either worked further using his home computer or relaxed, watching TV with his wife and children. As he wrote this down, David was surprised to realize just how much time he sat during the day. He decided he was going to pay keen attention to the lecture.

THE BIRTH OF EXERCISE EPIDEMIOLOGY

The physiatrist first remarked that the modern study of exercise was spurred, in part, by a landmark study conducted by Morris and colleagues in the 1950s.[1] In a classic study, these investigators followed drivers and conductors of double-decker buses among London's Transport Workers, comparing bus drivers (sedentary occupation) with conductors (active occupation). The bus drivers had a classically sedentary job, whereas the conductors were constantly standing, going between the first and second levels of the bus. During the follow-up period, the conductors were observed to have a significantly lower incidence of cardiac events. In subsequent work, these investigators also followed sedentary clerical workers versus postmen in the British civil service. Again, the more active group (ie, the postmen) developed less heart disease during follow-up.

Many subsequent epidemiologic studies have shown how important leisure-time physical activity is. For instance, in 1986 Paffenbarger et al. published their findings on the assessment of leisure-time physical activity levels in over 16,000

Harvard alumni who had been followed for 16 years (**Figure 60.1**).[2] As a result of the groundbreaking work by Morris, and those who followed, the field of exercise science was born.

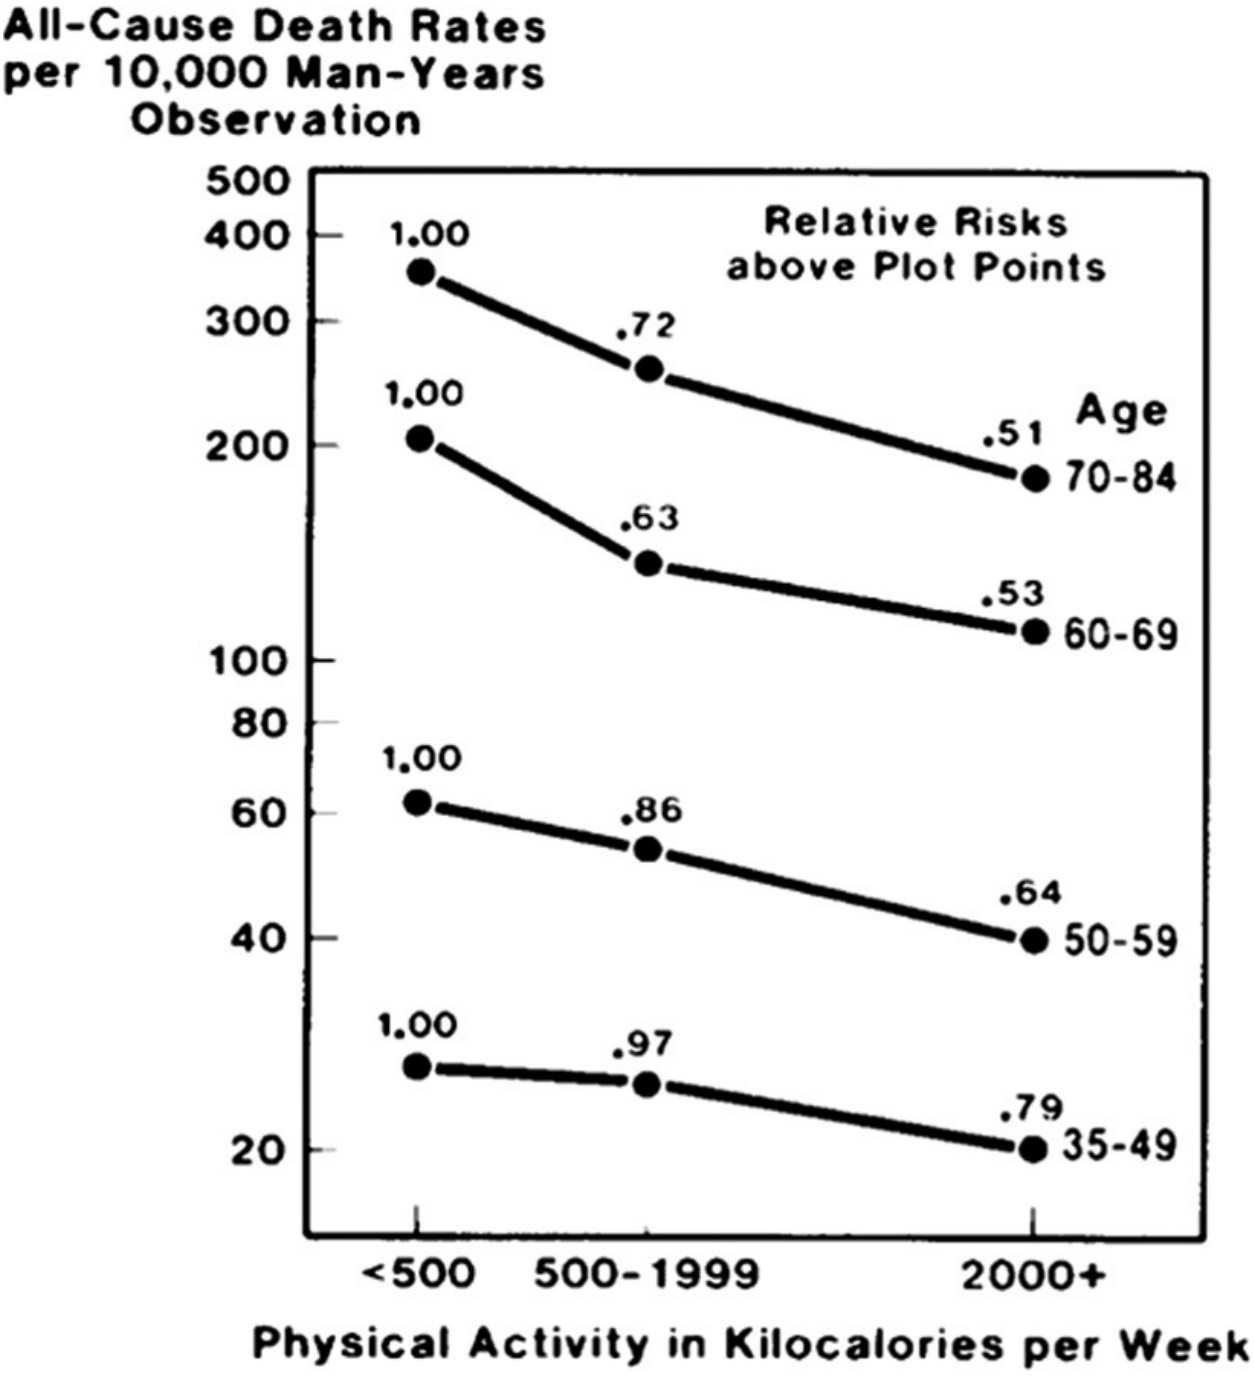

FIGURE 60.1 Decline in all-cause mortality with increasing physical activity, stratified by age groups.

ASSESSING EXERCISE ABILITY IN THE STRESS LABORATORY

The physiatrist then noted that at first, cardiologists had no formal ability to quantify an individual's exercise capacity in their offices. The first formalized approach was developed by Dr. Arthur Masters in the 1920s. His initial approach involved having patients step up and down two steps as fast as they could for 90 seconds (later extended to 3 minutes). The longer it took, the greater was the patient's risk of heart disease. Initially, this task was performed without electrocardiographic monitoring, but as this technology developed, postexercise ECG and then, eventually, ECG monitoring both during and following exercise were added to the evolving stress test.

A major advance was the development of the motorized treadmill, which allowed the performance of progressively higher levels of exercise while patients were electrocardiographically monitored. In 1963, Dr. Robert Bruce validated what has subsequently been called the Bruce protocol: a progressive graded exercise test, increased by two degrees of incline and by increasing speed during each 3 minutes of exercise.[3] Today, the Bruce treadmill exercise protocol is still the standard for performing exercise ECG testing in cardiac practice.

Exercise electrocardiography permits the assessment of ischemia (how much ST-segment deviation is elicited during exercise), patients' clinical response to exercise (ie, whether chest pain was elicited during stress testing), and the assessment of patients' overall exercise functional capacity (eg, how many minutes patients were able to exercise). Hundreds of outcome studies have shown that all three of these parameters are prognostically useful, but the most potent parameter is patients' functional exercise capacity. For example, Myers et al. followed 6,213 individuals for 6.2 years after exercise ECG testing, including a group with and without known cardiovascular disease (CVD).[4] In both groups, after adjusting for age, the mean exercise capacity, measured in metabolic equivalents (METs), was the strongest predictor of outcome. For each 1-MET increase in exercise capacity, there was a 12% improvement in survival.

In another particularly large study, Gupta et al. reported on the follow-up of 66,371 individuals without preexisting heart disease who underwent exercise ECG testing as part of the Cooper Center Longitudinal Study between 1970 and 2006. All subjects were followed for CVD mortality.[5] The presence of traditional risk factors, such as hypertension, diabetes, and smoking, was associated with an

increased risk of CVD events during follow-up (**Figure 60.2**). However, consideration of exercise capacity was quite important. After adjusting for the presence of these risk factors, each quintile of increasing exercise fitness was associated with a progressively greater decrease in the risk of CVD mortality.

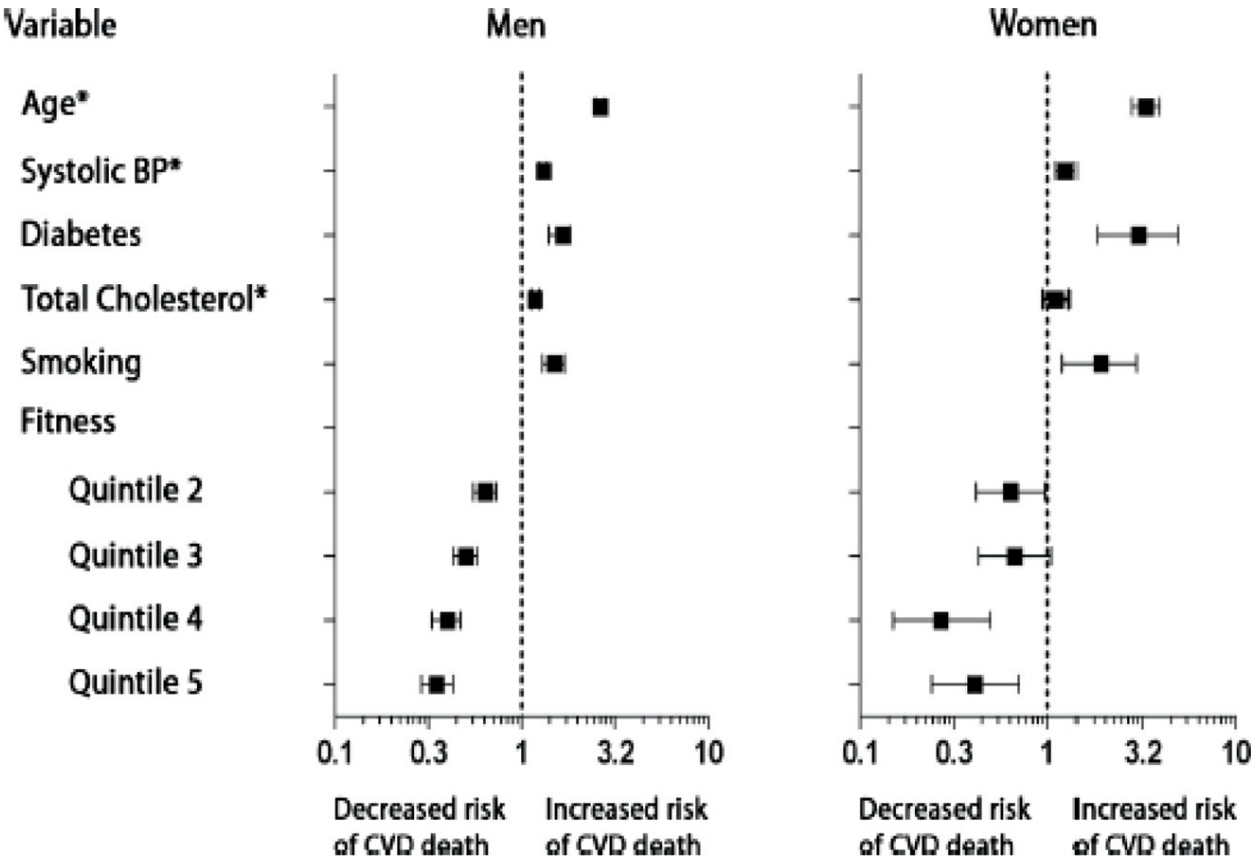

FIGURE 60.2 Lower risk of cardiovascular death (CVD) with increasing quintiles of cardiorespiratory fitness. Even in the lowest quintile (Q2) of fitness, there is a reduced risk of cardiovascular death.
*Hazard ratios are per 1 SD (per 10 years for age, per 14 mm Hg for systolic blood pressure and per 40 mg/dL for total cholesterol).

THE PHYSIOLOGIC BENEFITS OF EXERCISE

The physiatrist then turned his attention to the principal mechanisms by which physical activity and exercise promote better health. The beneficial physiologic effects are shown in **Table 60.1**. Among these is a favorable reduction in blood pressure. Although acute bouts of exercise cause transient elevations in heart rate

and blood pressure, the hours immediately following exercise are characterized by consistently lower systolic and diastolic blood pressure readings and a lower pulse. In a review of 14 studies by Thompson et al., the mean change in systolic and diastolic blood pressure after acute dynamic exercise was −2.1 mm Hg and −0.3 mm Hg, respectively.[6] In contrast, regular physical activity and cardiorespiratory fitness have been consistently associated with −3.4 to −10.5 mm Hg and −2.4 to −7.6 mm Hg reductions in systolic and diastolic blood pressure, respectively.[7] Although these reductions in blood pressure may not seem clinically important, epidemiologic data inform us that a 2-mm Hg reduction in systolic and diastolic blood pressure translate into a 14% and 17% reduction in stroke, and a 9% and 6% reduction in coronary artery disease.[8]

TABLE 60.1 Beneficial Physiologic Effects of Exercise

- Reduced blood pressure
- Increases serum high-density lipoprotein level; minimal lowering of serum low-density lipoprotein levels
- Lowering of triglyceride levels
- Improved glucose metabolism
- Increased insulin sensitivity
- Decrease in inflammatory markers
- Improved autonomic function
- Enhanced endurance and muscle strength
- Promotes bone and joint health
- Promotes positive vascular remodeling
- Improves endothelial function
- Aids weight management
- Promotes cognitive function and reduces dementia risk
- Promotes better moods

Another favorable effect of exercise is its influence on serum lipids, including a rise in serum high-density lipoprotein (HDL) cholesterol, and reduction in serum triglycerides. But extensive research has shown that even chronic, high-intensity aerobic exercise leads to only modest improvements in total and low-density lipoprotein (LDL) cholesterol. Thus, exercise is not a primary tool used to lower serum LDL cholesterol.

Exercise has many other effects, including an enhancement in glucose metabolism and insulin sensitivity; decrease in negative inflammatory markers; better autonomic function (ie, increased vagal tone); increased endurance and muscle strength; and greater bone strength and joint health.

In addition, exercise helps promote better vascular health through a number of mechanisms. Vascular function, which is a measure of how well the arteries expand and contract in response to every heartbeat, is known to be significantly

better among individuals with versus without cardiorespiratory fitness. The mechanism behind improved vascular function is thought to be related to exercise-induced reduction in oxidative stress and chronic inflammation, as well as enhanced production of nitric oxide, a potent vasodilator. In addition, exercise promotes favorable vascular remodeling, including enlargement of the coronary vessels, and it improves the endothelial function of blood vessels, thus making them less susceptible to negative pathophysiologic changes, such as the buildup of plaque.

Regular physical activity is also an important component of weight loss as well as the prevention of weight gain after successful weight loss. Even among obese individuals unable to successfully achieve meaningful weight loss, regular physical activity and cardiorespiratory fitness are important goals to achieve. As shown by Barry et al. in a meta-analysis of 10 studies, all-cause mortality rates were similar among those individuals demonstrating cardiorespiratory fitness, regardless of their body mass index (normal weight or obese).[9]

Finally, exercise has important psychological benefits. Exercise can help reduce feelings of stress, anxiety, and depression. In fact, randomized controlled studies have found exercise to be comparable to antidepressant medications for reducing depression symptoms in those studies.[10]

THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND CHRONIC DISEASE

After reviewing the physiologic benefits of exercise, the physiatrist reviewed the particular benefits of exercise with respect to disease prevention. He pointed out that given the diverse benefits of regular physical activity on various bodily functions (eg, cardiovascular, metabolic, bone health) that he had just discussed, it is not surprising that physical activity has been found to significantly reduce the risk of many chronic diseases. For example, in a large prospective cohort study, Wen et al. assessed leisure-time physical activity in over 400,000 individuals and then followed them for an average of 8 years.[11] Relative to the inactive group, those in the low, medium, high, or very high activity levels had significant reductions in all-cause as well as cancer- and cardiovascular-related mortality (**Figure 60.3**). Of note, even among those able to engage in only 15 minutes of leisure-time physical activity per day, a 14% reduction in all-cause mortality and a 3-year longer life expectancy was observed. In related work,

Blair and colleagues examined how changes in fitness over time impacted mortality.[12] As expected, those who were found to be fit by treadmill testing at both baseline and follow-up visits had the lowest all-cause and cardiovascular mortality. However, among those who improved their fitness level (unfit at baseline → fit on follow-up), a 44% reduction in mortality was observed. This association was maintained even after correcting for age, health status, and other factors associated with premature mortality. These findings underscore the importance of establishing a regular physical activity program, even if one is not healthy or fit at baseline.

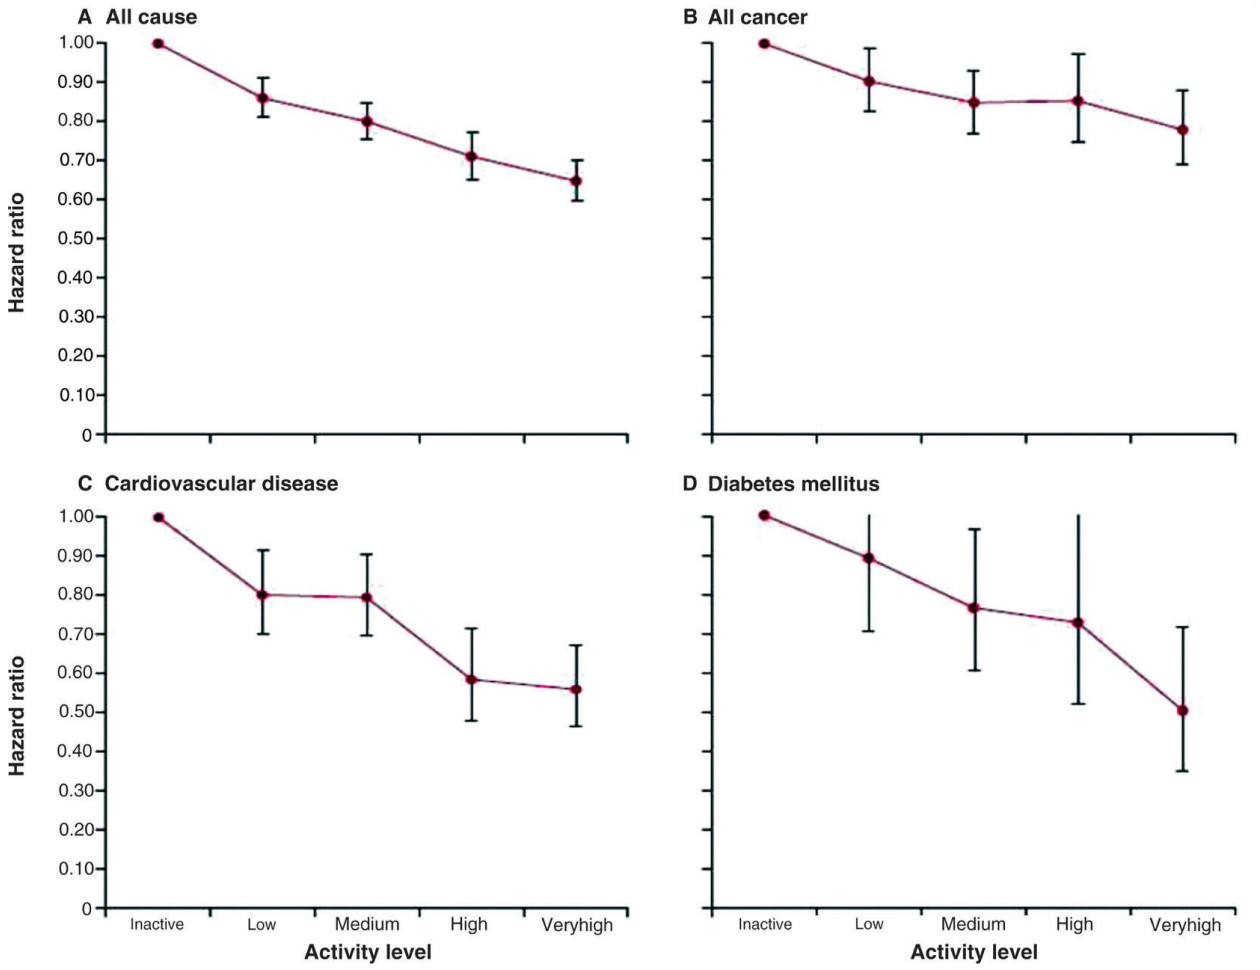

FIGURE 60.3 Decline in all-cause mortality, cancer, cardiovascular disease, and diabetes with increasing levels of leisure-time physical activity.

In related work, Moore et al. examined the association between leisure-time physical activity and 26 different types of cancer in over 1.4 million subjects.[13] After 15+ years of follow-up, regular leisure-time physical activity was associated with substantial reductions in many cancers, including lung, kidney, endometrial, colon, rectal, myeloid leukemia, and bladder.

Regular physical activity, as well as physical activity that is part of a comprehensive lifestyle modification program, has also been shown to substantially reduce the risk of developing diabetes mellitus. In a review of 10 studies involving over 300,000 participants, brisk walking (≥2.5 hours/week) was associated with a 30% reduction in new onset diabetes mellitus.[14] In the landmark Diabetes Prevention Program trial, involving over 3,000 patients, regular physical activity along with healthy eating and modest weight loss

reduced the incidence of diabetes mellitus by 58%.[15]

Another beneficial effect of exercise is its role in maintaining bone health and muscle strength during the aging process. For instance, regular physical activity has been shown to be of critical importance in preventing osteoporosis and frailty. In a review by Hendricks et al., regular exercise reduced the risk of developing osteoporosis and subsequent injuries by promoting bone strength as well as strengthening muscle groups that contribute to balance, coordination, and gait stability.[16] In recent years, frailty has emerged as an important threat to successful aging and has been associated with a number of poor health outcomes.[17,18] Specifically, frailty is defined as a clinical syndrome involving any three of the following characteristics: unintentional weight loss, low physical activity, weakness, fatigue or exercise intolerance, and slowed motor performance.[19] In a recent review by de Labra et al., exercise was found to be an effective intervention for older adults exhibiting signs of frailty, although the exact type and duration of exercise remain unclear.[20]

Another important and exciting area of exercise science relates to cognitive function. In a recent review by Bherer et al., regular physical activity was shown to have a significant and positive impact on cognitive function among a variety of individuals, ranging from asymptomatic elderly adults to those with established cognitive impairment.[21] In related work, Erickson and colleagues concluded that physical activity can induce important, dynamic changes in cognitive function that can slow or delay the onset of cognitive decline.[22] In particular, physical activity can promote brain plasticity and enhance the growth of the prefrontal and hippocampal regions, which are involved in memory function.

THE CURRENT RISE OF PHYSICAL INACTIVITY

At this point of his presentation, the physiatrist paused to summarize the physiologic and medical benefits of exercise. He then moved on to an interesting aspect of his presentation: how societal trends were leading to decreasing, rather than increasing, levels of physical activity. He began this section by citing many recent studies that have documented population-level declines in physical activity. For example, Church et al. identified a significant decline in occupational physical activity over a 50-year time frame (**Figure 60.4**).[23] Similar declines in physical activity have been observed across the globe (**Figure**

60.5),[24] as well as in different demographic groups.[25]

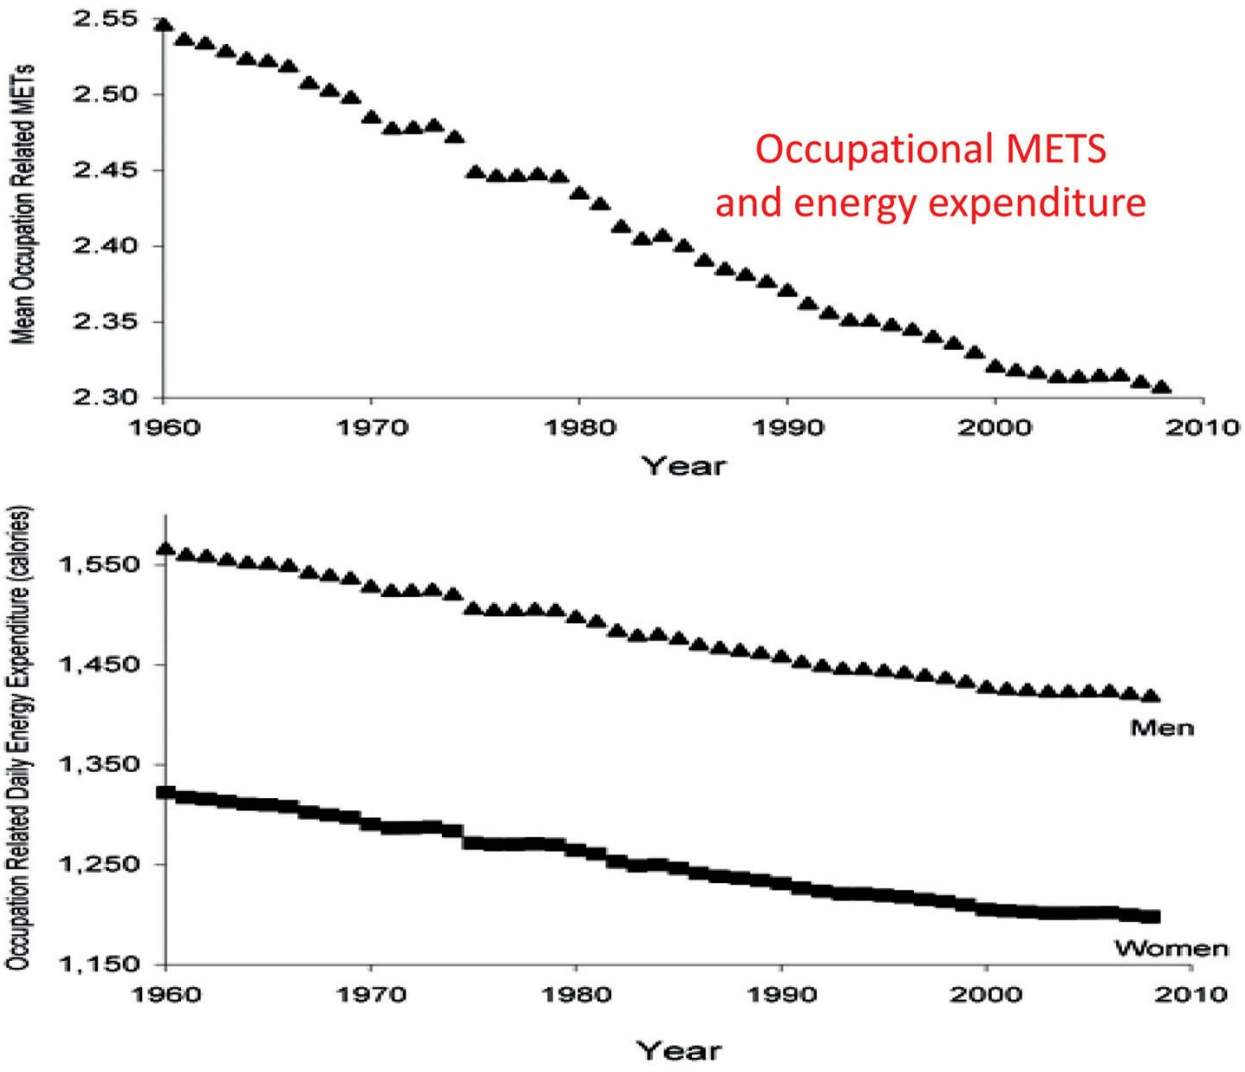

FIGURE 60.4 Progressive decline in occupational physical activity (METs) and energy expenditure (calories) over a 50-year period.

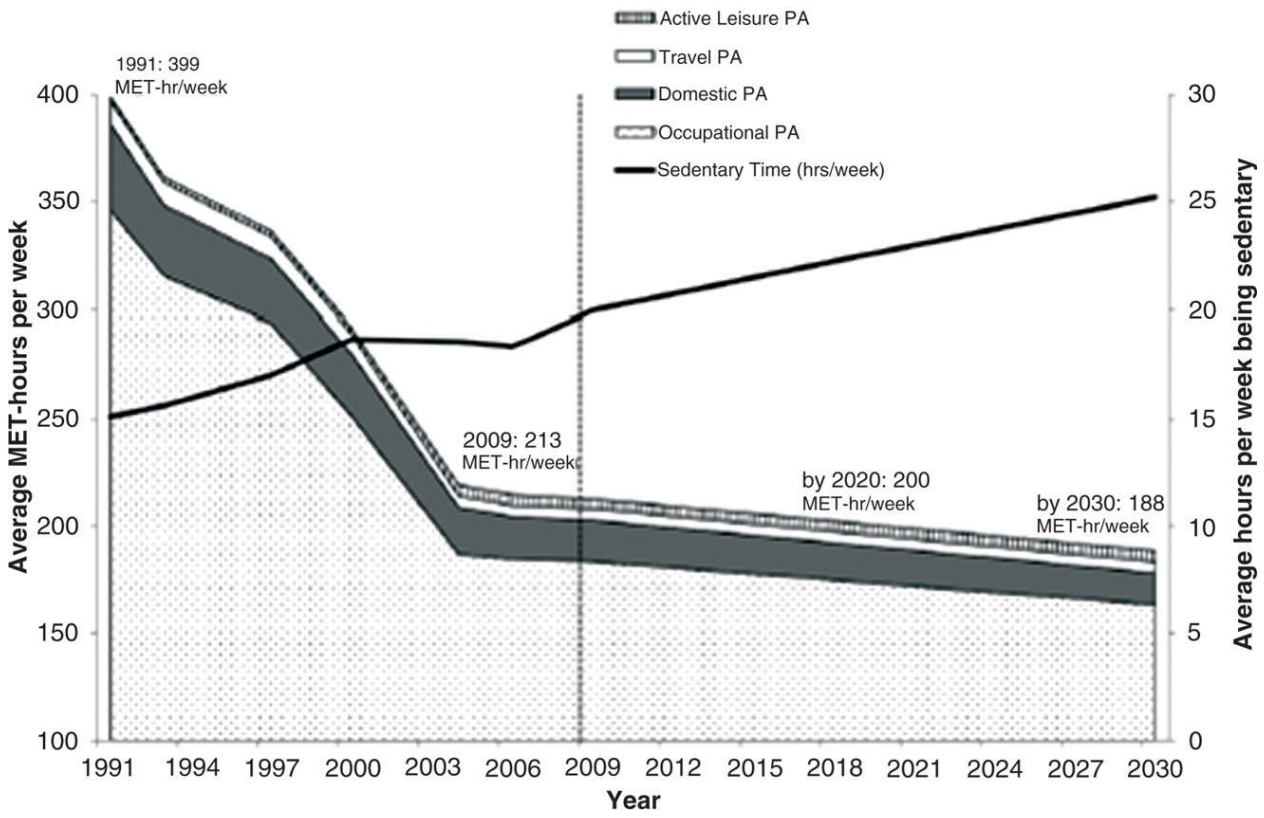

FIGURE 60.5 Progressive decline in all types of physical activity, and increasing sedentary time, over a 25-year period in China.

Another trend causing concern is the amount of screen time (TV, computer/tablets, phone) individuals engage in each day. According to the U.S. Bureau of Labor Statistic's Time Use Survey for 2015, at least 56% of all daily leisure-time activity involves screen time (**Figure 60.6**). This has had a particularly detrimental effect on youth, and significant declines in leisure-time physical activity have been documented in children and adolescents.[26,27]

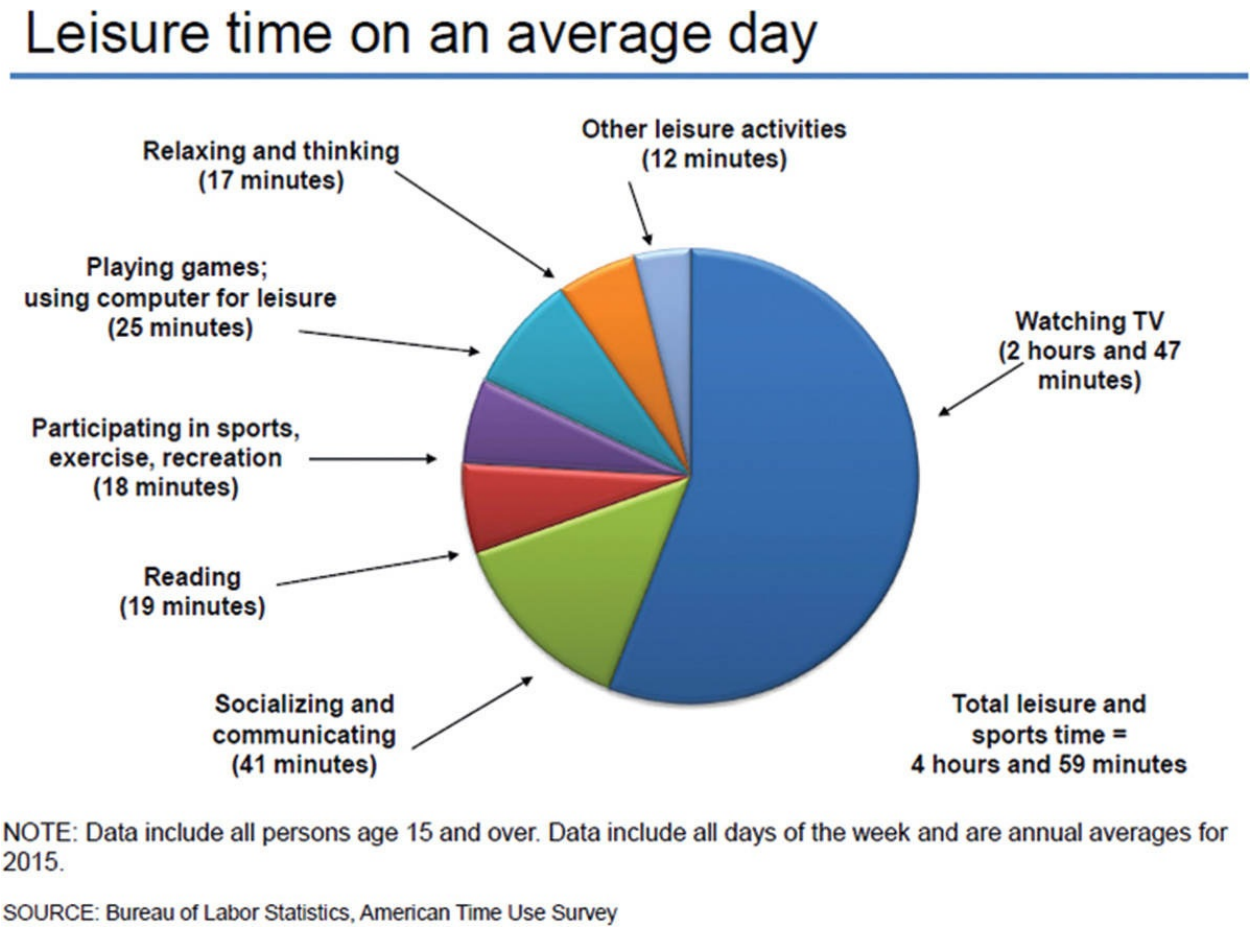

FIGURE 60.6 Time spent in various leisure-time activities, according to the U.S. Bureau of Labor Statistics. Note the significant amount of time per day spent on screen-related activities (eg, computers, video games, television).

Relatedly, there has been increasing research into the health detriments posed by excessive sitting. Although often necessary for occupational, transportation, and recreational needs, excessive sitting time (often related to excessive screen time—computers, TV, video games) has now been linked to a variety of negative health outcomes, including obesity, diabetes, CVD, cancer, and all-cause mortality (**Figure 60.7**).[28–31] Although initial studies linking sitting time with health outcomes were often based on subjective questionnaires, more recent studies involving objectively measured sitting time using accelerometers yielded similar results. A recent study involving over 5,000 individuals examined the interaction between objectively measured (via accelerometer) sedentary time and moderate to vigorous physical activity (MVPA).[32] Although both outcomes (sedentary time and MVPA) were independently associated with all-cause

mortality, interestingly, among those above the median level of MVPA, sedentary time was no longer associated with mortality. What this suggests is that, among those who are perhaps committed to prolonged sitting time (eg, occupational or transportation-related sitting), those who are able to engage in MVPA are somewhat protected from the deleterious effects of excessive sitting. To combat excessive sitting, health professionals recommend standing/walking breaks every 30 to 60 minutes. In fact, pointed out the physiatrist, a recent study found that standing > 2 hours per day (vs < 2 hours per day) was associated with a 10% reduction in all-cause mortality.[33]

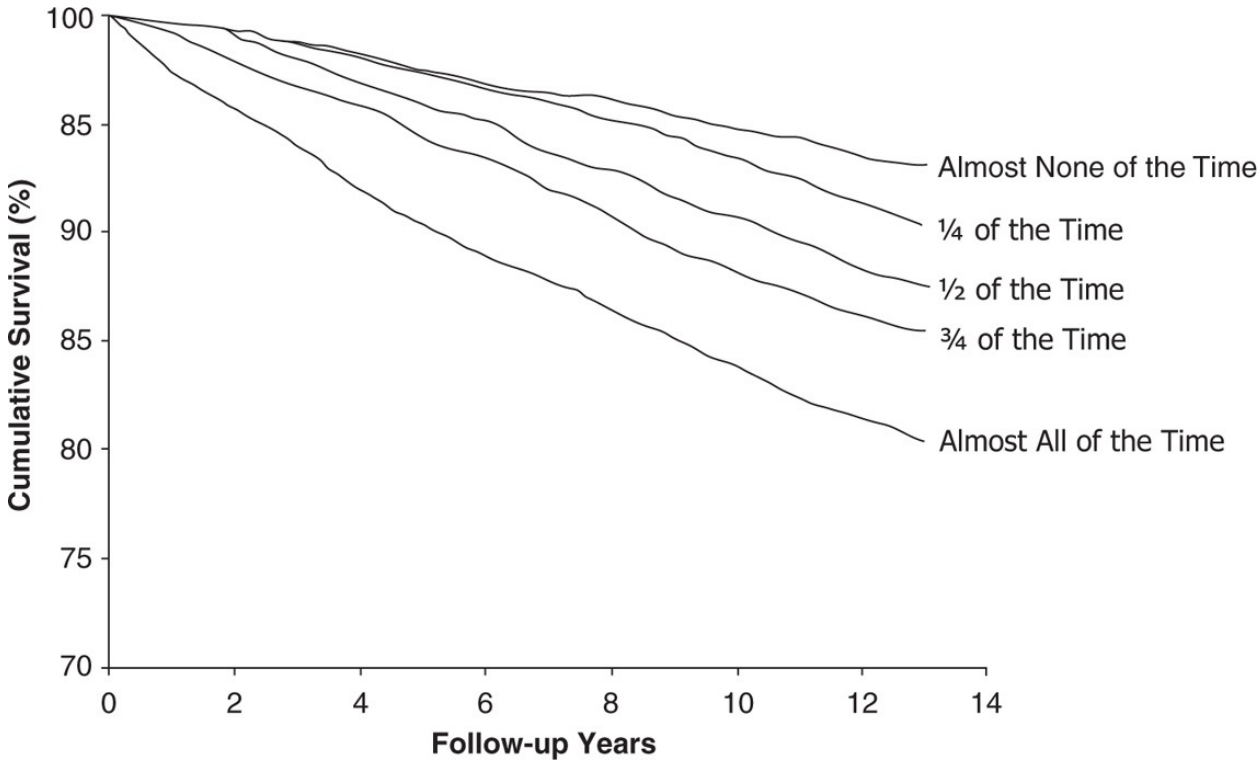

FIGURE 60.7 Daily sitting time and its association with all-cause mortality, cardiovascular disease, and cancer.

EXERCISE ACTIVITIES

At this point, the physiatrist turned his attention toward a general discussion of exercise activities. Aware that many individuals in the audience were people like

David, with different forms of cardiac conditions, the physiatrist emphasized that the initiation of exercise among cardiac patients should be done only under medical supervision. He thus said that although he would cover general points about exercise, patients should check with their doctors before initiating a specific exercise program. The physiatrist covered three general forms of activity:

AEROBIC EXERCISE

According to the U.S. physical activity guidelines,[34] adults should work toward achieving 150 minutes of moderate-intensity aerobic exercise per week. Alternatively, individuals can engage in 75 minutes of vigorous-intensity exercise per week for similar health benefits. Examples of moderate and vigorous exercise activities are listed in **Table 60.2**. It should be emphasized that although substantial health benefits are achieved with these levels of physical activity, research indicates that any amount of regular physical activity can promote cardiovascular health and wellness. As for patients, many of whom have been completely sedentary, transitioning from sedentary behavior to aerobic physical activity can be quite daunting, and should be taken up with a graduated program that minimizes the risk of physical injury.

TABLE 60.2 Examples of Moderate- and Vigorous-Intensity Physical Activities

MODERATE INTENSITY (3.0–5.9 METs)	VIGOROUS INTENSITY (≥ 6.0 METs)
Brisk walking	Running or jogging (10-min mile or faster)
Bicycle riding on level ground	Bicycle riding at brisk pace/up hills
Doubles tennis	Singles tennis
Mowing the lawn (push mower)	Shoveling/carrying heavy loads
Washing windows/vacuuming/mopping	Basketball
Water aerobics	Lap swimming
Ballroom dancing	Soccer
	Aerobic classes (Zumba, spinning, etc.)

One tool that has been shown to be effective in promoting the initiation and maintenance of exercise activities is pedometers. These portable electronic devices are capable of monitoring one's daily steps, thus tracking physical activity. More advanced devices are even able to track sitting time and issue alarms when the user has exceeded a predetermined amount of sitting (eg, 1 hour). Pedometers have become so prevalent and technologically advanced that most smartphones and smart watches now have them built in. A useful way to start using a pedometer is to simply wear the device (from first thing in the morning till bedtime) every day for 1 week. Do not worry about monitoring step counts, sitting time, etc.; just wear the device and carry on with your usual weekly activities. At the end of 1 week, review the recorded data for total daily step count and calculate the average number of steps per day (eg, 3,000 steps/day). This will now serve as your baseline level of physical activity from which you can start to add steps.

It is worth noting that time recommendations can be achieved in a variety of ways. For example, for moderate-intensity activities, 30 minutes/day, 5 days/week will fulfill the 150-minute/week goal. The 30 minutes/day can even be divided into three 10-minute bouts of activity throughout the day.

STRENGTH (RESISTANCE) TRAINING

Although not well known, strength training is an equally important component of any exercise routine, and should be performed at least 2 times/week (in addition to the aerobic exercise recommendations). As noted earlier, strength training is important for maintaining muscle tone and strength, which are essential for successful aging and the prevention of injuries. Examples of strength (resistance) training exercises are listed in **Table 60.3**. In general, strength training can include the use of weights or, alternatively, resistance from body weight (eg, push-ups) or elastic bands. For optimal results, strength training should include as many large muscle groups as possible, including hips, back, legs, arms, chest, abdomen, and shoulders. Although no fixed rule exists, in general, strength (resistance) training exercises should be performed in 1 to 3 sets of 8 to 12 repetitions each.

TABLE 60.3 Examples of Strength (Resistance) Training Exercises

Light free or machine weights
Push-ups/sit-ups/pull-ups

Yoga
Pilates
Fitness bands

BALANCE TRAINING

Older adults, and those at increased risk for falls, should engage in balance training in addition to aerobic and strength exercises. Numerous studies have noted benefits from balance training relating to overall strength, coordination, and prevention of falls and fall-related injuries among older adults. Established balance exercises include backward and sideways walking, heel walking, toe walking, and repeated standing from a sitting position (**Table 60.4**). Tai chi is also an accepted form of balance training, many exercises of which can also be used for strength training.

TABLE 60.4	Examples of Activities for Promoting Balance

THE QUESTION-AND-ANSWER SESSION

After completing his general presentation, the physiatrist asked the audience to write down any questions they had and to hand them to his assistant. He briefly reviewed these questions and then chose the following questions to discuss with the entire audience:

HOW DO I KNOW IF I AM GETTING ENOUGH EXERCISE?

The official recommendations for leisure-time physical activity are 150 minutes of moderate-intensity exercise each week or, alternatively, 75 minutes of vigorous-intensity exercise each week. This time requirement, regardless of whether it is moderate or vigorous, can be divided into different blocks throughout the day or week. For example, one can engage in 30 minutes of moderate-intensity exercise daily for 5 days, 25 minutes of vigorous-intensity exercise daily for 3 days, or any combination of moderate and/or vigorous activity to achieve the weekly recommendation. However, for those individuals just starting with exercise activities, these recommendations may be too demanding to achieve at first. Rather, one should start by committing to walking or another similar activity for a few minutes per day. After achieving some degree of success, and developing a new habit of regular exercise, one can work toward achieving progressively higher levels of exercise activity.

WHAT ARE METs AND VO_2 MAX, AND DO I NEED TO KNOW THESE TO START MY EXERCISE PROGRAM?

METs are metabolic equivalents and represent energy expenditure by the body during various physical activities. 1 MET is the amount of energy expended by the body at rest. Thus, various physical activities represent multiples of the baseline energy expenditure. For example, if resting quietly is equal to 1 MET, a brisk walk might be 3 to 4 METs, and jogging might be 6 to 7 METs.

VO_2 max represents the maximal amount of oxygen an individual can use during high-intensity exercise. Although typically used to help train high-level athletes, it is also used to guide the evaluation and management of patients with advanced heart and lung disease.

If the goal is to initiate and maintain a physical activity program for the purposes of health and wellness, it is not necessary to learn and use METs or VO_2 max. Rather, it would be more useful to understand which activities are generally classified as being of moderate versus vigorous intensity to help identify the types of activities and the time duration needed to meet official recommendations (Table 60.2).

WHAT IS THE DIFFERENCE BETWEEN PHYSICAL ACTIVITY AND PHYSICAL FITNESS?

Physical activity simply refers to the act of engaging in coordinated movements of the body for the purpose of achieving health (eg, walking, jogging, sports).

Fitness, on the other hand, refers to the ability of the heart and lungs to adequately supply oxygen to the muscles during regular sustained exercise activity. Cardiorespiratory fitness is a more specific form of fitness that integrates not only physical and aerobic capacity, but other factors as well, including age, gender, and ethnicity. Thus, it is no surprise that cardiorespiratory fitness is the most potent measure of fitness and correlates the most with various health outcomes. In fact, cardiorespiratory fitness has been found to be as strong a predictor of all-cause mortality as other commonly accepted risk factors, including smoking, diabetes mellitus, high blood pressure, and high cholesterol. In general, cardiorespiratory fitness levels < 5 METs are associated with a higher risk of mortality, whereas levels > 8 METs are associated with increased survival.[35] Another important distinction is that physical activity, and even fitness, can be assessed by detailed questionnaires, whereas cardiorespiratory fitness can be assessed only by actual exercise testing.

IS THERE SUCH A THING AS TOO MUCH EXERCISE?

One can think of exercise in terms of both volume (duration of time spent) and intensity (low or moderate or vigorous). In terms of volume, as we noted earlier in this chapter, even the lowest level of activity (eg, standing for > 2 hours per day vs < 2 hours per day) is associated with better health outcomes. As shown by Powell et al., progressively larger volumes of exercise are associated with greater reductions in CVD, with no apparent upper limit beyond which benefit is lost (**Figure 60.8**).[36] Of note, the greatest reductions in cardiovascular risk appear to be when transitioning from sedentary to low or moderate activity. With respect to exercise intensity, no upper limit of low- or moderate-intensity exercise exists beyond which benefit is lost. In terms of vigorous-intensity exercise, some data suggest an upper limit of benefit (11 MET-hours/week); however, there is no consistent evidence of actual harm.[37]

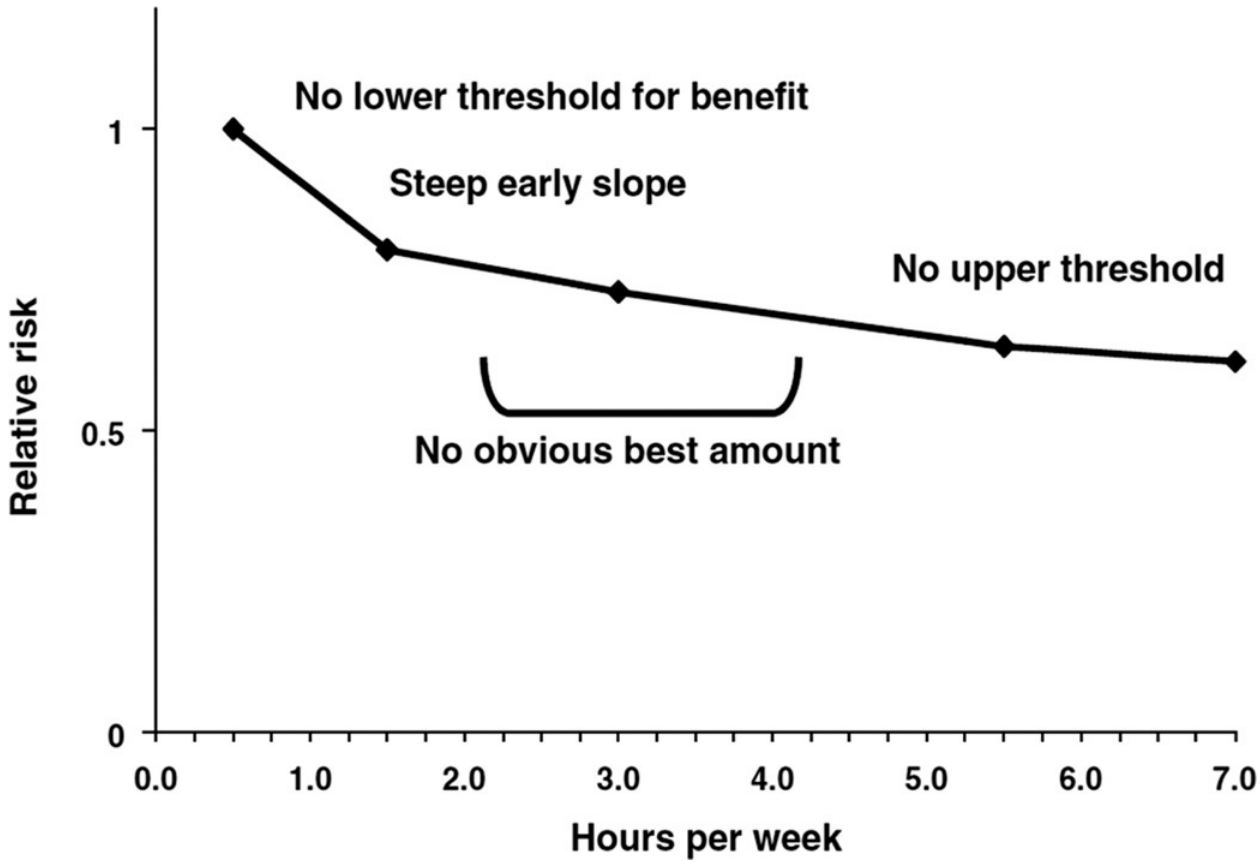

FIGURE 60.8 Risk of all-cause mortality according to hours per week of moderate to vigorous physical activity (MVPA). Note the lack of an upper or lower threshold above or below which benefit of MVPA is lost.

THE PHYSIATRIST'S SUMMARY

The physiatrist concluded by reiterating the value of making regular physical activity an important part of one's daily routine. He reminded the audience that there is now an overwhelming amount of scientific research that associates physical activity with a reduced likelihood of many chronic diseases. Furthermore, physical activity can even be used as a successful treatment of various diseases and in some cases lead to the regression of disease (eg, type II diabetes mellitus). Another compelling reason to engage in regular physical activity is to promote one's sense of wellness and vitality. He told the audience that as the U.S. population ages, those who are hitting social security age (age 65) can expect to now live, on average, another 20 years. Unfortunately, too

many elderly adults find themselves living with chronic debilitating diseases (eg, arthritis, obesity) in older age. This can greatly impair one's sense of wellness and vitality, decreasing one's ability to enjoy and contribute to all that life has to offer. The goal, therefore, should be to defer chronic disease and disability to the last *few years* of one's life, not the last *few decades*. This concept is referred to as the "compression of morbidity" and is tightly linked to maintaining health, wellness, and a sense of vitality for as many years as possible before illness and disability set in.[38]

If deferring illness and disability to the latter years of one's life is not sufficient reason to engage in physical activity, perhaps saving money will be another, as shown by a recent study in which higher fitness in middle age was associated with less health costs in later life (**Figure 60.9**).[39] As we learned earlier in this presentation, said the physiatrist, physical inactivity has been directly associated with an increased risk of obesity, diabetes mellitus, cardiovascular disease, and cancer, and can greatly impair cognitive function and promote musculoskeletal dysfunction and injury, as well as overall unsuccessful aging. At an economic level, physical inactivity has been estimated to contribute to over $53 billion in worldwide health care costs, creating a substantial economic burden on the public and private sectors, as well as individual households.[40] In the United States alone, physical inactivity has been estimated to contribute to approximately 11% of aggregate health care expenditures.[41]

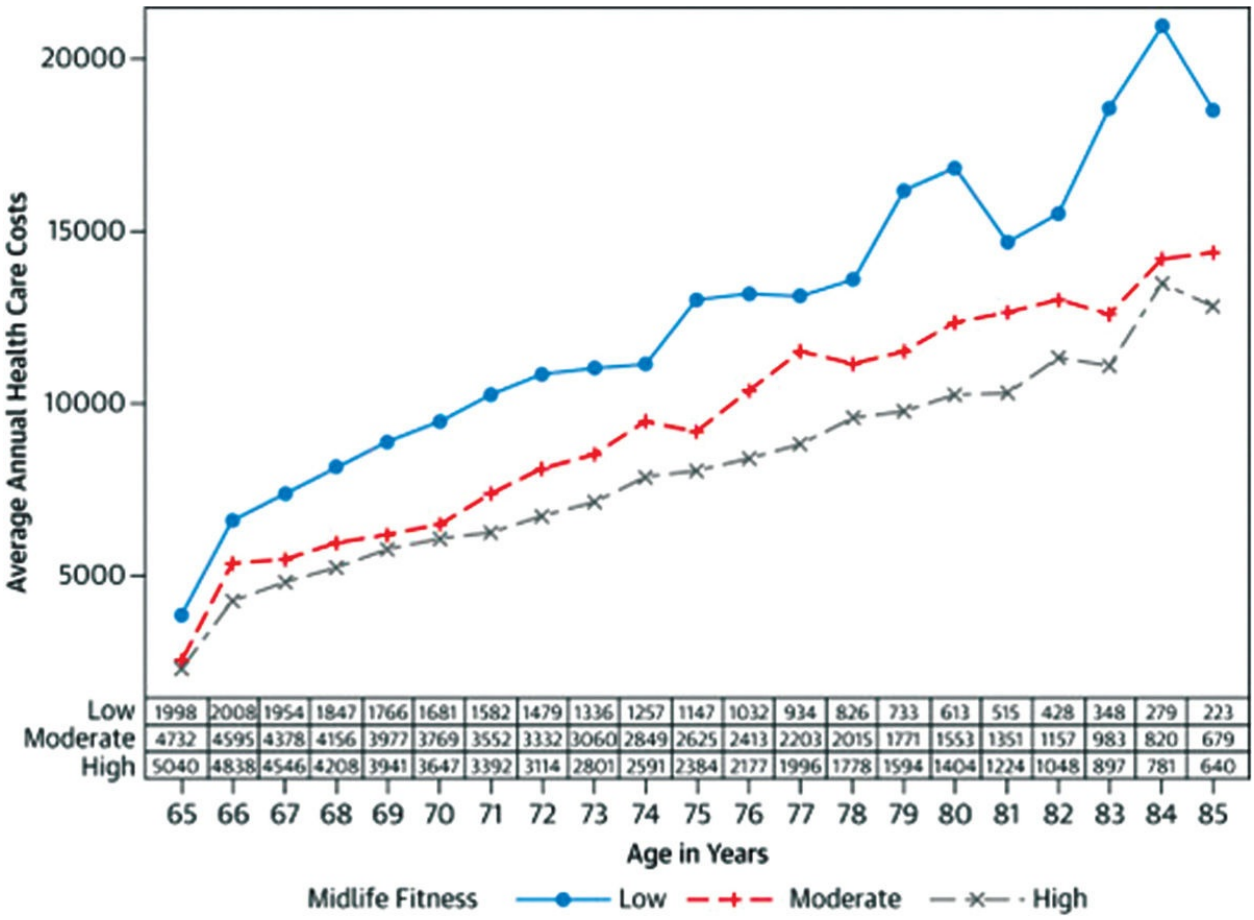

FIGURE 60.9 Health care–associated costs later in life according to cardiorespiratory fitness level in middle age.

David's Follow-Up Visit With His Cardiologist

David scheduled a return visit to his cardiologist, as suggested, a week after the lecture. It was clear that David had been very inspired by the lecture and was motivated to start adding an exercise program to his health regimen. Knowing that inspiration is fleeting, his cardiologist decided to get David to commit to a specific exercise plan before he left the office. He first suggested a formal cardiac rehabilitation program that David was eligible for, which involved group exercise under medical supervision, including electrocardiographic monitoring. However, the Rehabilitation Center was located 40 minutes away from David's work, and he was afraid the time involved in traveling would make the program prohibitive. However, the cardiologist was aware of this type of problem and knew of alternative options

within the community. He suggested that David join a general gym that also sponsored a cardiac patient program three nights per week between 6 and 7 pm and that was also conducted by members of the Hospital's Rehabilitation team. David indicated that option would work fine. The cardiologist wrote down the name of the gym and the contact person for David and asked him when he would make the call to join. David promised to do so that very afternoon.

His cardiologist then suggested that David also purchase a pedometer and gave him a sheet with various options.

Finally, he asked David if there was anything else he planned to do. David mentioned that he was particularly impressed about the discussion regarding the hazards of sitting and that he had already gone ahead and ordered a standing desk. His cardiologist was very impressed. He saw that David had not only been inspired to be more physically active, but had now taken important steps to anchor this motivation into a plan that would promote David's health for years to come.

Applying Psychological Principles for the Lifestyle Management of Cardiac Patients

Fifteen months after sustaining his heart attack, David is scheduled for a routine follow-up with his cardiologist. Now 53 years old, David's preexisting hypertension and high cholesterol are presently well controlled on his current medical regimen and dietary changes. David had also been noted to have a high HgbA1C after his heart attack (6.2%), signaling a prediabetic state, but this value has now decreased to 5.7%. At his 3, 6, and 9-month follow-up visits, David had sustained his new health habits, including a strict adherence to a restricted-calorie (1,800 calories) Mediterranean diet, and an exercise regimen that he had adopted after his three-month visit, including joining a health club, which he attended for 45 to 60 minutes 3 times/week. During this time, he had also bought a standing desk and purchased a pedometer, which he wore every day.

However, 5 months before his current visit, David began to experience more stress at his law firm, which had recently expanded its operations. As one of the senior associates, David was traveling more and cutting back on some of his sleep. Feeling quite time pressed, he decided he would defer his exercise program for a week or 2, and he allowed himself permission to eat an extra

snack or 2 during the day. Without thinking about it, David had resumed a prior pattern of night eating, and once he stopped exercising, he did not restart his exercise program. By the time he saw his cardiologist, he had regained 8 of the 14 lb he had previously lost during the first 9 months following his heart attack. David was pleased that his risk factors were under control, but he was quite discouraged by his failure to maintain his new health habits.

However, David's cardiologist was not perturbed by the setback. Instead, he praised David for his initial success and said that this proved he could do it again. He then mentioned to David that he knew a health psychologist, Dr. Jones, who helped coach patients who were having trouble adopting new health behaviors and maintaining them for the long term. He mentioned that Dr. Jones gave a monthly lecture on stress and heart disease at the hospital and suggested that David attend the lecture.

David was very eager to do so. At the lecture, Dr. Jones explained that his presentation was divided into three parts. First, he would discuss the scope of psychological factors that are related to heart disease. Second, he would describe psychological principles related to the management of health behaviors and stress management. Third, he would provide the participants with a self-reflective exercise that could guide their future self-management of their health goals.

PSYCHOSOCIAL RISK FACTORS FOR HEART DISEASE

Dr. Jones began the first portion of his lecture by showing a slide that listed the psychological domains that he would discuss (**Table 61.1**). He then spent a few minutes discussing the following essentials regarding each psychological domain that was listed on the slide.

TABLE 61.1 Psychosocial Risk Factors for Cardiovascular Disease

1. Depression
2. Anxiety syndromes
   - Elevated anxiety symptoms
   - Phobias
   - Generalized anxiety disorder
   - Posttraumatic stress disorder
3. Pessimism
4. Hostility/anger

5. Loneliness and poor social support
6. Lack of life purpose
7. Chronic stress
   - Work stress
   - Marital stress
   - Caregiver stress
   - Effects of trauma and abuse
   - Chronic illness
8. Fatigue states
   - Vital exhaustion
   - Burnout
   - Lack of sleep

DEPRESSION

Depression is a common psychological symptom that can range from very mild symptoms to those that are very severe. Severe or “major depression” is said to be present when patients experience a markedly depressed mood or the lack of interest in nearly all of their activities in life for at least 2 consecutive weeks, in conjunction with other psychological symptoms, including either loss or increase in appetite, insomnia, fatigue, difficulty concentrating, and feelings of guilt.

The systemic pathophysiologic effects of depression are profound. When depression is chronic, it can result in persistent activation of the hypothalamic pituitary adrenal axis and dysregulation of the sympathetic nervous system, leading to a rise in serum cortisol levels and elevated norepinephrine levels. This in turn can lead to profound systemic effects affecting many physiologic functions and organ systems, as shown in **Figure 61.1**.[1] For instance, people suffering from depression have a higher frequency of insulin resistance and elevated risk for diabetes. They are also more prone to develop abdominal obesity and elevation in inflammatory proteins, as well as pathology in the inner lining of blood vessels (“endothelial dysfunction”). Depression also leads to platelet abnormalities in the blood. All of these changes combine to accelerate the development and progression of atherosclerosis in the coronary vessels.

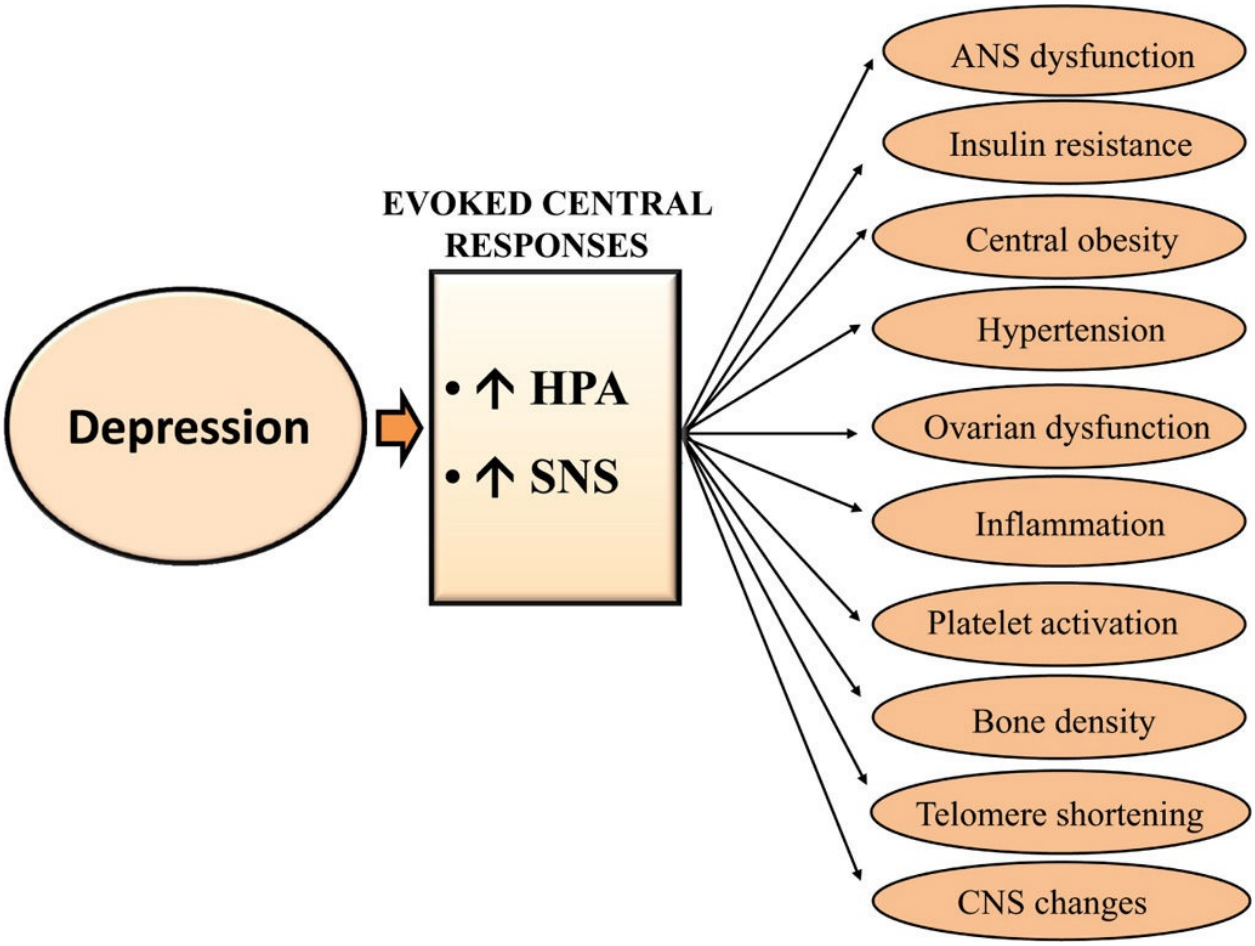

FIGURE 61.1 In the presence of chronic depression, there is persistent stimulation of the sympathetic nervous system and the hypothalamic pituitary axis (HPA). The result is diverse pathophysiologic effects, as shown. ANS, autonomic nervous system. (Modified from Rozanski A, Blumenthal JA, Davidson KW, Saab PG, Kubzansky L. The epidemiology, pathophysiology, and management of psychosocial risk factors in cardiac practice: the emerging field of behavioral cardiology. *J Am Coll Cardiol*. 2005;45:637-651.)

Secondly, depression also has an important negative effect on the health habits of individuals. People who are depressed are more likely to eat poorly, be sedentary, smoke, and be less proactive about their health in general. Moreover, once depression sets in, people find it harder to comply with recommended behavioral changes, such as suggestions for exercise, or even with their prescription medications.

Epidemiologic study indicates that chronic depression is a particularly potent factor for promoting heart disease. In a large meta-analysis of 54 epidemiologic studies, the adjusted risk for developing adverse cardiac events among individuals who were depressed was increased nearly 2-fold among depressed versus nondepressed subjects in both community cohorts as well as in patients

with prior cardiovascular disease (CVD) (**Figure 61.2**).[2]

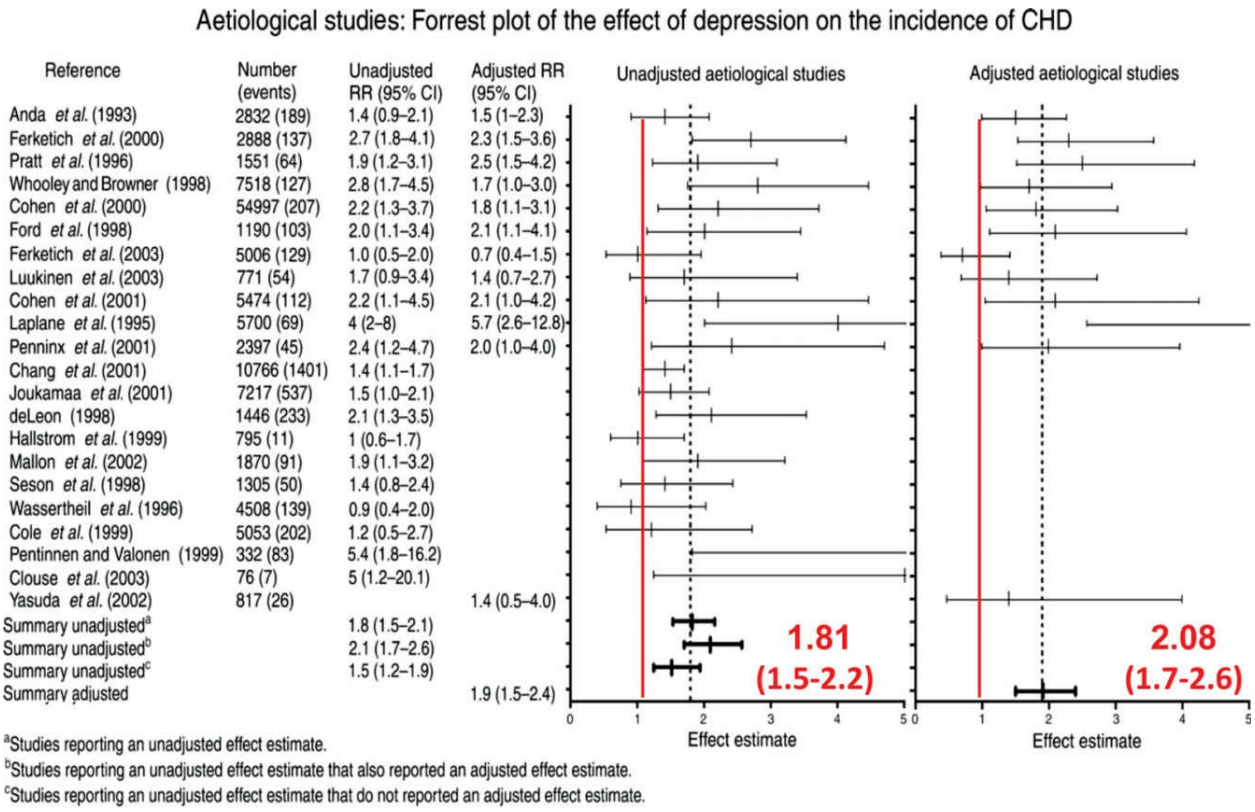

FIGURE 61.2 Relative risks (RR) are shown for the occurrence of coronary disease events (cardiac death or myocardial infarction) in association with depression among community cohorts, according to both unadjusted and adjusted data. A substantial elevation in risk is noted. RR, risk ratio; CHD, coronary heart disease; CI, confidence interval. (From Nicholson A, Kuper H, Hemingway H. Depression as an aetiologic and prognostic factor in coronary heart disease: a meta-analysis of 6,362 events among 146,538 participants in 54 observational studies. *Eur Heart J*. 2006;27:2763-2774.)

Investigators have also found a graded relationship between the degree of depressive symptoms and the likelihood of adverse cardiac events. For example, Lesperance et al.[3] conducted a follow-up study in 896 patients who had sustained a myocardial infarction. All patients filled out a questionnaire (the Beck Depression Inventory) to assess their degree of depressive symptoms at baseline, and were then followed for 5 years (**Figure 61.3**). The risk of cardiac mortality during the follow-up period increased in direct proportion to the magnitude of depressive symptoms. Notably, even mild depressive symptoms increased risk somewhat in comparison with patients who had no signs of depressive symptoms.

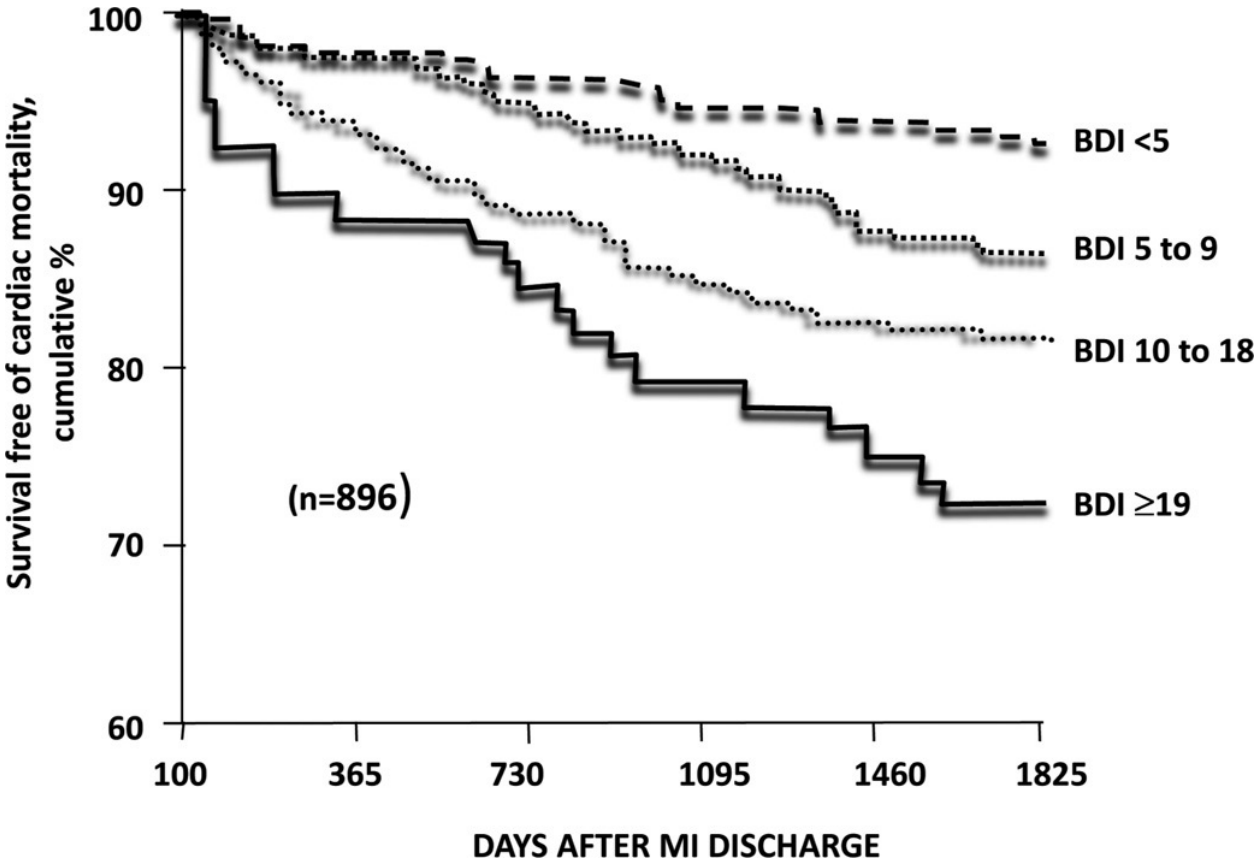

FIGURE 61.3 A 5-year follow-up of 896 post–myocardial infarction (MI) patients who were assessed according to their degree of depressive symptoms according to the Beck Depression Inventory (BDI), ranging from no depressive symptoms (BDI < 5) to moderate to severe depressive symptoms (BDI ≥ 19). There was a gradient relationship between the magnitude of depressive symptoms and the frequency of subsequent deaths. (From Lesperance F, Frasure-Smith N, Talajiv M, Bourassa MG. Five-year risk of cardiac mortality in relation to initial severity and one-year changes in depression symptoms after myocardial infarction. *Circulation*. 2002;105:1049-1053.)

Notably, the prevalence of depression is substantial among cardiac patients. The 1-month community-based prevalence of major depression is approximately 4% to 5%. By contrast, this prevalence is approximately 2-fold higher in cardiac populations.[4] In addition, depressive symptoms of a milder degree than major depression are found in another 15% of cardiac patients.[4] The high prevalence typifies a reciprocal relationship: depression is a risk factor for heart disease, but in addition, the development of heart disease can lead to depressive symptoms in some patients.

ANXIETY

Anxiety symptoms are also common in society and increase in prevalence

among patients with heart disease and other chronic medical symptoms. As with depression, symptoms may range from mild symptoms to severe psychiatric conditions, including phobias, panic disorder, generalized anxiety disorder, and posttraumatic stress disorder (PTSD). The relationship between anxiety and cardiac disease was recently assessed in a very large meta-analysis of 46 studies, involving 2,017,276 participants and 222,253 subjects with anxiety.[5] Anxiety was associated with a moderately elevated risk for cardiac disease, cardiac death, stroke, and heart failure, as shown in **Figures 61.4 and 61.5**.

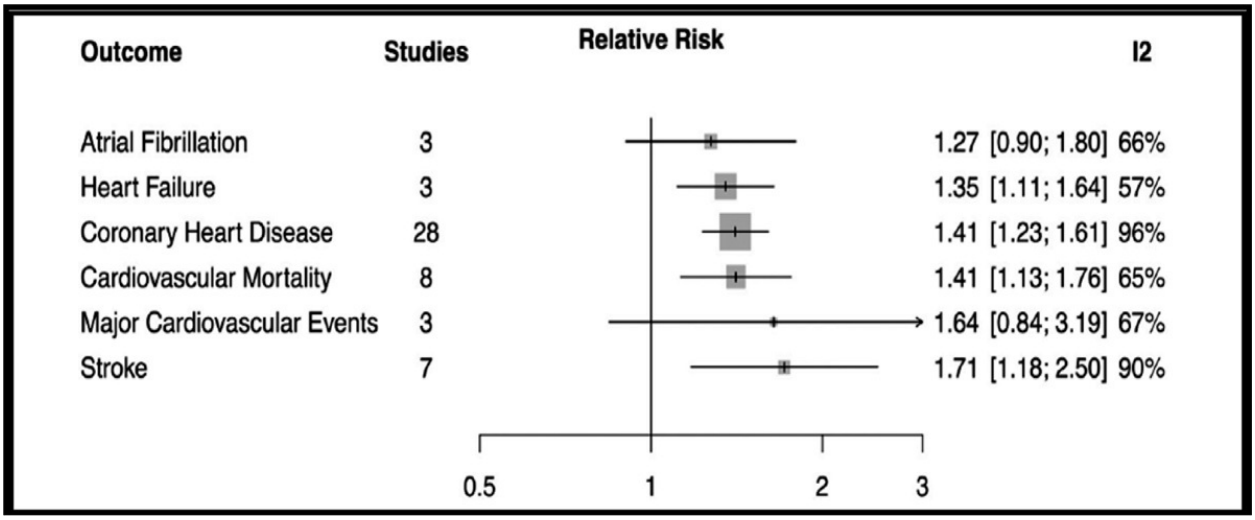

FIGURE 61.4 The relative risk posed by anxiety in association with various cardiac conditions. (From Emdin CA, Odutayo A, Wong CX, et al. Meta-analysis of anxiety as a risk factor for cardiovascular disease. *Am J Cardiol*. 2016;118:511-519.)

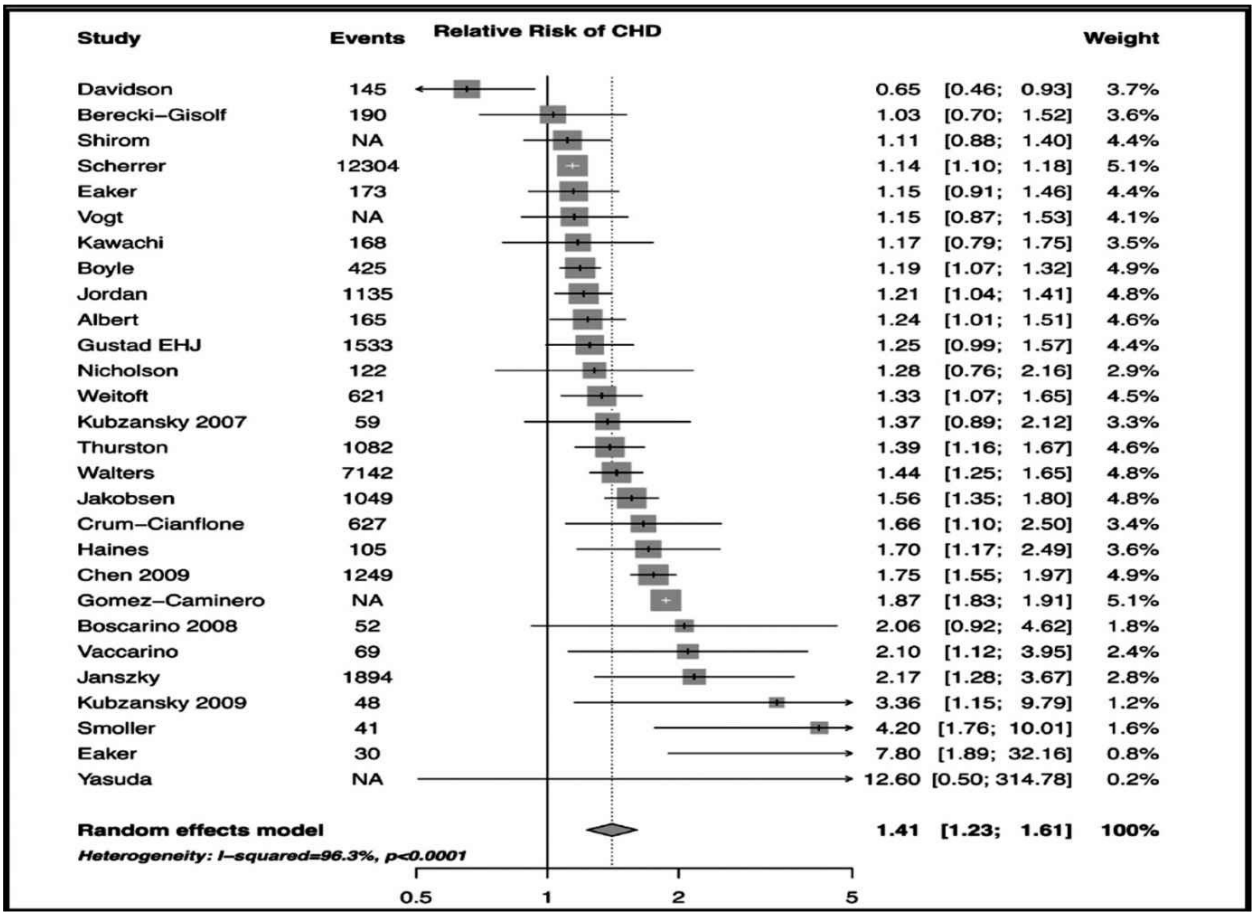

FIGURE 61.5 The relative risk of developing coronary heart disease (CHD) is shown for each of 28 studies included in this meta-analysis. (From Emdin CA, Odutayo A, Wong CX, et al. Meta-analysis of anxiety as a risk factor for cardiovascular disease. *Am J Cardiol*. 2016;118:511-519.)

Psychiatric-level anxiety syndromes are associated with even further cardiac risk.[6–9] For instance, an interesting study concerning PTSD was conducted in 562 twins in whom only one of the two twins had suffered from PTSD. The twins were followed for a mean of 13 years.[10] The presence of PTSD in one of the twins was associated with a more than 2-fold increase in cardiac disease.

PESSIMISM

It has been demonstrated that optimism is a general life asset, associated with greater likelihood of successful goal achievement in life and an enhanced sense of resilience. Pessimism, by contrast, can diminish coping skills and self-confidence, and it is associated with an increased risk of depression. Studies on the specific effects of pessimism versus optimism as a cardiac risk factor, however, have only been recent.

Pessimism is generally characterized as a personality disposition toward expecting negative outcomes in the future. Optimists, on the other hand, tend toward expecting positive outcomes. Another way psychologists have assessed optimism versus pessimism in the past is by examining people's "explanatory style." Pessimists tend to evoke an explanatory style of self-blame when negative events occur, and they tend to expect that these events will be persistent and affect many aspects of their lives. Optimists, on the other hand, tend to avoid self-blame for negative events, and view these events as transient and limited in scope.

Both dispositional and explanatory pessimism have been linked to negative health outcomes. The results, in fact, have been quite consistent. Pessimism is associated with reduced longevity and increased risk of cardiovascular events and stroke.[11–15] Optimism has the opposite effect. As with most psychological risk factors, a graded relationship has been noted between the level of pessimism or optimism and the occurrence of these negative events. Recent data from the Nurses' Health Study (NHS) have also demonstrated important effects of optimism on reduction of other health outcomes, including cancer, respiratory disease, and infection.[16]

As with other psychological risk factors, the impact of optimism versus pessimism on health appears to be related to both biologic and behavioral mechanisms. Biologic mechanisms include a positive effect of optimism on immune function, better autonomic function, and, pending further study, potentially slower rates of telomere shortening over time. In addition, optimists tend to exhibit a higher likelihood of engaging in exercise, eating a healthy diet, and a lower likelihood of smoking and other negative behaviors.

HOSTILITY

Hostility is a broad construct that encompasses the traits of anger, cynicism, and mistrust. The study of hostility has been an outgrowth of initial work by Friedman and Rosenman to study a personality complex that they termed "Type A behavior pattern," based on three features: the presence of easily provoked hostility, a competitive drive, and a sense of time urgency and impatience. Over time, epidemiologic data did not confirm initial positive findings concerning Type A behavior pattern as a cardiac risk factor, but the hostility component has been shown to demonstrate a modest relationship to heart disease. This construct is hard to study because many patients with hostility tend to have some degree of

self-denial or lack of self-awareness about their anger and hostility. Nevertheless, a large meta-analysis found that individuals with a pattern of anger/hostility have about a 20% to 25% elevated risk for heart disease compared to individuals without hostility.[17]

LONELINESS AND POOR SOCIAL SUPPORT

Individuals have a basic need to be socially connected to others. Here, we can make a distinction between being alone and feeling lonely. People vary in the depth of their need for connectivity to others, but unmet social needs and/or a feeling of loneliness is not only painful, but often health damaging. One of the first studies to examine the relationship between social factors and adverse outcomes was the "Alameda County study."[18] This study asked individuals to characterize how many people were in their social network and then followed them for a number of years. The investigators found that as the size of one's "social network" decreased, the risk of all-cause mortality increased (**Figure 61.6**). Since then, this finding has been reproduced in many studies. Similarly, other studies have demonstrated that a variety of social factors are related to health, including the size, structure, and frequency of contacts within one's social network, and the quality of either functional and/or emotional support that one receives from others. A recent meta-analysis of 148 studies found that individuals who scored high on a measure of social integration had an approximately 2-fold increase in survival compared to individuals who were less socially integrated.[19] Such an increase in survival is a substantial health benefit when compared to other clinical parameters that can affect health.

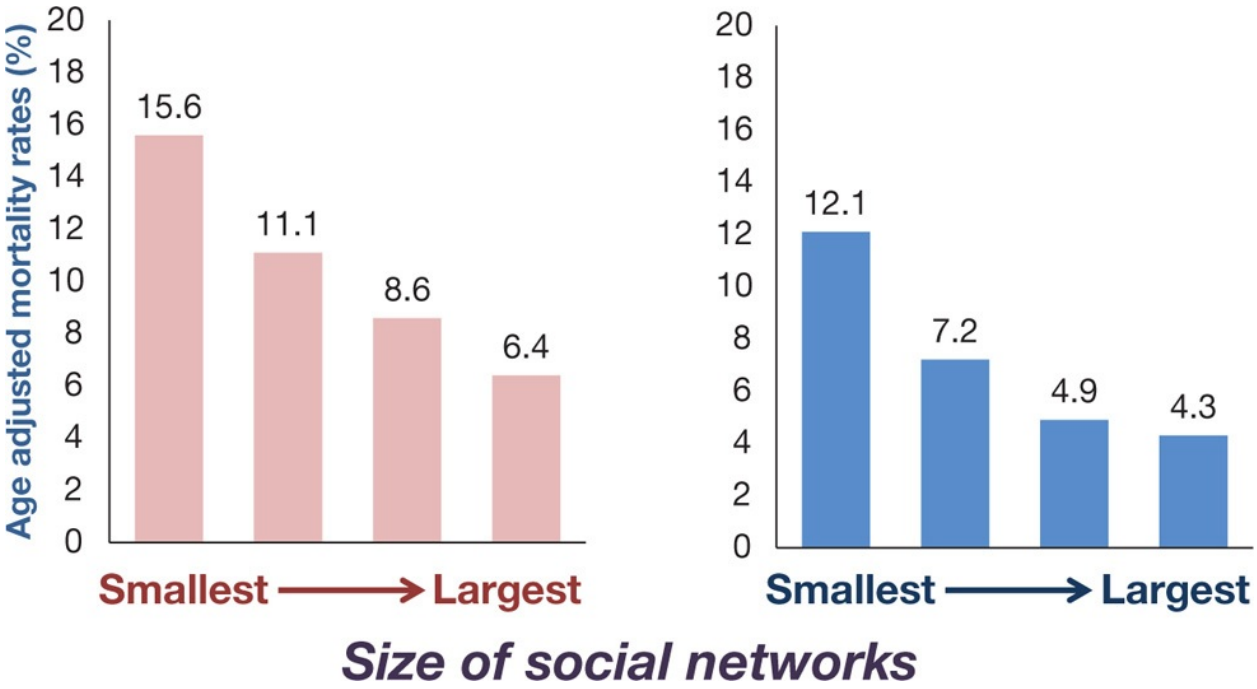

FIGURE 61.6 The age-adjusted mortality results are shown for men and women who were characterized at baseline according to the size of their social network size in the Alameda County study. Mortality rates were highest in those with small social networks and lowest in those with high social networks. (From Berkman LF, Syme SL. Social networks, host resistance, and mortality: a nine-year follow-up study of Alameda county residents. *Am J Epidemiol*. 1979;109:186-204.)

PURPOSE IN LIFE

Living with intentionality and goal directedness provides individuals with a strong sense of life purpose. By contrast, a lack of life purpose is associated with boredom and increases the risk of future depression. Over the last decade, a series of studies have studied the relationship between one's sense of life purpose and important clinical outcomes, such as heart disease, dementia, and longevity. In one recent meta-analysis of 10 prospective studies that involved over 136,000 subjects, investigators found that a high sense of life purpose was associated with a reduced risk ratio for cardiac events and for all-cause mortality (**Figure 61.7**).[20] The results were highly consistent among the individual studies constituting this meta-analysis. A higher sense of purpose has also been linked to a reduced risk of stroke, future physical disability, and dementia. Prospective study is needed to study the mechanisms by which this occurs, but preliminary data suggest that people who live with a high sense of life purpose tend to maintain more positive health behaviors and have a greater sense of psychological well-being. In addition, purpose in life may be associated with greater resilience, as suggested by a meta-analysis of 70 studies that found that

purpose in life was associated with a greater sense of competence, stronger social integration, and more positive affect.[21]

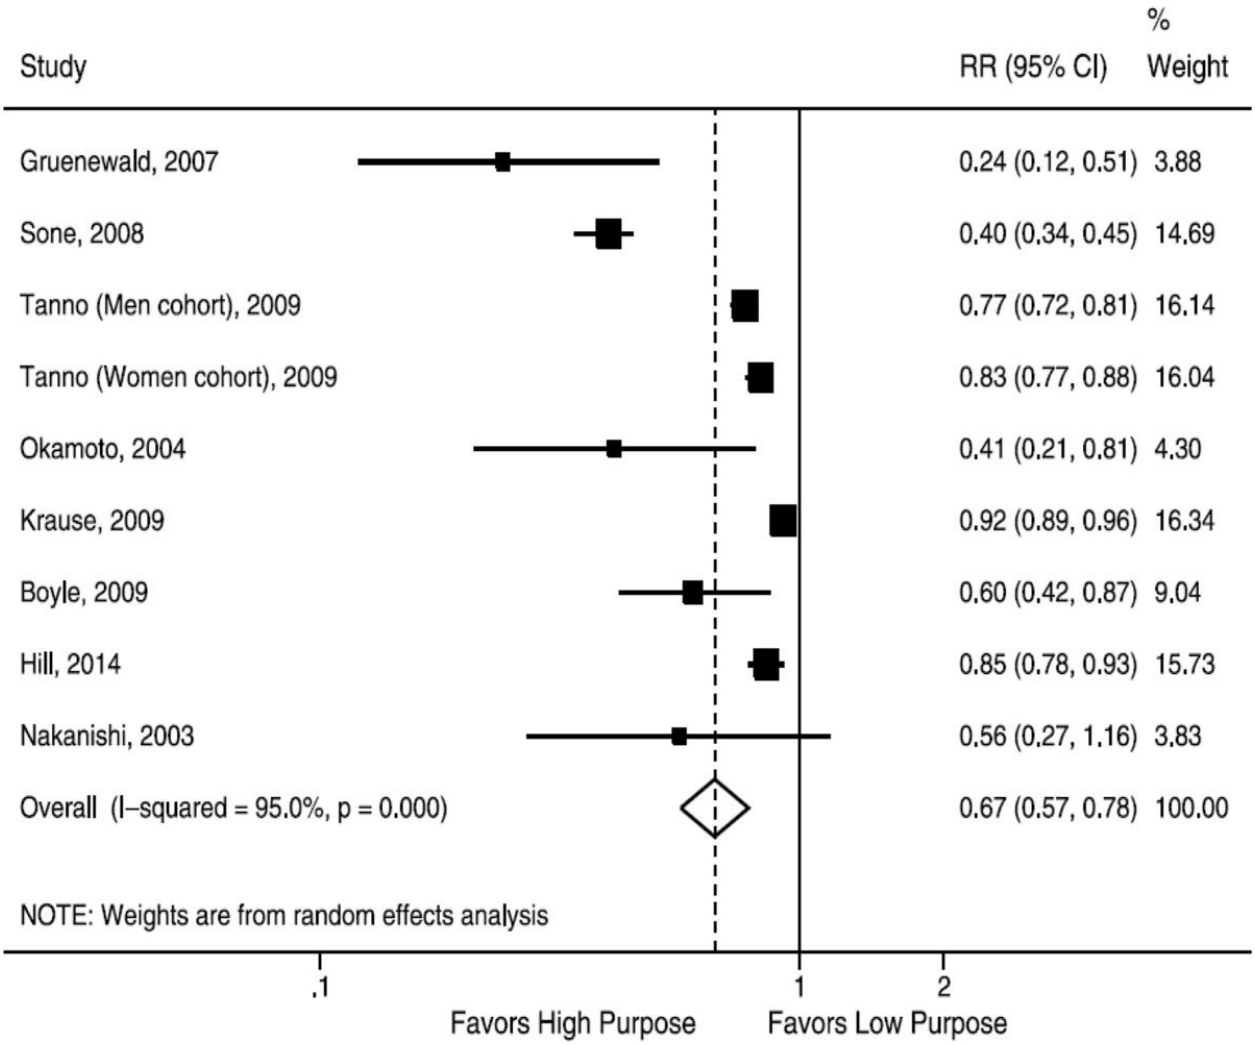

FIGURE 61.7 Meta-analysis of the risk ratio for having adverse cardiac outcomes according to the presence of having a high versus low sense of life purpose. The presence of high purpose was associated with a diminished risk of cardiac events. CI, confidence interval; RR, risk ratio. (From Cohen R, Bavishi C, Rozanski A. Purpose in life and its relationship to all-cause mortality and cardiovascular events: a meta-analysis. *Psychosom Med*. 2016;78:122-133.)

CHRONIC STRESS

Another psychological factor associated with heart disease is chronic stress. More distinctively, it is “toxic” stress, or a chronic sense of distress, that seems to be associated with adverse medical outcomes. That is, not all stress is bad. Rather, individuals, as part of their desire to live a life of purpose, like to take on life challenges. Successful coping with life stress can provide both life satisfaction and an increased sense of self-esteem.

As with depression, chronic distress can lead to stimulation of the hypothalamic–pituitary–adrenocortical axis and the sympathetic nervous system,

leading to many similar effects on physiologic functions and organ systems. Of note, people under chronic distress are also more likely to become physiologic "hyper-reactors," meaning that there is a tendency for heart rate and blood pressure responses to rise higher and recover more slowly following acute stimulations compared to people who are not under distress. Other studies indicate that chronic distress can lead to signs of accelerated aging, as measured by DNA evidence.[1,22] Finally, chronic distress can result in adverse changes in the brain's plasticity, including increase in the size of the amygdala, which is the brain's fear center, and reduction in the size of the hippocampus and prefrontal cortex.[23]

There are various types of distress that have been linked to a higher risk of heart disease, including work stress and marital strain. In addition, acute and chronic illnesses can also produce a stress response among some patients. For instance, Edmonsdon et al.[24] found that among patients presenting with acute coronary syndrome (ACS) patients, 12% developed symptoms of PTSD. Other common negative chronic stressors include caregiving strain and the enduring effects of childhood abuse or trauma. For instance, in the NHS II, involving a 16-year follow-up of 66,798 women, a history of childhood abuse was associated with an approximately 1.5-fold increase in the onset of cardiovascular events by middle age.[25] The investigators found that adult risk factors such as smoking, diabetes, and increased body mass index, as well as the presence of other psychosocial factors, such as depression, accounted for the majority of this elevated risk.

NEGATIVE FATIGUE STATES

Another negative psychological risk factor is the presence of negatively charged fatigue states (ie, a feeling of tiredness that is intermixed with negative emotions or a sense of tension). This is in contrast to calm-tiredness, which may occur after a long day of satisfying work. The latter is regenerative, whereas a state of "tense-tiredness" can induce negative moods and a need for quick fix behaviors.[26,27] When individuals are in sync in terms of physical health, social well-being, and a sense of purpose, they have a greater sense of vitality. The presence of vitality promotes an overall sense of well-being and provides people with energy for successful coping and emotional regulation. On the other end of the spectrum is the presence of "vital exhaustion," a condition of excessive fatigue, feelings of demoralization, and increased irritability, which has been

postulated to be a result of prolonged distress.[28] Epidemiologic study has consistently linked vital exhaustion to an increased risk of cardiac events and/or all-cause mortality. For instance, vital exhaustion was recently compared to other CVD risk factors in a follow-up of 8,882 individuals who were initially free from CVD in the Copenhagen City Heart Study.[29] Vital exhaustion was found to be a strong independent risk factor for the development of CVD in both genders, with manifestation of a strong risk-adjusted gradient relationship. Another negative fatigue state is the presence of burnout, which is characterized by a sense of exhaustion, depersonalization, and diminished efficacy at work. Preliminary study also suggests that burnout can increase the risk for heart disease.[30-31] In addition, chronic poor sleep, including insomnia, represents another risk factor for heart disease.[32,33]

"CLUSTERING" OF PSYCHOSOCIAL RISK FACTORS

Although psychosocial stresses are often studied in isolation, in life they often tend to cluster together. For example, people with poor social support are also more likely to feel life stress. When such negative psychosocial risk factors cluster, they tend to magnify the potential pathophysiologic effects of these factors. For example, in a study of post–MI patients, the presence of high levels of life stress and social isolation were both found to be associated with an approximately 2-fold increase in subsequent clinical events.[34] But overall clinical risk was increased 4-fold among post–MI patients reporting both social isolation and life stress. Similarly, clinical risk is magnified among patients who report both anxiety and depression.[35] Notably, psychosocial factors also interact synergistically with physical risk factors to increase overall clinical risk. For example, depressed patients who are physically inactive are at increased risk for future cardiac events (**Figure 61.8**).[36] Such data emphasize the need to treat any and all risk factors as best as one can to reduce the overall clinical risk among patients.

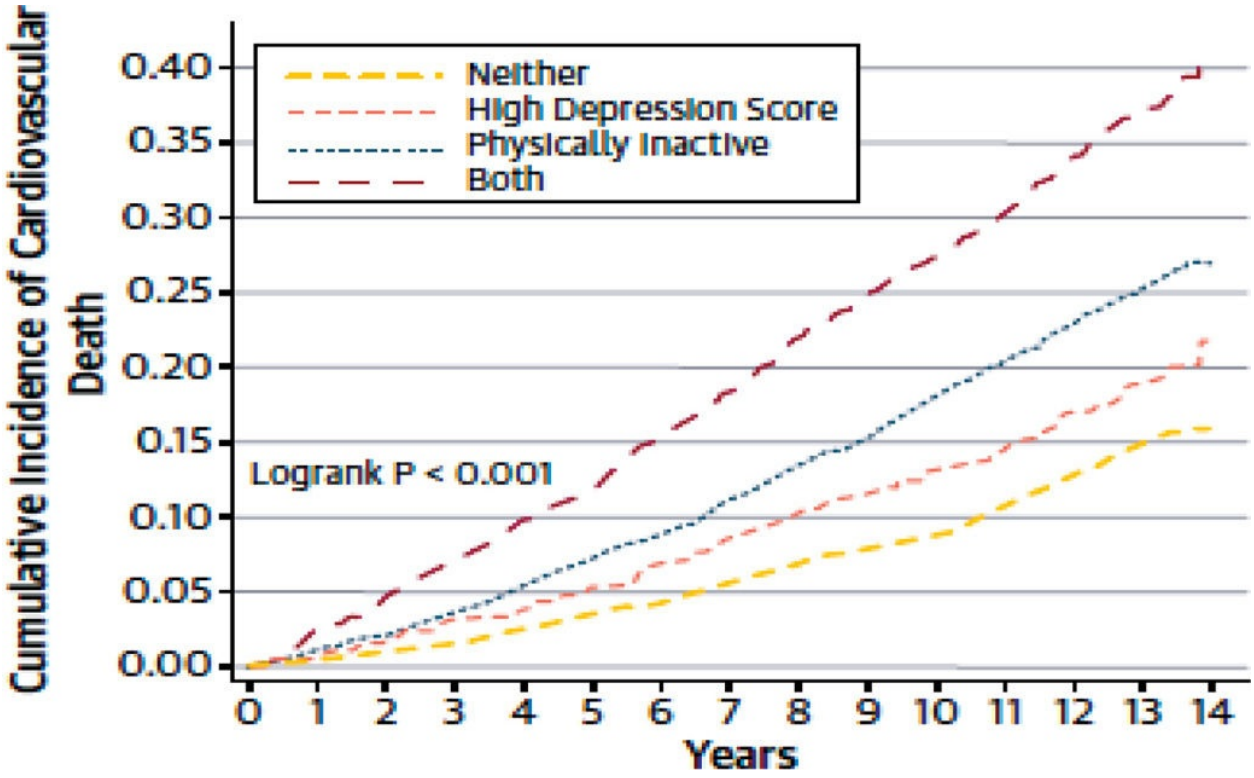

FIGURE 61.8 The cumulative incidence of cardiovascular death among patients divided into four groups according to being physically active or inactive and according to having a high versus low depression score in the Cardiovascular Health Study. (From Win S, Parakh K, Eze-Nliam CM, et al. Depressive symptoms, physical inactivity and risk of cardiovascular mortality in older adults: the Cardiovascular Health Study. *Heart*. 2011;97:500-505.)

MANAGING HEALTH BEHAVIORS AND LIFE STRESS

After providing the audience with this overview, Dr. Jones asked if there were any questions and then began the second portion of his lecture. He mentioned that any health goal, like goals in general, could be broken down into three phases, as illustrated in another slide he showed them (**Figure 61.9**). These three phases included: (1) motivation; (2) goal execution; and (3) goal maintenance. Under each category, Dr. Jones listed a number of representative tools and techniques that could be used by individuals to foster that phase of goal pursuit. To save time, Dr. Jones chose to address just a few of these tools in his lecture, as follows:

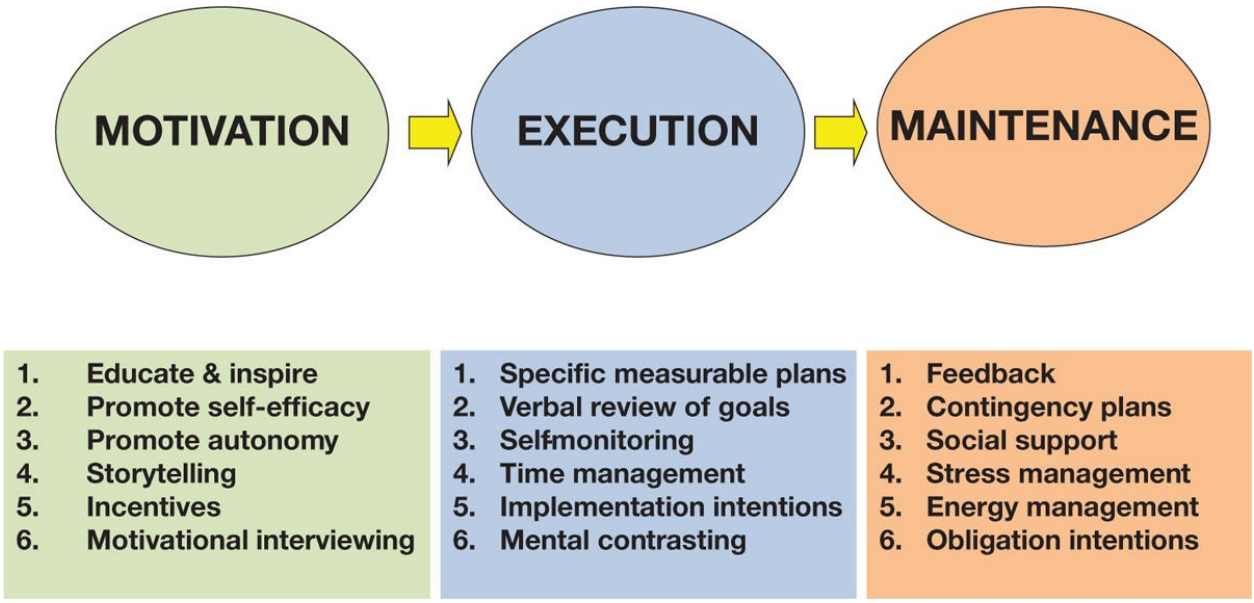

FIGURE 61.9 The pursuit of goals can be divided into three components, as shown. Techniques that can be used to foster motivation, execution, and maintenance in each group are shown. (From Rozanski A. Behavioral cardiology: current advances and future directions. *J Am Coll Cardiol*. 2014;64:100-110.)

AUTONOMY

Motivation can be classified as either "intrinsic" or "extrinsic" in origin. Examples of extrinsic motivation include warning, provision of incentives, or the provision of case managers. When motivation comes from within, this is termed internal motivation. Patients, as with all people, are more likely to stick with a goal that is derived from internal motivation. The desire to choose a goal based on your own volition rather than being told by someone else what to do is termed "autonomy." For instance, whereas physicians can provide patients with compelling health reasons for exercise, diet, and so forth, a schooled physician will also look for other angles by which to foster internal motivation in patients. For instance, a patient may want to start a diet to feel good or to please a spouse or merely to please his or her physician. The more compelling the personal reason is, the more likely the patient will follow through. In addition, merely asking patients to verbalize their own personal reasons helps patients to take more ownership of their health goals. Various studies have found that when patients leave their doctors' office with a sense of autonomy regarding a suggested health goal, they are more likely to adhere to their health goals over time.

SELF-EFFICACY

The setting of unrealistic goals is a prescription for failure. By contrast, the more someone believes that a certain goal can be accomplished (ie, the greater the sense of "self-efficacy"), the more the person will be willing to try. For instance, health organizations recommend that individuals get at least 20 to 30 minutes of moderate physical exercise on most days of the week. Although this is a reasonable goal for people who are generally fit, this is generally too hard for a completely sedentary person. It is more important that sedentary people first establish a goal that is compatible with their individual sense of "self-efficacy," even if this means a very minimal goal at first, such as walking 5 to 10 minutes/day. Once patients have tasted some success in a new health domain, goals can then be increased incrementally.

SPECIFIC ACTION PLANS

Vague action plans are another prescription for failure. Rather, the more specific the action plan, the greater the likelihood of patient adherence. For instance, establishing a goal to get more exercise is a vague goal. Deciding to join a gym is more specific. Even better is committing to which days of the week one may go to the gym and for how long. Writing down one's goals helps build one's sense of commitment.

SELF-MONITORING

Self-monitoring helps to anchor health goals by providing a mechanism for daily self-awareness and personal feedback. The most obvious example of self-monitoring is using a scale to weigh oneself daily. Studies indicate that overweight individuals who weigh themselves daily are more successful in maintaining weight loss compared to individuals who do not. More recently, the use of pedometers as a means of self-monitoring one's physical activity has become increasingly promulgated. For example, a review of medical studies found that the use of pedometers was associated with a 27% increase in physical activity compared to physical activity before initiating pedometer use.[37] The use of pedometers has a number of potential advantages: it is a way of becoming more cognizant of one's physical activity; it can be motivational for some to monitor their steps and try to increase them; and the information can also represent a form of feedback to patients as they learn to monitor and track their daily steps.

There are different potential walking goals that can be established with the use

of a pedometer. Some providers have popularized a goal of achieving 10,000 steps/day, but caution needs to be employed, because such a goal may not be practical initially for many older adults, those with chronic illnesses, or those who are significantly deconditioned. Rather, an incremental approach in terms of increasing pedometer steps based on one's baseline level of activity is preferred for those who are initially sedentary. For instance, after determining baseline step counts based on a week of observation, patients may begin by seeking to increase their physical activity by a mere 100 to 200 steps/day, with progressive increases according to an individual's sense of self-efficacy during subsequent weeks.

IMPLEMENTATION INTENTIONS

When a patient commits to a new health goal, the new practice is highly vulnerable because of the pressures of daily life. A new practice must be repeated continually before it becomes a habit. To strengthen habit formation, a group of investigators, Gollwitzer and colleagues, have developed a technique called "implementation intentions."[38] An implementation intention involves the use of an external stimulus to cue a specific behavior ("X"), followed by a specific action ("Y") that will be initiated when that cue occurs. The cue can be a stimulus in time, place, or situation. Gollwitzter et al. suggest that the formulation should always be stated as follows:

> **"When it is X, I will do Y," where "X" is the cue, and "Y" is the behavior.**

Although this technique might seem simple, a large meta-analysis of many studies involving the use of implementation intentions has found that implementation intentions are associated with a moderate to large effect in stimulating successful goal achievement.[39] One such example comes from a study of women who were being encouraged to perform breast self-examination (BSE) to promote early detection of breast cancer.[40] In the study, all women received a lecture on the importance of BSE, but half of the women were also asked to perform an implementation intention around how and when they would perform this task (eg, *"On the first evening of each new month, I will perform my breast self-examination."*). Notably, the women who were asked to form an implementation intention concerning BSE manifested a substantially higher rate of adherence to this health practice during follow-up.[40] Similar findings were

noted in a study concerning implementation intentions and physical activity (**Figure 61.10**).[41]

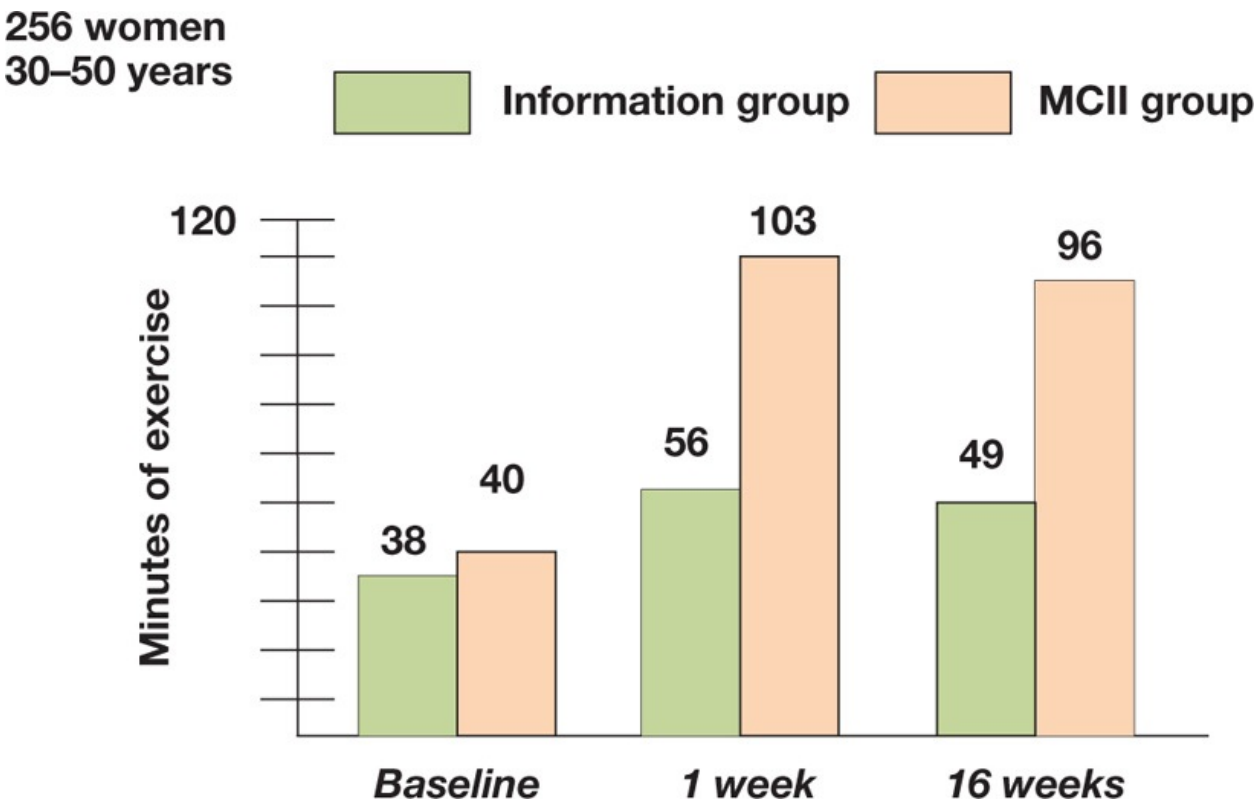

FIGURE 61.10 Minutes of moderate to vigorous physical activity per week among two groups of women, randomized to either an information group about exercise or to a group that were also asked to perform mental contrasting and make an implementation intention about exercise (MCII). The MCII group had nearly double the amount of physical activity at both one week and four months. (From Stadler G, Oettingen G, Gollwitzer PM. Physical activity in women: effects of a self-regulation intervention. *Am J Prev Med*. 2009;36:29-34.).

CONTINGENCY PLANS

Developing contingency plans around new goals is an important step in fostering long-term goal maintenance. Stressful life events, boredom, new competing priorities, and many other factors frequently intervene to challenge a patient's ability to stick with a new health goal. The key thing during such times is to not let the desired goal activity go down to zero, since the complete cessation of activity increases the risk that the health goal will not be reinstituted. A contingency plan represents a certain floor of minimal activity that will be maintained during times of stress. For example, if a patient has committed to exercising at the gym five times per week, the contingency plan may be a

temporary reduction to exercising only 2 times/week.

SOCIAL SUPPORT

Having social support can provide both renewable motivation and coping help to maintain new health goals. Medical studies reveal that when social support is lacking, patients are less likely to adhere to their physicians' health recommendations.[42] Building appropriate social support is highly personal and depends on many factors, such as one's personal need for social support, the availability of friends, social opportunities in one's community, and time constraints.

FEEDBACK

Feedback represents a specific form of tangible support, combining components of the aforementioned tools. Knowing that feedback will be provided by one's health provider tends to increase one's sense of accountability. Feedback may also help people gain insights into the natural blind spots that they experience when pursuing difficult goals. Feedback also provides a sense of social support and a sense of teamwork—"we're in this thing together."

STRESS MANAGEMENT

One of the common reasons why patients fail to maintain new health habits over the long term is their difficulty in balancing this new commitment with other life priorities. Many patients can benefit from enhanced stress management skills. One useful approach that may be particularly relevant for cardiac patients is to consider stress from the perspective of one's sense of energy and sense of tension. This was the focus of research by Dr. Robert Thayer years ago.[26,27] Through his work, he developed his model of tension and energy, as shown in **Figure 61.11**. He observed that when people are both tense and tired, they tend to be more moody and more likely to resort to "quick fix" behaviors that will reduce their tension or increase their energy. Very often, these quick fixes are counterproductive and health damaging, such as the use of cigarette smoking to reduce tension or frequent ingestion of candy bars to mollify stress or increase energy.

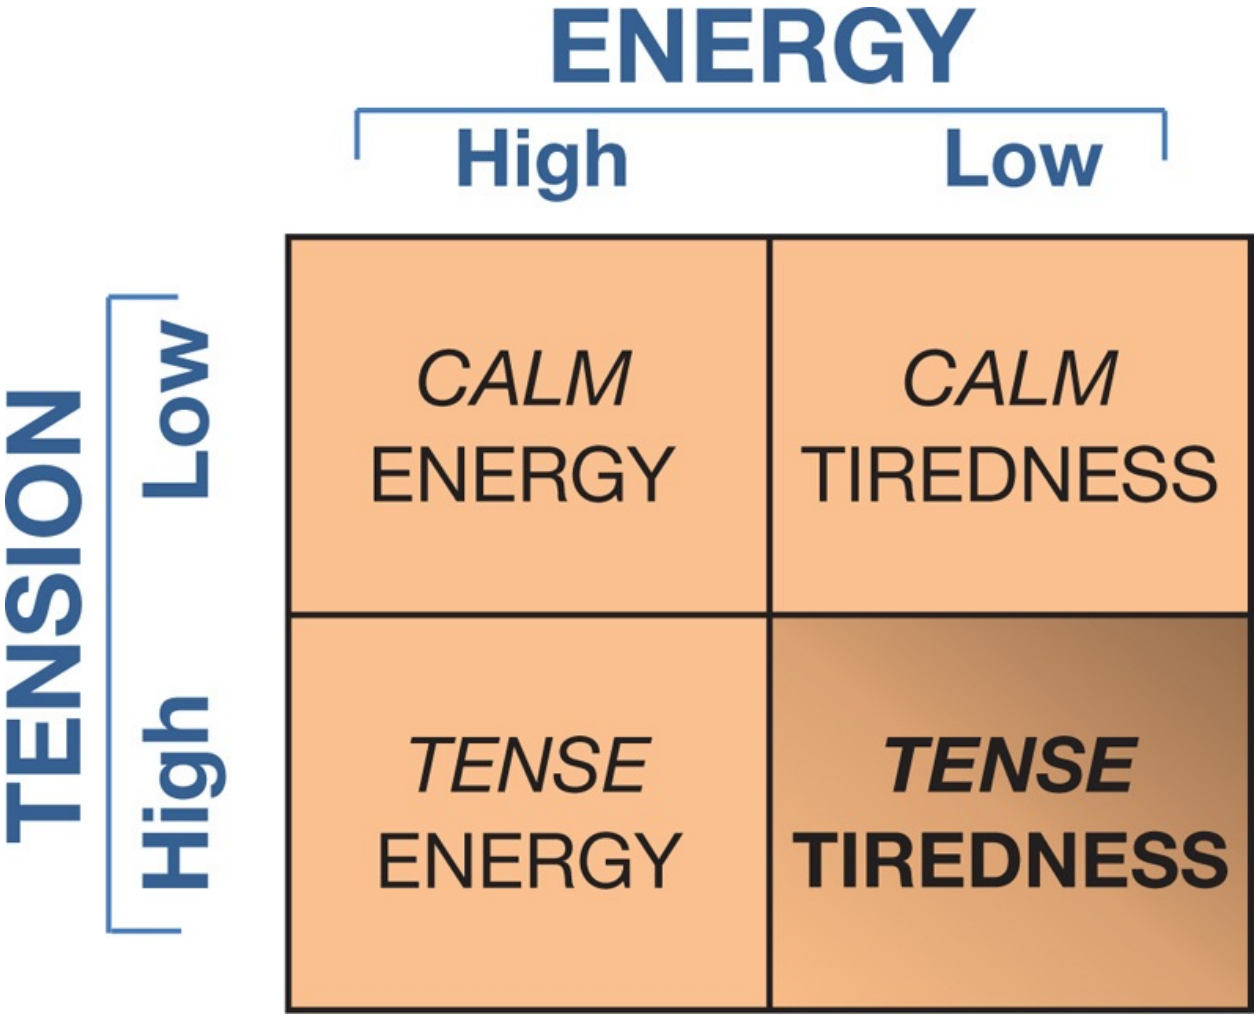

FIGURE 61.11 Per work developed by Thayer et al., personal states can be characterized by one's level of energy and tension, as shown. Periods of tense-tiredness tend to be characterized by a higher frequency of low moods and quick-fix behaviors.

Either increasing energy and/or reducing stress can be used to decrease the frequency of tense-tiredness that a person may feel. The best way to reduce chronic stress is to reduce the source of the tension. However, even when this is not possible, the breakup of continuous tension can be quite beneficial. Tension-busters include breathing exercises, guided meditation exercises, engaging in interests that one finds stimulating or relaxing, and social diversions. In addition, individuals may turn to specific forms of stress-reducing physical activities such as yoga and tai-chi.

Alternatively, individuals can attempt to reduce tense-tiredness by taking steps to increase their general energy level. Importantly, research shows that people tolerate their stress better when they feel energetic. Taking on positive health

behaviors, such as exercise, adequate sleep, and a healthy diet plan all help in this regard. In addition, if a person realizes that there is a point in the day at which they are particularly prone to feeling tired, they can build an energy plan around that, such as taking a short nap, or developing the habit of taking out a 10- to 15-minute physical or mental breather that is restorative of energy during energetically low points of the day.

When one feels that their stress is unmanageable, seeking the advice of trained coaches may be useful for isolated problems, such as poor time management skills, and/or the consideration of mental health counseling, particularly if there is also an overlay of anxiety, depressive symptoms, increasing pessimism, sleeping problems, an inability to relax physically or mentally, or feelings of social alienation.

AN EXERCISE IN LIFESTYLE MANAGEMENT

After completing the second phase of his lecture, Dr. Jones explained that life stress and psychological challenges are commonplace, and can frequently be exaggerated by acute or chronic illnesses. He then mentioned that there is no specific formula for dealing with life stress, because of the highly varied differences in individuals' "life settings" (eg, income, social circumstances), personalities, coping skills, level of conflicting priorities, and many other factors, intrinsic talents, upbringing to them. To illustrate some of the points of his lecture, Dr. Jones gave the audience participants the following assignment:

First, he asked the people to identify all negative health habits and psychological problems that were relevant to them on the basis of his lecture presentation. David thought about this. He certainly did not feel depressed, unduly anxious, or hostile toward anyone. He was quite dissatisfied with his failure to exercise and to maintain his new diet. In addition, he recognized that he was overdoing it at work and that he had to work on his time management skills He was also not getting enough sleep. David realized that he had a lot on his plate.

Dr. Jones then asked each individual to identify one problem that they would like to work on over the next 3 months. This did not preclude working on other problems, but he explained that strong success in one area often breeds energy to succeed in other arenas. David was fascinated by the question. He decided to take on the issue of restarting an exercise program. He recalled how good he had

felt when he was getting more physically fit and how that had helped him to maintain his health diet during that time.

Dr. Jones then asked each participant to form a specific health goal to address a chosen problem, with the greatest specificity possible. David realized that the only time he was likely to exercise was when he left work. He got to work too early to consider exercise, and exercising during the day was not an option. Once he got home at night, he was either too distracted or tired to go out to the gym again. Thus, the only practical option was to exercise after leaving the office, before he got home. As to the frequency, David figured he would try to exercise daily after work, so that he could make this more habitual. He further decided to devote a total of 1 hour at the gym per session, which would include time to change into and out of his gym gear and a 30-minute workout.

Dr. Jones then asked the audience to form an implementation intention around their new health goal. David had really enjoyed that part of the lecture and he quickly formulated his intention (**Figure 61.12**):

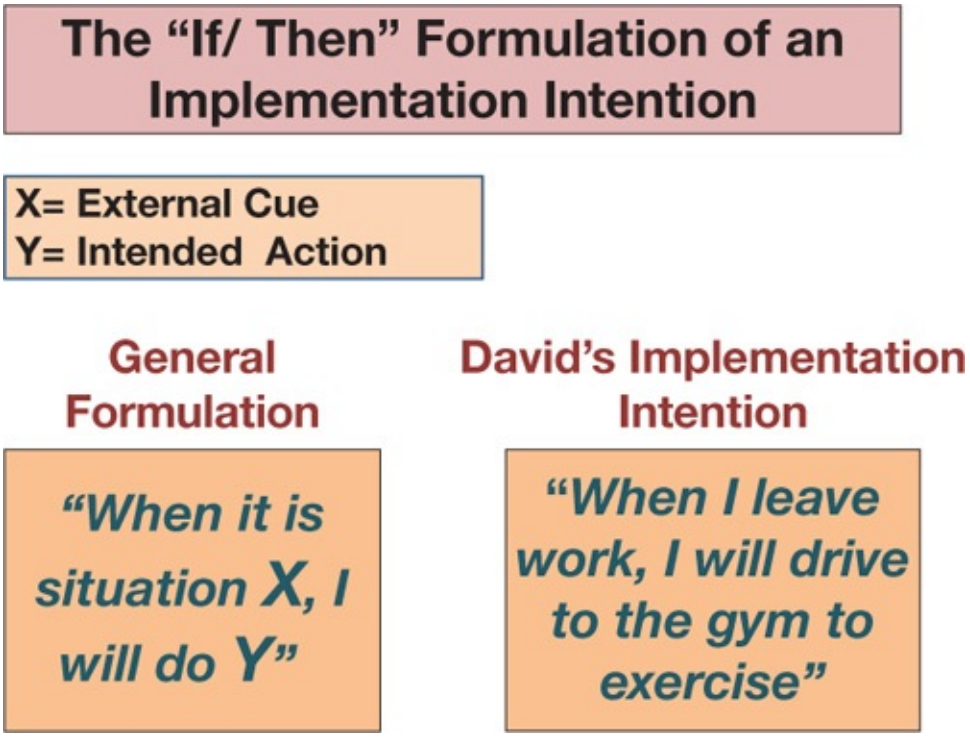

FIGURE 61.12 General formulation of an Implementation Intention and the specific Implementation Intention formulated by David. "X" is the external cue, which may be a specific time, place, or situational cue. "Y" is the intended action.

"When I leave the office on Monday through Friday, I will drive

directly to the gym to work out for 30 minutes."

Leaving work was David's cue to engage in his health behavior. Working out at the gym was the specific behavior.

Finally, Dr. Jones suggested that each individual formulate a contingency plan for their new goal. For David, this amounted to going to the gym on Fridays, for one half-hour of exercise, with a second makeup session on the weekends.

Dr. Jones then asked the participants to write down their implementation intention and share it with someone who could hold them accountable. He also suggested that the participants calendar their intended program, if possible, in their daily planners.

David left the lecture feeling very pleased with what he learned. Over the course of the next 3 months, David found himself exercising nearly every day during the week. At first, it was very difficult. As he drove to the gym, he found himself having all sorts of complaints, such as "I am too tired tonight" or "I have too much to do" or "I am hungry." But he stuck with the plan and was now realizing that the goal was taking root as a new habit. In fact, he was beginning to feel uncomfortable on the days that he did not go to the gym. During this time, David had also begun to eat better again and had lost 4 lb. He was excited to make his next follow-up meeting with his cardiologist. David shared with him his success, the life skills he felt he had learned in the process, and his overall sense of feeling quite energetic. At the end of the visit, David thanked his physician for being attuned to the psychological dimensions of health care and left the office with a sense of confidence about his health and his future.
